**Abstract.** Nitrous acid (HONO) is an important precursor of the hydroxyl radical (OH) in the lower troposphere. Understanding HONO chemistry, particularly its sources and contribution to HO<sub>x</sub> (=OH+HO<sub>2</sub>) production, is very important for understanding atmospheric oxidation processes. A highly sensitive instrument for detecting atmospheric HONO based on wet chemistry followed by liquid waveguide long path absorption photometry was deployed in the Biosphere Effects on Aerosols and Photochemistry Experiment (BEARPEX) at Blodgett Forest, California in late summer 2007. The median diurnal variation shows minimum HONO levels of about 20–30 pptv during the day and maximum levels of about 60–70 pptv at night, a diurnal pattern quite different from the results at various other forested sites. Measured HONO/NO<sub>2</sub> ratios for a 24-h period ranged from 0.05 to 0.13 with a mean ratio of 0.07. Speciation of reactive nitrogen compounds (NO<sub>y</sub>) indicates that HONO accounted for only ~3% of total NO<sub>y</sub>. However, due to the fast HONO loss through pho-

tolysis, a strong HONO source (1.59 ppbv day<sup>-1</sup>) existed in this environment in order to sustain the observed HONO levels, indicating the significant role of HONO in NO<sub>y</sub> cycling. The wet chemistry HONO measurements were compared to the HONO measurements made with a Chemical Ionization Mass Spectrometer (CIMS) over a three-day period. Good agreement was obtained between the measurements from the two different techniques. Using the expansive suite of photochemical and meteorological measurements, the contribution of HONO photolysis to HO<sub>x</sub> budget was calculated to be relatively small (6%) compared to results from other forested sites. The lower HONO mixing ratio and thus its smaller contribution to HO<sub>x</sub> production are attributed to the unique meteorological conditions and low acid precipitation at Blodgett Forest. Further studies of HONO in this kind of environment are needed to test this hypothesis and to improve our understanding of atmospheric oxidation and nitrogen budget.

## 1 Introduction

Nitrous acid (HONO) plays an important role in atmospheric chemistry because its photolysis results in the formation of the hydroxyl (OH) radical, the key atmospheric oxidant that initiates the oxidation of many primary and secondary pollutants leading to the formation of ozone and fine particles. Previous studies have found HONO photolysis to be a major or an important OH source in forested (Winer and Biermann, 1994; Harrison et al., 1996; Alicke et al., 2003, 2006a; Kleffmann et al., 2005; Ren et al., 2006) and urban environments (Alicke et al., 2003; Ren et al., 2003; Acker et al., 2006a; Mao et al., 2010). Measurement of HONO within these environments can reveal the contribution of HONO photolysis to HO<sub>x</sub> (=OH+HO<sub>2</sub>) radical production and oxidation capacity. Furthermore, recent studies have demonstrated that the photolysis of HONO is an important OH source, not only in the early morning when other OH sources (such as the photolysis of O<sub>3</sub>) are still small, but also throughout the day. This indicates the existence of a strong daytime OH source from HONO photolysis. In these studies, the contribution of HONO photolysis to HO<sub>x</sub> production was often found to be greater than or comparable to the contribution from the photolysis of ozone and formaldehyde (Neftel et al., 1996; Staffelbach et al., 1997; Zhou et al., 2002a; Kleffmann et al., 2003, 2005, 2006; Vogel et al., 2003; Acker et al., 2006b, 2007; Ren et al., 2003, 2006; Elshorbany et al., 2009; Mao et al., 2010).

Despite the importance of HONO in atmospheric chemistry, HONO source strengths and its detailed formation mechanisms, especially during daytime, are not well understood. In addition to the homogeneous HONO formation from the reaction of NO with OH, Li et al. (2008) found that the reaction of photolytically excited NO<sub>2</sub> with water can form HONO and OH, but its reaction rate and yield are still under debate (Carr et al., 2009) and this mechanism likely contributes insignificantly to atmospheric HONO formation. Models taking into account only the homogeneous HONO sources typically predict significantly lower HONO concentrations than measurements. Heterogeneous processes are thus considered as major HONO sources, along with the homogeneous formation and direct emissions from combustion processes. Major heterogeneous processes to form HONO include: (1) heterogeneous conversion of NO<sub>2</sub> adsorbed on humid surfaces (Ammann et al., 1998; Finlayson-Pitts et al., 2003; Ndour et al., 2008); (2) photosensitized reduction of NO<sub>2</sub> on organic surfaces such as aromatics and humic acids (George et al., 2005; Stemmler et al., 2006; Qin et al., 2009), and (3) photolysis of surface adsorbed nitric acid (HNO<sub>3</sub>) and nitrate (Zhou et al., 2001, 2002b, 2003). Heterogeneous conversion of NO<sub>2</sub> on fresh soot particles and secondary organic aerosols can also form HONO (Ammann et al., 1998; Arens et al., 2001; Ziemba et al., 2010), but the roles of these processes are still under discussion (Arens et al., 2001; Bröske et al., 2003; Aubin et al., 2007; Qin et al.,

2009). Lastly, photolysis of *o*-nitrophenol and its methylated analogues can produce HONO (Bejan et al., 2006), but this mechanism is only important in urban areas where concentrations of nitrophenols are high.

