17 **1. Size distributions of different particle types**

18 In China, most of the biomass burning particles come from crop residue burning. In this work,  
19 based on our laboratory research on the particles emitted from rice straw, wheat straw and corn  
20 stalk burning (paper in preparation), we set several criteria for identifying biomass burning  
21 particles: 1) There should be K-clusters such as <sup>113</sup>K<sub>2</sub>Cl<sup>+</sup> and <sup>213</sup>K<sub>3</sub>SO<sub>4</sub><sup>+</sup> in the positive MS. 2)  
22 <sup>26</sup>CN<sup>-</sup> should occur in the negative MS. 3) No <sup>7</sup>Li<sup>+</sup> should be observed (Liu et al., 2003; Spencer et  
23 al., 2008; Furutani et al., 2011). Biomass burning particles have been shown to have significant  
24 signals at *m/z* +23 (Na<sup>+</sup>) and +39 (K<sup>+</sup>/C<sub>3</sub>H<sub>3</sub><sup>+</sup>) in the positive spectra and *m/z* -26 (CN<sup>-</sup>) in the  
25 negative spectra. As shown in Fig. 2a, a 0.12 μm difference (0.28 versus 0.40 μm) was observed  
26 between the maxima of the size distributions of fresh and aged biomass burning groups, which is  
27 consistent with previous studies (Reid et al., 2005). Note that in the larger size range (>0.8 μm),  
28 aged biomass burning aerosols still make up 15% of particles observed with the ATOFMS.

29 Characterized by peaks of *m/z* +18 (NH<sub>4</sub><sup>+</sup>), +27 (C<sub>2</sub>H<sub>3</sub><sup>+</sup>), +39 (K<sup>+</sup>/C<sub>3</sub>H<sub>3</sub><sup>+</sup>) and +43 (C<sub>2</sub>H<sub>3</sub>O<sup>+</sup>)  
30 in the positive spectra, organic carbon (OC) particles account for 26.6% of all particles. A peak  
31 gap (about 0.1 μm) exists between the maximum of the size distribution of fresh and aged OC  
32 types, with the peak of fresh OC type at a smaller diameter of 0.48 μm. Elemental Carbon/Organic  
33 Carbon (ECOC) particles have mass spectra containing a mixture of carbon clusters (C<sub>n</sub><sup>+</sup>) and  
34 major OC peaks, and account for 8.7% of particles observed. Both fresh and aged ECOC groups  
35 have secondary markers of (NH<sub>4</sub><sup>+</sup>) and (C<sub>2</sub>H<sub>3</sub>O<sup>+</sup>). The size distribution of ECOC is bimodal. For  
36 the fresh ECOC type, the mode with higher number concentration is centered around 0.28 μm and  
37 the other is around 0.64 μm. It is the same situation for the aged type, however, the larger size  
38 mode is higher compared to the fresh (Fig.2, 0.32 and 0.68 μm, respectively). The mass spectral  
39 pattern of the ammonium group has a significant ion peak of *m/z* +18 (NH<sub>4</sub><sup>+</sup>) in the positive  
40 spectra. Other peaks include OC fragments of *m/z* +27 (C<sub>2</sub>H<sub>3</sub><sup>+</sup>), +39 (K<sup>+</sup>/C<sub>3</sub>H<sub>3</sub><sup>+</sup>), +43 (C<sub>2</sub>H<sub>3</sub>O<sup>+</sup>) in  
41 positive spectra and -46 (NO<sub>2</sub><sup>-</sup>), -62 (NO<sub>3</sub><sup>-</sup>), -97 (HSO<sub>4</sub><sup>-</sup>), and -125 (H(NO<sub>3</sub>)<sub>2</sub><sup>-</sup>) in negative spectra.  
42 The size distribution of the number fraction of the ammonium type increases with the diameter.

