## S1 ALABAMA

Several thousand single particle mass spectra were analyzed for each CFA sample. The chemical compounds contained in the quasi-monodisperse samples were investigated by calculating the signal average for every mass-to-charge ratio and by considering the relative abundance of mass-to-charge signals within the sample. Note that different ions can occur on one mass-to-charge ratio. The averaged mass spectra (see Fig. S1) must always be regarded in conjunction with the relative abundance, i.e., the information how many of the investigated particles contain a certain species (see Fig. S2). For determination of the relative abundance, only particle related signals should be considered. Therefore, signal thresholds were derived by averaging ~1900 background spectra (without particles) to exclude signals which originate from, e.g., molecules evaporating from surfaces, vacuum grease, or remaining air molecules. Threshold values for anions ( $21.6 \text{ mV} \pm 5.1 \text{ mV}$ ) and cations ( $8.2 \text{ mV} \pm 0.8 \text{ mV}$ ) were derived by averaging the means of the mass-to-charge ratios plus five times their standard deviation over all background spectra. In case the signal intensity at a certain mass-to-charge ratio was above (below) the threshold, the particle was classified as (not) containing this species. The averaged mass spectra include all signals regardless of whether the signals of the mass-to-charge ratios were above or below the mentioned thresholds.

Averaged mass spectra show that components frequently occurring in natural mineral dust are also typical constituents of dry-generated submicron CFA particles. This comprises species containing  $\text{Al}[-^{43}\text{AlO}, -^{59}\text{AlO}_2, +^{27}\text{Al}]$ ,  $\text{Ca}[+^{40}\text{Ca}, +^{44}\text{Ca}, +^{56}\text{CaO}, +^{104}\text{CaSO}_2]$ ,  $\text{K}[+^{39}\text{K}, +^{41}\text{K}]$ ,  $\text{Fe}[+^{54}\text{Fe}, +^{56}\text{Fe}]$ ,  $\text{Si}[-^{60}\text{SiO}_2, -^{76}\text{SiO}_3, -^{88}(\text{SiO})_2, -^{103}\text{AlSiO}_3, -^{119}\text{AlSiO}_4, -^{179}\text{AlSi}_2\text{O}_6]$ ,  $\text{Na}[+^{23}\text{Na}]$ , and  $\text{Mg}[+^{24}\text{Mg}, +^{25}\text{Mg}, +^{26}\text{Mg}]$ . More than 80 % of particles from all samples contain  $-^{16}\text{O}$ ,  $+^{27}\text{Al}$ ,  $+^{40}\text{Ca}$ ,  $+^{44}\text{Ca}$ , and  $+^{56}\text{CaO/Fe/Si}_2\text{/KOH}$ . Besides,  $\text{SO}_n$  and  $\text{PO}_n$  are frequently found in the CFA particles. Single particle mass spectra with high signals of  $(\text{CaO})_n$ ,  $(\text{CaO})_n\text{H}$ , and  $\text{Ca}(\text{CaO})_n$  cluster series together with  $\text{SO}_n$  may be related to  $\text{CaSO}_4$ , as shown by Gallavardin et al. (2008).

It has been reported that especially submicron CFA particles often show an enrichment in trace elements (Davison et al., 1974; Kaakinen et al., 1975; Block and Dams, 1976; Gladney et al., 1976; Tan et al., 2002). This is also true for our samples as  $\text{Li}[+^6\text{Li}, +^7\text{Li}]$ ,  $\text{Ti}[+^{46}\text{Ti}, +^{47}\text{Ti}, +^{48}\text{Ti}]$ ,  $\text{Co}[+^{59}\text{Co}]$ ,  $\text{Zn}[+^{64}\text{Zn}, +^{66}\text{Zn}, +^{68}\text{Zn}]$ ,  $\text{Sr}[+^{86}\text{Sr}, +^{87}\text{Sr}, +^{88}\text{Sr}, +^{104}\text{SrO}]$ ,  $\text{Ba}[+^{136}\text{Ba}, +^{137}\text{Ba}, +^{138}\text{Ba}, +^{154}\text{BaO}]$ , and  $\text{Pb}[+^{206}\text{Pb}, +^{207}\text{Pb}, +^{208}\text{Pb}]$  were detected. Especially Ti, Sr and Ba frequently occur in the sampled CFA particles. At least 50 % of the CFA particles contained  $+^{48}\text{Ti}$ ,  $+^{88}\text{Sr}$  and  $+^{138}\text{Ba}$ , making them to potential markers for the detection of unprocessed atmospheric CFA particles. However, Gallavardin et al. (2008) showed that these elements are components of some mineral dust types such as illite, too.  $\text{Pb}[+^{206}\text{Pb}, +^{207}\text{Pb}, +^{208}\text{Pb}]$  is present in ~20 % of CFA1 particles and ~10 % of CFA2 particles. In CFA3 and CFA4 almost no particles contained Pb signals above the threshold, and hence it cannot be used as a marker for CFA.