Comparison of different techniques for detecting HONO is vital to evaluate and enhance their capabilities. This type of intercomparison has been conducted in field campaigns, especially between well accepted long path differential optical absorption spectroscopy (LP-DOAS) and chemical techniques such as denuder (Appel et al., 1990; Febo et al., 1996; Spindler et al., 2003), long path absorption photometry (LOPAP) (Heland et al., 2001; Kleffmann et al., 2006; Acker et al., 2006a), and mist chamber (Stutz et al., 2010). The results in these studies showed consistent agreement in general, although occasionally there were significant differences that could be explained by either an NO<sub>2</sub> artifact of the DOAS instruments or possible interferences in the chemical methods (Heland et al., 2001; Kleffmann et al., 2006; Stutz et al., 2010). Excellent agreement has been obtained between LOPAP and LP-DOAS (Acker et al., 2006a; Kleffmann et al., 2006). Chemical Ionization Mass Spectrometry (CIMS) has proven to be a powerful technique to measure many atmospheric trace gases. It has been used to measure HONO in the laboratory (Hirokawa et al., 2009), but rarely in the real atmosphere (Yokelson et al., 2009). Comparison of this new technique with other established techniques for HONO measurement is of particular interest.

Here we present HONO measurement results from the Biosphere Effects on Aerosols and Photochemistry Experiment (BEARPEX) at Blodgett Forest, California in late summer 2007. The mixing ratios and diurnal profile of atmospheric HONO at this site are compared to results obtained from other forested sites. HONO measurements made by wet chemistry and CIMS are compared over three days. Using other concurrent measurements of trace gases and meteorological parameters, a box model was developed and the contribution of HONO photolysis to HO<sub>x</sub> production was calculated.

## 2 Experimental

### 2.1 Site description

Measurements of HONO were made within a ponderosa pine plantation adjacent to the University of California at Berkeley's Blodgett Forest Research Station (BFRS). The site is located in the western foothills of the Sierra Nevada mountains (38°58'42.4" N, 120°38'3.4" W, 1315 m elevation), ~75 km northeast of Sacramento, CA. Average tree height within the daytime fetch was 7.9 m, and leaf area index (LAI) was estimated as 3.2 m<sup>2</sup> m<sup>-2</sup> (Wolfe et al., 2009). Typical meteorological conditions at the site have been described in detail elsewhere (e.g., Goldstein et al., 2000; LaFranchi et al., 2009; Wolfe et al., 2009; Bouvier-Brown et al.,

**Fig. 1.** Schematic of a HONO generation system. MFC represents a mass flow controller.

for analysis from the center of the large flow as described in Crouse et al. (2006) with the difference that ambient air was diluted with UHP N<sub>2</sub> in a 1:3.5 ratio to reduce the water vapor mixing ratio in the flow tube ( $J$ ). Also the glass inlet tube was encased in a stainless steel tube and shielded from light.

Due to the time needed to measure other chemical species, the ion channel  $m/z=66$  was only monitored 2.8% of the time (i.e., 0.5 s every 18 s). Instrument zeros were conducted approximately once every 15 min by passing ambient air through a filter filled with nylon wool that was coated with sodium bicarbonate. In-situ calibrations were conducted approximately once every 1.5 h using H<sub>2</sub>O<sub>2</sub> and HNO<sub>3</sub> standards, and proxied to HONO using laboratory calibrations curves. The primary interference to the HONO signal, formic acid product ion (<sup>13</sup>CH(O)O<sup>-</sup>HF), has been removed using the signal at  $m/z=65$  (<sup>12</sup>CH(O)O<sup>-</sup>HF). Additional detailed information about this instrument can be found elsewhere (Crouse et al., 2006). The precision for a 0.5-s integration period was about 25 pptv ( $1\sigma$ ).

The Caltech-CIMS was operational between 15 August and 27 September, 2007 with the exception of several periods of downtime due to rain and technical difficulties. The wet chemistry HONO measurements covered the period between 25 September and 10 October, 2007. Both wet chemistry and CIMS measured HONO on three overlapping days, 25–27 September, allowing for the HONO intercomparison between wet chemistry and CIMS.