1 Other groups including EC, dust, metal-containing, and Na-K-rich groups are named after  
2 their mass spectral features, and together they account for 15.9% of all observed particles. EC  
3 particles are characterized by clusters of carbon ( $C_n^{+/}$ ), mainly distributed in the small size range  
4 (making up ~50% of all particle groups with diameter smaller than 0.24  $\mu\text{m}$ ). The particles with  
5 signals from  $m/z$  +40 ( $Ca^+$ ), +57 ( $CaOH^+$ ), -60 ( $SiO_2^-$ ), -76 ( $SiO_3^-$ ), and -79 ( $PO_3^-$ ) were classified  
6 as dust. They are also mixed with Na, K, nitrate and sulfate. Most dust particles have diameters of  
7 0.8 - 1.2  $\mu\text{m}$ . Particles containing typical metal elements, e.g. Na, Mg, Al, K, V, Mn, Fe, and Pb,  
8 combine to make up the metal-containing group. The Na-K-rich type has strong intensities of Na  
9 and K in the positive spectra. Metal-containing and Na-K-rich particles all have nitrate and the  
10 nitrate cluster in the negative spectra. Most particles in these two groups have diameters larger  
11 than 0.6  $\mu\text{m}$ .

12 Metal-containing particles consist of several sub-groups including Fe-, Na-Al-K-Mn-, V- and  
13 Pb-containing particles, accounting for 4.3%, 2.0%, 0.7% and 1.2% of total particles, respectively.  
14 The Fe-containing particles can be further divided into three sub-types as well (Na-K-Fe-, 0.9%;  
15 Fe-S-N-, 1.7%; Fe-N-, 1.7%), according to the mass spectral patterns and temporal variations. Pb-  
16 and Fe-S-N-containing particles had similar temporal variations in number fraction (both having  
17 peaks during Period 2), indicating their sources were from the northwest of Shanghai.  
18 V-containing particles occurred only when the wind blew from the east suggesting ship emissions  
19 as their source (Ault et al., 2010). Fe-N- and Na-Al-K-Mn-containing particles had a nearly  
20 constant number fraction, indicating regional sources. Na-K-Fe-containing particles only occurred  
21 in Oct 13 with two spikes at around 11:00 and 16:00, possibly originating from a local source.

## 22 **2. Discussion of sulfate-, nitrate-, and ammonium- containing particle fractions**

23 Fig. S5 shows the size distributions of the number fraction of sulfate-, nitrate- and  
24 ammonium- containing particles sampled with the ATOFMS in the three time periods. The  
25 particles were filtered by the relative intensity of each marker using a threshold (relative peak  
26 areas greater than 0.1, 0.1, and 0.05, respectively). Note that all particles containing peaks due to  
27 ammonium are included here, even if they are assigned to other particle types. Sulfate particles  
28 were typically found in the size range of 0.4 - 0.6  $\mu\text{m}$  (about 80%). The increased sulfate in Period  
29 1 likely results from the high number fraction of EC particles, as discussed in the main document.  
30 The number fraction of nitrate- containing particles stayed nearly constant at around 80% for  
31 particles with size larger than 0.4  $\mu\text{m}$ . This indicates that about 60-80% of particles incorporated  
32 more nitrite as they grew. The number fraction of ammonium-containing particles also increased  
33 as the diameter grew, and the maximum number fraction got as high as 55% around 1.2  $\mu\text{m}$  in  
34 Period 2.  
35

36 The size distribution trends of sulfate, nitrate, and ammonium were nearly the same in the  
37 three time periods. However, the nitrate- containing number fraction was almost 20% larger in  
38 Period 2 than in Periods 1 and 3 for particles larger than 0.4  $\mu\text{m}$ . In addition, ammonium- and  
39 sulfate- containing number fractions exceeded nearly 30% and 20% in the size range of 0.8 - 1.2  
40  $\mu\text{m}$ . Periods 1 and 3 shared fairly similar size distributions of number fraction in the three periods.  
41 The shift of number fraction between different time periods could also be due to the influence of  
42 regional transport on local aerosol chemical properties. The higher fraction of nitrate and  
43 ammonium in Period 2 supports the suggestion of an input of  $NO_x$  and ammonia. Ammonia  
44 prefers partitioning from the gas phase to the particle phase when RH is high. High RH during

1 Period 2 (average RH ~83%, see Fig. S1) promoted the partitioning of ammonia into the particles.  
2 The enhancement of particulate ammonium attracts more acid into the particle phase. To  
3 neutralize ammonium, sulfuric acid first gets exhausted. Then more nitrate acid partitions into the  
4 particle to neutralize the excess ammonium. So in the second period both the sulfate- and nitrate-  
5 containing particle number fraction was greater than in the other two periods, especially in the  
6 large size range.