In order to find a systematic difference in the chemical composition of dry- and wet-generated CFA particles, the signal ratio wet/dry was determined (see Fig. S3). In the following, we only focus on features that are characteristic of all CFA samples. A significant enhancement of signal intensity up to several hundreds of percent can be seen for mass-to-charge ratios [ $+57$ ,  $+113$ ], hinting at hydration of CaO. To explain the observed changes in signal intensity, we suggest the reactions R1, R2, R5, and R6, where R1 and R2 represent the hydration reaction, and R5 and R6 represent a possible molecular fragmentation after vaporization and ionization in ALABAMA. An increase was also found for mass-to-charge ratios [ $+105$ ,  $+155$ ], indicating the hydration of SrO and BaO (R3, R4 and R7, R8). Furthermore, a decrease of S-containing substances was registered:  $-^{32}\text{S}$ ,  $-^{48}\text{SO}$ ,  $-^{64}\text{SO}_2$ ,  $-^{80}\text{SO}_3$ ,  $-^{81}\text{HSO}_3$ ,  $-^{96}\text{SO}_4$ , and  $-^{97}\text{HSO}_4$  all appear to be reduced in wet-generated particles, which could be an indication for S being dissolved from 300 nm particles.

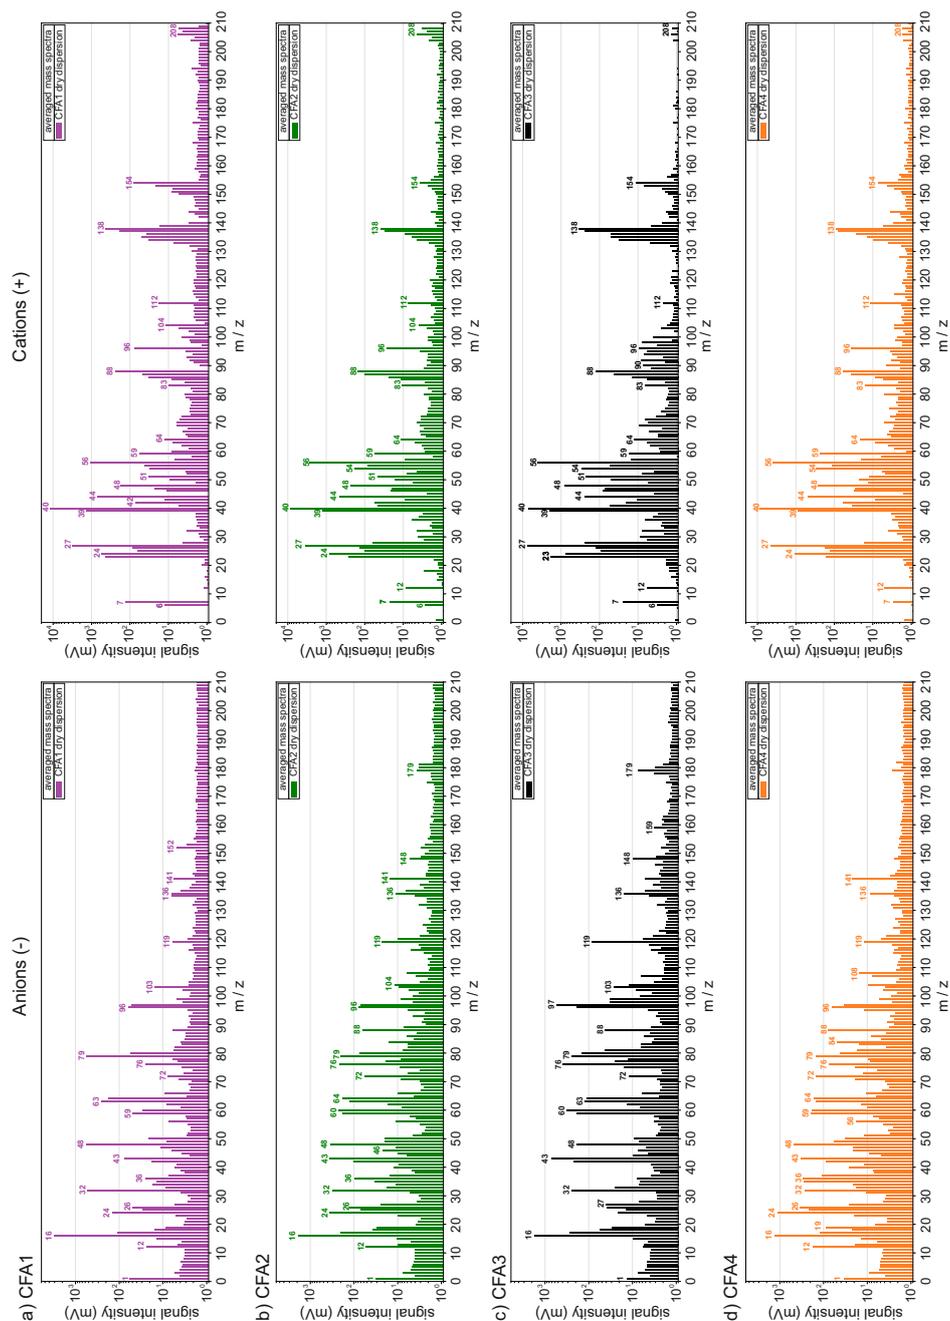

10 Averaged mass spectra of dry-dispersed CFA particles were used for identifying species that contribute to or do not seem to have an impact on the observed immersion freezing behavior. This was done by searching the mass spectra for species whose signal intensity correlates or anti-correlates with  $f_{\text{ice}}$  from LACIS measurements of the CFA samples (see Fig. S4). In case of correlation (see Fig. S4 a), only those peaks are shown for which the signal intensity is highest for CFA1 and lowest for CFA3. In case of anti-correlation (see Fig. S4 b), only those peaks are shown for which the signal intensity is highest for CFA3 and lowest for CFA1. CFA2 and CFA4 were not considered separately as they have a very similar immersion freezing behavior.