### 2.2.3 Other measurements

Other concurrent measurements used in this analysis include ozone based on UV absorption, NO<sub>2</sub>, alkyl nitrates (ANs) and peroxy nitrates (PNs) based on thermo-dissociation laser induced fluorescence (TD-LIF) (Thornton et al., 2000), OH and HO<sub>2</sub> based on laser-induced fluorescence (Faloona et al., 2004), and meteorological parameters, including ambient temperature, pressure, relative humidity, wind direction, wind speed, and solar radiation. There were no direct mea-

surements of photolysis frequencies ( $J$  values). The NCAR Tropospheric Ultraviolet and Visible (TUV) transfer model (<http://www.acd.ucar.edu/TUV>) was used to calculate clear sky  $J$  values with the O<sub>3</sub> column density measured by the Total Ozone Mapping Spectrometer (TOMS, data available at [http://toms.gsfc.nasa.gov/teacher/ozone\\_overhead.html](http://toms.gsfc.nasa.gov/teacher/ozone_overhead.html)). In order to correct for solar attenuation by clouds, the calculated  $J$  values on a clear day were used to calculate a cloudiness factor. The field experiment log and the profile of the solar radiation measured on 1 September 2007 indicated that it was a clean day with a clear sky. Thus the ratio of clear-sky photolysis frequency to solar radiation intensity for each photolytic species on this day was calculated and used as a reference to correct the cloud attenuation. The  $J$  values on other days were then scaled to the measured solar radiation intensity.

During this study, the measurement of NO failed due to technical difficulties. Previous studies at this site have found that NO, NO<sub>2</sub>, and O<sub>3</sub> approximately reached photostationary state (PSS) during midday (e.g., Day et al., 2009). With the PSS approximation and the concurrent measurements of NO<sub>2</sub>, O<sub>3</sub> and HO<sub>2</sub>, daytime NO concentrations were calculated using Eq. (2):

$$[\text{NO}]_{\text{SS}} = \frac{J_{\text{NO}_2}[\text{NO}_2]}{k_{\text{O}_3+\text{NO}}[\text{O}_3] + k_{\text{HO}_2+\text{NO}}[\text{HO}_2] + \sum_i k_{\text{RO}_2i+\text{NO}}[\text{RO}_2i]} \quad (2)$$

Peroxy radicals were not measured and we assume that total RO<sub>2</sub> levels were 1.6 times HO<sub>2</sub> levels, a median daytime RO<sub>2</sub>/HO<sub>2</sub> ratio in the box model. We also assume that the rate coefficients for the RO<sub>2</sub>+NO reactions are the same as the rate coefficient for the CH<sub>3</sub>O<sub>2</sub>+NO reaction. Nighttime NO concentrations are assumed to be the same as the mean nighttime concentrations measured during BEARPEX2009 in summer 2009. As NO only contributed a small fraction (2–10%) to NO<sub>y</sub> at this site (Fig. 8), the uncertainty in the calculated NO does not significantly affect the NO<sub>y</sub> speciation (Sect. 3.4).

## 2.3 Laboratory characterization of the wet chemistry HONO instrument

### 2.3.1 HONO generation system

A HONO generation system was developed to quantitatively produce HONO with high purity and high stability. It is based on the reaction between gaseous hydrogen chloride (HCl) and solid sodium nitrite (NaNO<sub>2</sub>) (Febo et al., 1995):

The gaseous HCl was produced using a piece of thin-wall Teflon tubing that was immersed into a concentrated hydrochloric acid solution (9–12 mol L<sup>-1</sup>, Fig. 1). A small zero air flow was introduced into the Teflon tubing as a carrier gas.

Because of the partial pressure difference in  $\text{HCl}_{(\text{g})}$  between the inside and outside of the Teflon tubing, small amount of gas phase  $\text{HCl}$  diffused into the carrier gas. The produced  $\text{HCl}$ /air mixture was mixed with some humidified air produced with a water bubbler before entering a small reactor containing  $\text{NaNO}_2$  powder (the  $\text{NaNO}_2$ - $\text{HCl}$  reactor), where the  $\text{NaNO}_2$ + $\text{HCl}$  reaction occurred. The produced  $\text{HONO}$  flow was diluted by zero air before it was measured by an  $\text{NO}$ - $\text{NO}_x$  analyzer (TEI, Model 42i-TL, Thermo Fisher) and/or the wet chemistry  $\text{HONO}$  instrument. The  $\text{NO}$ - $\text{NO}_x$  analyzer contains a molybdenum catalytic converter to quantitatively convert  $\text{HONO}$  into  $\text{NO}$  followed by the chemiluminescence detection of  $\text{NO}$ . These chemiluminescence detectors with molybdenum converters have been proven to have near unit response to  $\text{HONO}$  (Allegrini et al., 1990; Pérez et al., 2007). In order to stabilize the  $\text{HONO}$  levels from the calibration source, the temperature of the hydrochloric acid solution and the  $\text{NaNO}_2$ - $\text{HCl}$  reactor, as well as the humidity in the air through the  $\text{NaNO}_2$ - $\text{HCl}$  reactor were controlled. The produced  $\text{HONO}$  levels can be varied over three orders, from a few tens of pptv to a few tens of ppbv by varying the length of the Teflon tubing immersed into the hydrochloric acid, the concentration and temperature of hydrochloric acid, and the dilution flow rate of zero air.

The  $\text{HONO}$  generation system was tested in the laboratory and the produced  $\text{HONO}$  was sampled simultaneously by the wet chemistry  $\text{HONO}$  instrument and the  $\text{NO}$ - $\text{NO}_x$  analyzer. The  $\text{HONO}$  instrument was calibrated using standard solutions of  $\text{NaNO}_2$  and the  $\text{NO}$ - $\text{NO}_x$  analyzer was calibrated with a cylindered  $\text{NO}$  calibration mixture (9.96 ppmv of  $\text{NO}$  in  $\text{N}_2$  with a  $\pm 2\%$  uncertainty, Matheson Tri-Gas). Very good agreement was obtained between the two measurements (Fig. 2), suggesting the reliability of the  $\text{HONO}$  instrument and  $\text{HONO}$  generation system.

### 2.3.2 Collection efficiency and delay time

In addition to the calibration of the wet chemistry  $\text{HONO}$  instrument, the  $\text{HONO}$  generation system was used to characterize the collection efficiency and delay time (the time when an air sample reaches the samplers to the time when the sample signal appears in the detection cell) of the  $\text{HONO}$  instrument. The coil samplers used in this study have an uptake efficiency of  $(99.6 \pm 0.5)\%$  for  $\text{HONO}$  at a sampling flow rate of  $2 \text{ L min}^{-1}$ . The instrument delay time was  $12.9 \pm 0.8 \text{ min}$ , which includes the derivatization time (5 min) and the time for the reagent solutions to flow through autoanalysis tubings attached onto the peristaltic pump. The gas-phase  $\text{HONO}$  source was also used to examine the loss of  $\text{HONO}$  in the sampling tubing. Pre-campaign and post-campaign tests show that the wall loss was little and  $(99.2 \pm 1.3)\%$  of  $\text{HONO}$  went through the tubing.

**Fig. 2.** Comparison of  $\text{HONO}$  measurements with a wet chemistry- $\text{HONO}$  instrument and a TEI  $\text{NO}$ - $\text{NO}_x$  analyzer.  $\text{HONO}$  source was produced by a  $\text{HONO}$  generation system.

### 2.3.3 Interference tests

$\text{HONO}$  measurements based on chemical methods can suffer from a variety of interferences (Kleffmann and Wiesen, 2008; Stutz et al., 2010). Therefore  $\text{HONO}$  instruments based on wet chemistry need to be carefully designed and characterized. Heland et al. (2001) and Huang et al. (2002) have tested several possible interferences for their instruments and all tested species showed insignificant interferences to  $\text{HONO}$  measurement. In the laboratory, we also tested several candidate chemicals, including  $\text{NO}_2$ ,  $\text{HNO}_3$ , nitrate, and  $\text{SO}_2$ , for possible interferences in our  $\text{HONO}$  instrument.

$\text{NO}_2$  is slightly soluble in liquid water with a Henry's Law constant of  $0.01 \text{ mol L}^{-1} \text{ atm}^{-1}$  (Schwartz and White, 1981). Assuming that the air sample contains 100 ppbv of  $\text{NO}_2$  at 1 atm pressure and  $\text{NO}_2$  reaches equilibrium when air passes through the glass coil sampler, the concentration of the formed nitrous acid in the aqueous phase is about  $1.0 \text{ nmol L}^{-1}$ , which corresponds to 3.4 pptv of  $\text{HONO}$  under typical sample conditions. Zero air containing approximately 100 ppbv of  $\text{NO}_2$  was used to test the actual  $\text{NO}_2$  interference to the  $\text{HONO}$  measurement. The  $\text{NO}_2$ -air mixture was generated by an  $\text{NO}_2$  permeation tube (VICI Metronics) using a Dynacalibrator (VICI Metronics). There was an observed small fraction of  $\text{HONO}$  (about 1% of  $\text{NO}_2$  level) in the  $\text{NO}_2$  source, either existing in the  $\text{NO}_2$  permeation tube or formed on the surfaces inside the Dynacalibrator. In order to test the true interference from  $\text{NO}_2$ , the  $\text{NO}_2$  mixture was passed through a dry glass annular denuder (URG) coated with sodium carbonate. The denuder removed all  $\text{HONO}$  but only removes about 5% of  $\text{NO}_2$ . The interference was found to be about 20 pptv of  $\text{HONO}$  per 100 ppbv of  $\text{NO}_2$ , or 0.02% of  $\text{NO}_2$ , which is small considering the relatively low  $\text{NO}_2$  levels at Blodgett Forest (i.e., up to  $\sim 3$  ppbv of  $\text{NO}_2$ ,

which corresponds to an interference level of  $\sim 0.6$  pptv of HONO). This interference level is comparable to what was found by Heland et al. (2001) with an interference level of  $(0.011 \pm 0.005)\%$ , but greater than the estimation based on the Henry's Law constant of  $\text{NO}_2$ , possibly due to the  $\text{NO}_2$  reaction with  $\text{H}_2\text{O}$ , leading to a larger effective  $\text{NO}_2$  solubility than the equilibrium based on the Henry's Law.