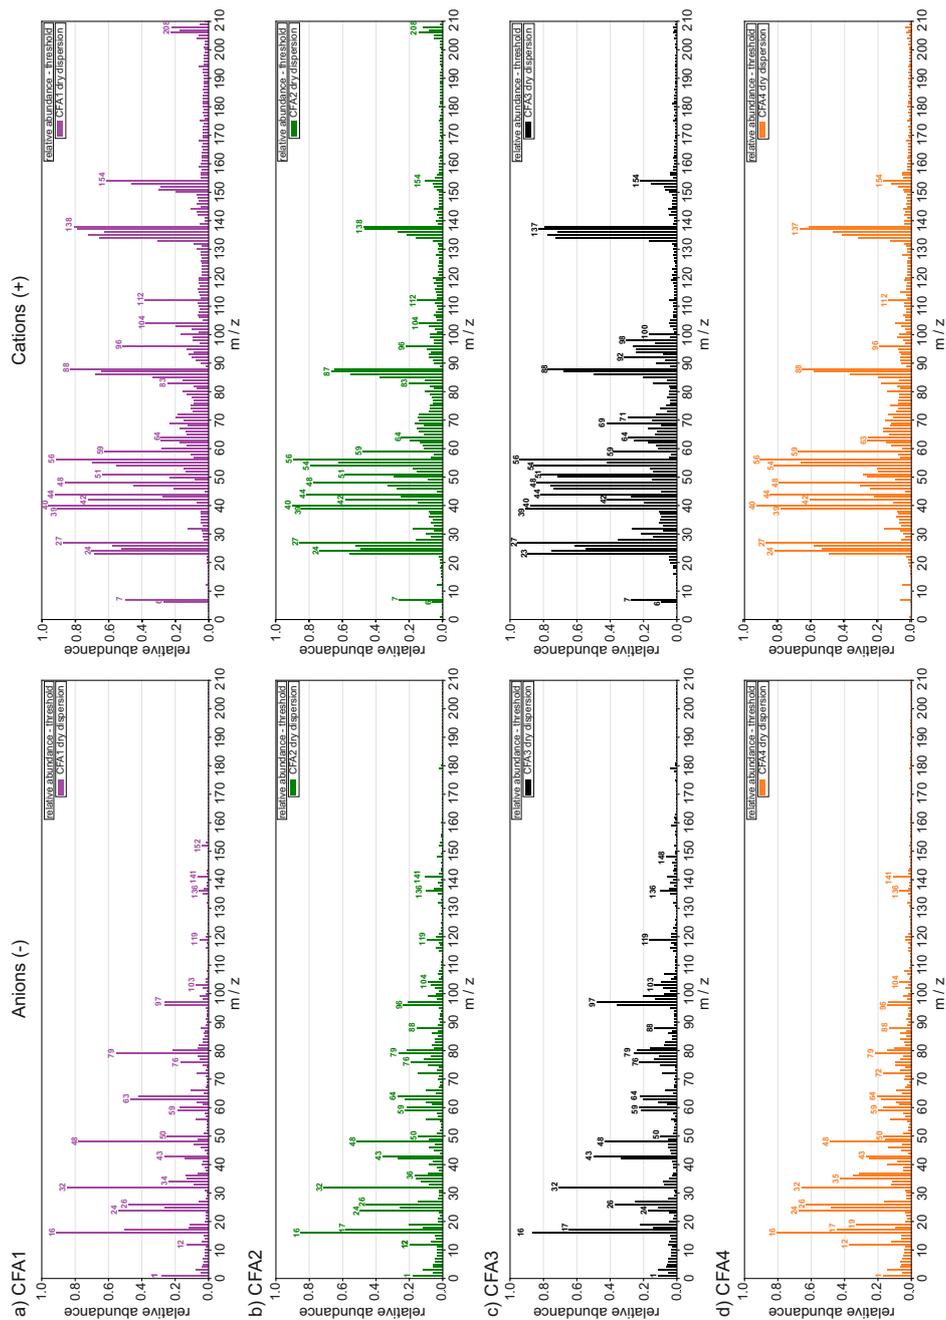

15 The above mentioned threshold was taken into account by just considering species, which were present in at least 10 % of CFA1 (correlation) or CFA3 (anti-correlation) particles.

Certain groups of compounds appear more often than others in relation to the total number of correlating/anti-correlating species.  $\text{Ca}[{}^{+40}\text{Ca}, {}^{+42}\text{Ca}, {}^{+44}\text{Ca}, {}^{+96}\text{Ca}_2\text{O}, {}^{+104}\text{CaSO}_2/\text{SrO}, {}^{+112}(\text{CaO})_2]$ - and  $\text{S}[{}^{-32}\text{S}, {}^{-48}\text{SO}]$ -containing species have highest signal intensities for CFA1 and lowest for CFA3. Also, correlation was found for  $\text{Pb}[{}^{+206}\text{Pb}, {}^{+207}\text{Pb}, {}^{+208}\text{Pb}]$ . Anti-correlation was found for many compounds amongst which  $\text{Si}[{}^{-60}\text{SiO}_2, {}^{-76}\text{SiO}_3, {}^{-77}\text{HSiO}_3, {}^{-99}\text{NaSiO}_3, {}^{-119}\text{AlSiO}_4, {}^{+28}\text{Si}, {}^{+56}\text{Si}_2]$ - and  $\text{Al}[{}^{-43}\text{AlO}, {}^{-119}\text{AlSiO}_4, {}^{+27}\text{Al}]$ -containing species occur frequently. In summary, the immersion freezing behavior of our CFA samples seems to be influenced by species containing Ca and S, and possibly by trace elements. Si and Al do not appear to contribute to the differences in immersion freezing efficiency that were observed between CFA samples.