Possible interferences from  $\text{HNO}_3$  and nitrate were tested using an  $\text{HNO}_3$  permeation tube (VICI Metronics) to generate an air flow with an  $\text{HNO}_3$  mixing ratio of  $\sim 5$  ppbv or using sodium nitrate standard solutions ( $80\text{--}400\text{ nmol L}^{-1}$ ). There was no detectable interference (below the detection limit) from either test. Interference from pure  $\text{SO}_2$  was tested with an  $\text{SO}_2/\text{air}$  mixture containing an  $\text{SO}_2$  mixing ratio of  $\sim 50$  ppbv, which was sampled by the HONO instrument. Interference from the  $\text{SO}_2+\text{NO}_2/\text{Air}$  mixture was also tested. The interference in both tests was found to be small and negligible.

In the field, another interference test was conducted using a dry annular denuder coated with sodium carbonate by connecting the denuder to the sampling inlet. The test was designed to characterize interferences from aerosols and other nitrogen species (e.g.,  $\text{NO}_x$ , PAN, and other organic nitrates) in air samples by removing HONO but retaining most of particles,  $\text{NO}_2$ , PAN or other organic nitrates in the air flow. The signals obtained from the ambient air through the denuder were essentially the same as the signals from zero air, indicating that there were no significant HONO interferences from the possible interfering species such as  $\text{NO}_2$ , aerosols, and organic nitrates in this environment.

### 3 Results and discussion

#### 3.1 Measurements of meteorological parameters and trace gases

Shown in Fig. 3 are meteorological measurements from the last two weeks of the BEARPEX2007 study, when the wet chemistry HONO measurements were available. Summer 2007 was cooler than usual. There were slight rainfalls on nights of 28/29 September and 9/10 October. An early snowfall came on 5 October 2007. During this period, wind directions were less regular due to a few cold fronts crossing over the site (Fig. 3).

HONO measurements made by wet chemistry during the last two weeks of BEARPEX2007 exhibit a large variability ranging from near 0 to 160 pptv (Fig. 4). Meteorological conditions affected the HONO mixing ratio significantly at this forested site. For example, a rapid drop in HONO mixing ratios from near 100 pptv to  $\sim 25$  pptv at  $\sim 21:30$  (PST) on 28 September (Fig. 4) was primarily caused by a rapid wind shift from southwesterly to northerly followed by a slight rainfall. Another example of meteorological influence on HONO took place on the night of 9/10 October when

**Fig. 3.** Time series of HONO photolysis frequency, temperature, relative humidity, rain fall, wind direction, and wind speed between 25 September and 10 October 2007 during BEARPEX2007 when the wet chemistry HONO measurements were available.  $J(\text{HONO})$  was calculated based on the TUV model and measured solar radiation (see Sect. 2.2.3 for details).

the wind started to shift from southwesterly to easterly at  $\sim 17:00$  (PST). In about two hours, the wind shifted back to southerly and remained in this direction for the remainder of the night. Because the southerly wind continued to blow the urban plumes to the site as a cold front passed by, HONO mixing ratios continuously increased to a maximum level of 160 pptv. A slight rainfall started at around 03:00 (PST) on 10 October when HONO mixing ratio started to drop dramatically (Fig. 4).

During this study, HONO and  $\text{NO}_2$  generally correlated well as expected (Figs. 4 and 5), indicating that  $\text{NO}_2$  might be a key HONO precursor in this environment. Simultaneously there were a few periods when HONO and  $\text{NO}_2$  did not correlate well. For instance, on both 3 and 4 October, measured  $\text{NO}_2$  mixing ratios were up to 3 ppbv in the late afternoon and early evening because the wind continuously blew from south and southwest without a regular wind shift (Fig. 3). However, when  $\text{NO}_2$  reached its peak values, HONO mixing ratios on both days remained at relatively low levels (near or below 50 pptv), possibly because of not enough interaction time between  $\text{NO}_2$  and surfaces before the air masses reached the site. The observed HONO-to- $\text{NO}_2$  ratios show a large variability ranging from near 0 to 0.5 (Fig. 4). For a 24-h period, the HONO/ $\text{NO}_2$  ratios ranged from 0.05 to 0.13, with a mean ratio of 0.07 (Fig. 5), which is comparable to the ratios at some forested sites in Europe (e.g., Acker et al., 2006b, 2007), but lower than the ratios observed at another forested site at Whiteface Mt., New York (Ren et al., 2006; Zhou et al., 2007), where the average HONO/ $\text{NO}_2$  ratios ranged from 0.15 to 0.40.

**Fig. 4.** Time series of measured ozone,  $\text{NO}_2$ , PAN, HONO, and HONO/ $\text{NO}_2$  ratio between 25 September and 10 October during BEARPEX2007. HONO measurements made by wet chemistry are shown. PAN was measured using CIMS (Wolfe et al., 2009).

### 3.2 Intercomparison of wet chemistry and CIMS

Time series of HONO measurements collected between 25 and 27 September, 2007 by wet chemistry and CIMS show very good agreement (Fig. 5), although the CIMS HONO measurements are a little noisy especially at low HONO levels, primarily due to the large uncertainty of the CIMS measurements and a small fraction ( $\sim 3\%$ ) of the CIMS measurement time dedicated to HONO measurement for the need of measuring other species. Using 10-min averages, the linear regression of the CIMS HONO versus the wet chemistry HONO produces a slope of 0.94 and an intercept of 4.6 pptv with  $r^2$  of 0.64 (Fig. 5). The fact that wet chemistry and CIMS are different techniques for HONO measurements indicates reliable HONO measurements by both instruments, unless both instruments have the same biases in the HONO measurements. In a recent HONO intercomparison (HINT2009) study in Houston, TX where we deployed our wet chemistry HONO instrument, very good agreement was also obtained between our wet chemistry and four different techniques, including LP-DOAS (within  $\pm 20\%$ ,  $r^2=0.79$ ) and tunable infrared laser differential absorption spectrometry (within  $\pm 15\%$ ,  $r^2=0.86$ ) (Thomas et al., 2010).

### 3.3 Diurnal trends of measured HONO

The diurnal profile during this study shows that the minimum HONO mixing ratios were about  $\sim 20$ – $30$  pptv in the midday and maximum levels of 60–70 pptv at night (Fig. 6). These daytime HONO levels are lower than levels observed in some

**Fig. 5.** Comparison of HONO measurements by wet chemistry (blue dots) and CIMS (red circles) over three days between 25 and 27 September, 2007. Left: time series with one-minute averages. Right: scatter plot of CIMS HONO versus wet chemistry HONO with 10-min averages.

other forested sites. For example, at two forested sites in Eastern US (in Whiteface Mountain, New York, Ren et al., 2006) and Europe (in Hohenpeissenberg, Germany, Acker et al., 2006b), daytime HONO levels of 80 to 120 pptv while minima of 20–60 pptv at night were observed. Thus the diurnal pattern of HONO observed at Blodgett Forest is quite different from what was observed in the other two studies. The reasons for these differences are uncertain, but they may be related to the dry climatology and unique diurnal wind pattern (i.e., southwesterly wind during the day and northeasterly wind at night) at Blodgett Forest. Another possible explanation may be related to the acid precipitation in Eastern US and Europe, where soil acidification has occurred (Menz and Seip, 2004). Soil acidification is less prominent in Western US than in Northeast US and Europe (Fenn et al., 2006), so the heterogeneously formed HONO on the ground surface at Blodgett Forest may be less likely to be released into the atmosphere than at other forest sites where soil acidification is significant. One piece of evidence supporting this hypothesis is the aerosol measurements by an aerosol mass spectrometer (AMS), which confirm that aerosols at Blodgett Forest were close to fully neutralized (D. Farmer, unpublished data).

Under less acidic conditions, nitrate photolysis may not be a significant HONO source, and heterogeneous hydrolysis of  $\text{NO}_x$  may act as a major HONO source. This can explain the different HONO behaviors at Blodgett Forest and at the sites in Eastern US and Europe, i.e., the lower daytime HONO at Blodgett Forest while daytime HONO maxima in Eastern US and Europe (Ren et al., 2006; Acker et al., 2006, 2007) and good correlation between HONO and  $\text{NO}_2$  at Blodgett Forest while low correlation ( $r^2 \sim 0.01$ – $0.05$ ) in Pinnacle and Whiteface Mountain, New York (Zhou et al., 2002a, 2007).

More evidence supporting this hypothesis came from recent studies in the Arctic and Antarctic. In the Arctic significant HONO emissions have been observed from the sunlight-exposed snowpack via the photolysis of  $\text{HNO}_3$ /nitrate (possibly involving electron transfer reactions of  $\text{NO}_2$  from

**Fig. 6.** Average diurnal profiles of  $\text{O}_3$ ,  $\text{NO}_2$ , HONO, and HONO/ $\text{NO}_2$ . HONO was measured at a height of 14 m ( $\sim 6$  m above the canopy) by the wet chemistry HONO instrument and  $\text{NO}_2$  was measured at a height of 12.7 m. The data were collected between 25 September and 10 October during BEARPEX2007. Error bars represent standard deviations in hourly bins.

photosensitized organics, Beine et al., 2006) that come primarily from the deposition of acidic aerosols transported from North America, Asia and Europe (Zhou et al., 2001; Honrath et al., 2002). In contrast, little HONO was produced from coastal snowpack in the Antarctic where significant sea-salt deposition occurred and  $\text{NO}_3^-$  ion was present primarily as  $\text{NaNO}_3$  in aged snows, thus preventing the release of or providing a reactive medium for newly formed HONO (Beine et al., 2006). Recent laboratory studies (H. Gao, unpublished data) also found that HONO production from surface  $\text{HNO}_3$ /nitrate photolysis diminished with higher pH. The rate of HONO production decreased to half for surface  $\text{NH}_4\text{NO}_3$  photolysis compared to  $\text{HNO}_3$  photolysis, but little HONO was produced from surface  $\text{NaNO}_3$  photolysis, consistent with the results by Beine et al. (2006). While it seems likely to us that the different behaviors of HONO observed at Blodgett Forest are associated with the low soil acidification and acid precipitation in Western US, further studies of HONO in this kind of environment are needed to test this hypothesis.