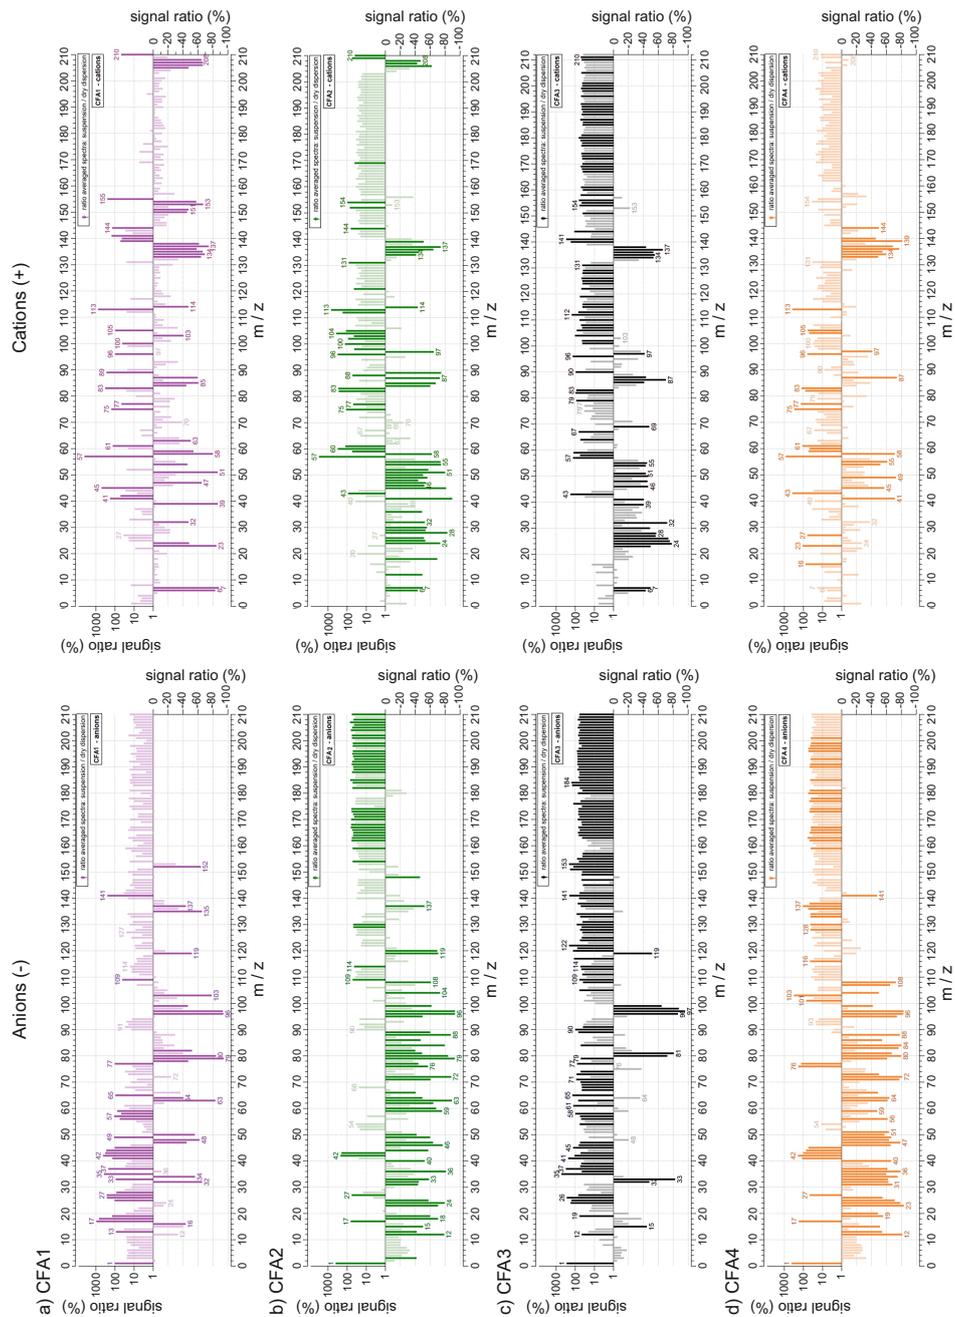

20

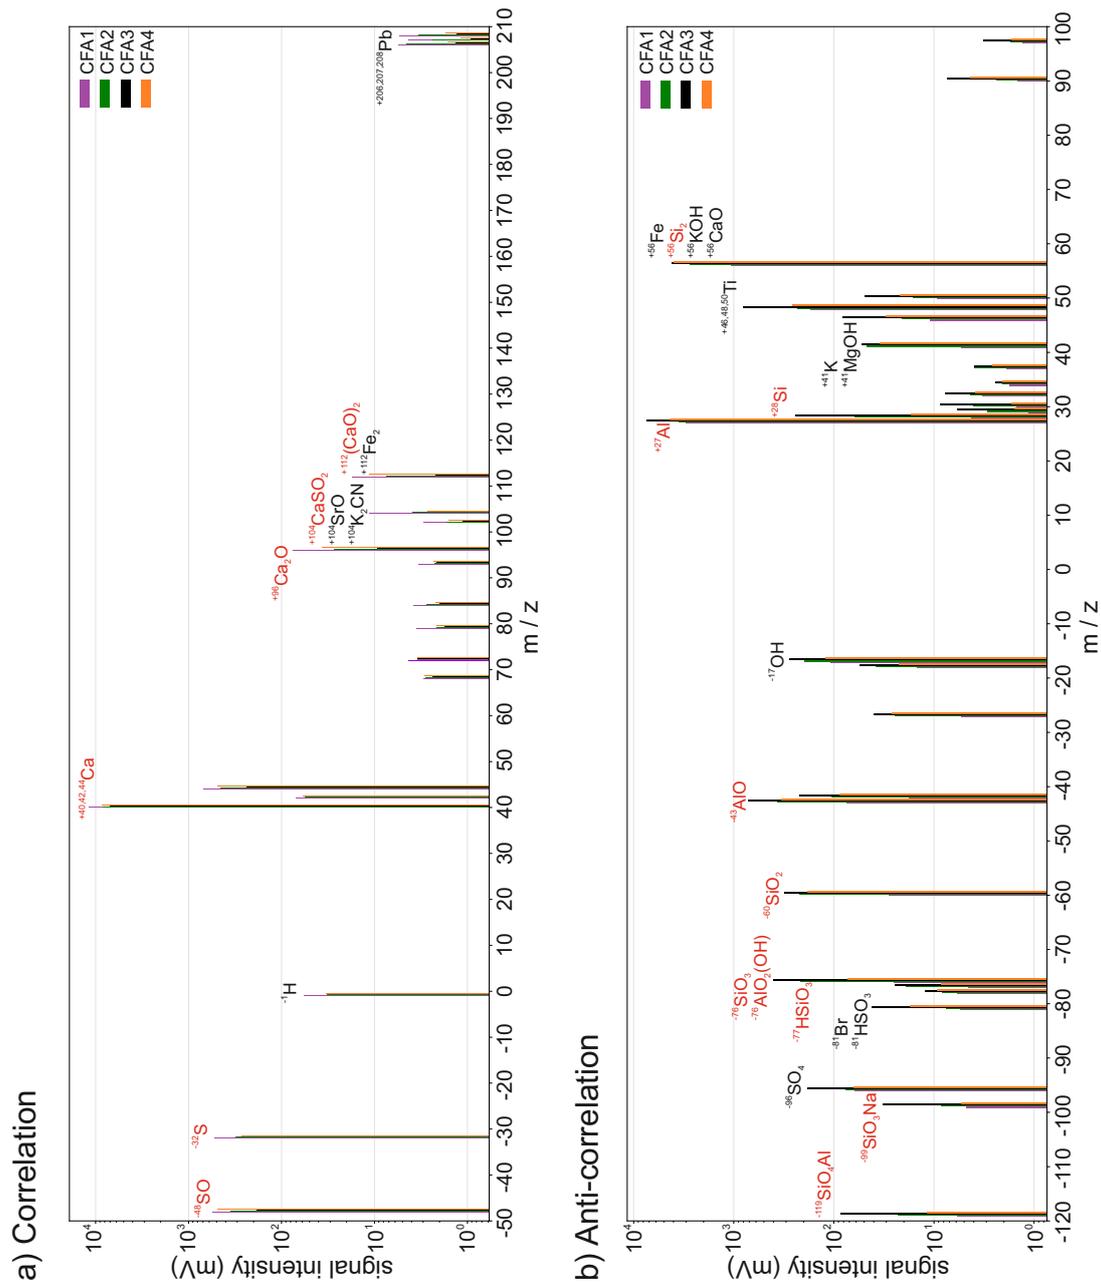

**Figure S1.** Averaged mass spectra for 300 nm dry-generated CFA particles. Common mass-to-charge ratios from left to right: [-16] O, [-32] S, [-43] AlO, [-48] SO, [-59] AlO<sub>2</sub>, [-60] SiO<sub>2</sub>, [-63] PO<sub>2</sub>, [-64] SO<sub>2</sub>, [-76] SiO<sub>3</sub>, [-79] PO<sub>3</sub>, [-80] SO<sub>3</sub>, [-88] (SiO)<sub>2</sub>, [-96] SO<sub>4</sub>, [-103] AlSiO<sub>3</sub>, [-119] AlSiO<sub>4</sub>, [-179] AlSi<sub>2</sub>O<sub>6</sub>, [+6, +7] Li, [+23] Na, [+24, +25, +26] Mg, [+27] Al, [+39, +41] K, [+40, +44] Ca, [+46, +47, +48] Ti, [+54] Fe, [+56] CaO/Fe/Si<sub>2</sub>/KOH, [+59] Co, [+64, +68] Zn, [+86, +87, +88] Sr, [+104] SrO/CaSO<sub>2</sub>, [+136, +137, +138] Ba, [+154] BaO, [+206, +207, +208] Pb.

**Figure S2.