**Fig. 7.** Left: time series of measured HONO mixing ratios by CIMS (1 min averages in yellow and 10 min averages in red) and by wet chemistry (in blue) and temperature (in green). The integration time is 2 min for the wet chemistry HONO instrument. The integration time is 0.5 s every 18 s and 1-min averages are shown in this figure. Right: diurnal variations of HONO mixing ratio during the warm period (red squares) and cool period (blue triangles). Also plotted are the photo-steady state (PSS) HONO mixing ratios (dashed black line) averaged for the entire study. In the PSS calculation, only gas phase HONO sources are included during the day between 08:00 and 16:00 (PST).

Temperature dependence of HONO mixing ratios was observed during BEARPEX2007. Figure 7 shows both HONO measurements made by CIMS and wet chemistry together with ambient temperature. There were two distinguishing periods: a warm period between 18 August and 12 September, and a cool period from 13 September to 10 October. There was a three-day overlap between CIMS and wet chemistry measurements, which will be discussed in detail in Sect. 3.3. Interestingly, the temperature dependence occurred mainly at night, with higher nighttime HONO mixing ratios during the warm period (Fig. 7). During the day, the two periods had very similar observed HONO levels at  $\sim 20$ – $40$  pptv. It is noted that diurnal variations of  $\text{NO}_2$  mixing ratios during these two periods are about the same, but the water mixing ratios in the air during the warm period was higher than in the cool period by a factor of 1.2, which may be partially responsible for the difference in the nighttime HONO mixing ratios during these two periods.

During the daytime (08:00–16:00 PST), the photolytic loss of HONO is very efficient due to its large photolysis rate coefficients ranging from  $0.001$  to  $0.002 \text{ s}^{-1}$ . It is reasonable to assume that HONO reaches photo-steady state (PSS) in the midday. If we assume that only gas phase HONO sources (mainly the  $\text{OH}+\text{NO}$  reaction) are involved in the HONO production, we can then calculate PSS HONO mixing ratios, shown in Fig. 7. The PSS HONO mixing ratios calculated with gas phase HONO sources only are lower than the measurements by a factor of 9 on average, indicating that other HONO sources are dominant in this environment. This result is consistent with previous studies (e.g., Zhou et al., 2002; Acker et al., 2006b, 2007). Calculations also show that a

**Fig. 8.** Median diurnal variations (left) and distribution (right) of NO<sub>y</sub> species during BEARPEX2007. ANs represents total alkyl nitrates and PNs represents total peroxy nitrates. The pie chart is representative of a 24-h basis. Data collected between 15 August and 10 October, 2007 are used in this figure.

significant HONO source ( $\sim 1.59 \text{ ppbv day}^{-1}$ ) is needed in order to sustain the observed HONO level, which presumably comes from heterogeneous processes.

### 3.4 NO<sub>y</sub> speciation

The sum of reactive nitrogen species in the atmosphere is called NO<sub>y</sub>, which is defined here as the sum of NO+NO<sub>2</sub>+HONO+HNO<sub>3</sub>+alkyl nitrates (ANs) + peroxy nitrates (PNs)+HO<sub>2</sub>NO<sub>2</sub>+NO<sub>3</sub>+2·N<sub>2</sub>O<sub>5</sub>. Box model results show that N<sub>2</sub>O<sub>5</sub> and NO<sub>3</sub> were lower than 1 pptv while HO<sub>2</sub>NO<sub>2</sub> was typically less than 10 pptv during BEARPEX2007 and thus they do not contribute significantly to the NO<sub>y</sub> budget. In the following discussion, we assume that NO<sub>y</sub> comprises NO, NO<sub>2</sub>, HONO, HNO<sub>3</sub>, ANs, and PNs.

Diurnal profiles of reactive nitrogen species exhibit a minimum at 06:00 (PST) and a maximum NO<sub>y</sub> at 18:00 (PST) (Fig. 8), due to the primary influence of the Sacramento urban plume and the unique diurnal wind pattern at Blodgett Forest. Similar diurnal variations have been observed in previous studies at this site (e.g., Murphy et al., 2006; Farmer et al., 2008; Day et al., 2009). Among the reactive nitrogen species, NO<sub>2</sub>, HNO<sub>3</sub>, and PNs are dominant and account for 85% of total NO<sub>y</sub> on a 24-h basis (Fig. 8). HONO accounted for only 2.8% of total NO<sub>y</sub> on average, with a percentage of 2.2% during the day and 3.3% at night. However, due to fast HONO loss through photolysis, a strong HONO production rate ( $1.59 \text{ ppbv day}^{-1}$ ) existed in this environment, suggesting that HONO plays an important role in NO<sub>y</sub> cycling. In contrast, HNO<sub>3</sub> production rate from the OH+NO<sub>2</sub> reaction was  $0.53 \text{ ppbv day}^{-1}$  on average, which is only one third of the HONO production rate.

The production of NO from the photolysis of HONO may potentially affect the cycling between NO<sub>2</sub> and NO. Calculations show that the HONO photolysis rate was only about 1.5% of the NO<sub>2</sub> photolysis rate, indicating that HONO photolysis did not significantly influence the NO-NO<sub>2</sub> cycling,

**Fig. 9.** Diurnal variation of HO<sub>x</sub> production rates from the photolysis of ozone followed by the consequent O(<sup>1</sup>D)+H<sub>2</sub>O reaction (diamonds), the photolysis of HCHO (circles), the photolysis of HONO (triangles), and from the reactions of O<sub>3</sub>+alkenes (squares).

mainly due to the low HONO levels during the day and fast cycling between NO<sub>2</sub> and NO.

### 3.5 Contribution of HONO photolysis to HO<sub>x</sub> production

A box model based on the Regional Atmospheric Chemistry Mechanism (RACM) (Stockwell et al., 1997) was developed to interpret the field measurements and investigate atmospheric oxidation chemistry in this environment. The model was constrained by the available simultaneous measurements in this study and calculated concentrations of free radicals, such as OH, HO<sub>2</sub>, and RO<sub>2</sub>. Similar model simulations have been conducted in previous studies (e.g., Ren et al., 2003, 2006). Using the model results, the contribution of HONO photolysis to HO<sub>x</sub> production can be calculated.

The diurnal profile of HO<sub>x</sub> production shows that HO<sub>x</sub> production was primarily from the photolysis of HCHO and O<sub>3</sub> during the day, while nighttime HO<sub>x</sub> was mainly produced from O<sub>3</sub>+alkene reactions (Fig. 9). The photolysis of HONO did not contribute significantly to HO<sub>x</sub> production even in the early morning due to its relatively low mixing ratios. On a 24-h basis, HONO photolysis only accounted for about 6% of total HO<sub>x</sub> production.

The insignificant contribution of HONO photolysis to HO<sub>x</sub> production at Blodgett Forest is in contrast with the results from some studies at other forested sites. For instance, at a forested site in Whiteface Mountain, Northern New York State, HONO photolysis was found to be a dominant HO<sub>x</sub> source in the early morning and late afternoon with an overall contribution of 34% to HO<sub>x</sub> production on a 24-h basis (Ren et al., 2006). At another rural site in New York State, the average radical production from HONO photolysis was  $2.3 \text{ ppbv day}^{-1}$  and accounted for 24% of the total HO<sub>x</sub>

production (Zhou et al., 2002a). In a study at the Meteorological Observatory Hohenpeissenberg in Germany, HONO photolysis was also found to be a dominant HO<sub>x</sub> source in the early morning and the overall contribution of HONO photolysis comprised 42% of total photolytic HO<sub>x</sub> production (Acker et al., 2006a). Kleffmann et al. (2005) found that HONO photolysis contributed about 33% of total OH production in a forest in Jülich, Germany.

The reasons for the smaller HONO mixing ratios and thus smaller contribution of HONO photolysis to HO<sub>x</sub> production at Blodgett Forest are uncertain. As discussed previously, it may be related to the dry climatology and low acid precipitation in this water-limited environment.

#### 4 Conclusions

The measurement suite of HONO and other NO<sub>y</sub> species during BEARPEX2007 at Blodgett Forest in summer/fall 2007 provides a great opportunity to study nitrogen chemistry in this forested environment. Measured HONO mixing ratios show a diurnal pattern with minimum levels of ~20–30 pptv during the day and maximum levels of ~60–70 pptv at night, which is significantly different from the results at other forested sites in Eastern US and Europe. The daytime HONO levels at Blodgett Forest are significantly lower compared to the other forested sites where minimum HONO levels during the day and maximum levels at night were often observed. This different diurnal pattern may be related to the unique diurnal wind pattern (i.e., upslope wind during the day and downslope wind at night), dry climatology, and low acid precipitation at Blodgett Forest. Intercomparison of HONO measurements by two different techniques, wet chemistry and CIMS, shows very good agreement, indicating reliable HONO measurements by both instruments. Although HONO only accounted for only 3% of total NO<sub>y</sub> on average, a strong HONO production rate (1.59 ppbv day<sup>-1</sup>) existed in this environment, indicating a fast cycling from other forms of NO<sub>y</sub> to HONO.

Because of relatively low mixing ratios of HONO in this environment, the photolysis of HONO did not contribute significantly to HO<sub>x</sub> production during this study. This is quite different from some studies in other forested areas, where HONO photolysis was typically found to be a dominant or at least an important HO<sub>x</sub> source. Further studies on HONO seasonal variations and HONO vertical fluxes are needed in order to improve our understanding of atmospheric oxidation and nitrogen budget in this kind of water-limited and anthropogenic pollution influenced environment with high biogenic emissions.