** Relative abundance of species in 300 nm dry-generated CFA particles. Background signals were determined and used as a threshold to decide whether a particle contained/did not contain a certain species. Common mass-to-charge ratios from left to right: [-16] O, [-32] S, [-43] AlO, [-48] SO, [-59] AlO<sub>2</sub>, [-60] SiO<sub>2</sub>, [-63] PO<sub>2</sub>, [-64] SO<sub>2</sub>, [-76] SiO<sub>3</sub>, [-79] PO<sub>3</sub>, [-80] SO<sub>3</sub>, [-88] (SiO)<sub>2</sub>, [-96] SO<sub>4</sub>, [-103] AlSiO<sub>3</sub>, [-119] AlSiO<sub>4</sub>, [+6, +7] Li, [+23] Na, [+24, +25, +26] Mg, [+27] Al, [+39] K, [+40, +42, +44] Ca, [+46, +47, +48] Ti, [+54] Fe, [+56] CaO/Fe/Si<sub>2</sub>/KOH, [+59] Co, [+64] Zn, [+86, +87, +88] Sr, [+104] SrO/CaSO<sub>2</sub>, [+136, +137, +138] Ba, [+154] BaO, [+206, +207, +208] Pb.

**Figure S3.** Signal ratio of 300 nm wet- vs. dry-dispersed CFA particles. Positive bars represent an increase in signal intensity for wet-generated particles in comparison to dry-generated particles. Stronger colors indicate species for which the signal intensity has changed by more than 40 %. Common mass-to-charge ratios from left to right: [-32] S, [-48] SO, [-64] SO<sub>2</sub>, [-80] SO<sub>3</sub>, [-81] HSO<sub>3</sub>, [-96] SO<sub>4</sub>, [-97] HSO<sub>4</sub>, [+57] CaOH, [+105] SrOH, [+113] Ca<sub>2</sub>O<sub>2</sub>H, [+155] BaOH.

**Figure S4.** Averaged mass spectra. Shown are only those species for which the signal intensity a) correlates (CFA1>CFA2,CFA4>CFA3) or b) anti-correlates (CFA3>CFA2,CFA4>CFA1) with  $f_{ice}$  of dry-generated CFA. Red labels indicate Ca- and S-containing species in case of correlation and Si- and Al-containing species in case of anti-correlation. Species with signal intensities < 10 were not considered, except for mass-to-charge ratios [+206, +207, +208] indicating a correlation with Pb.

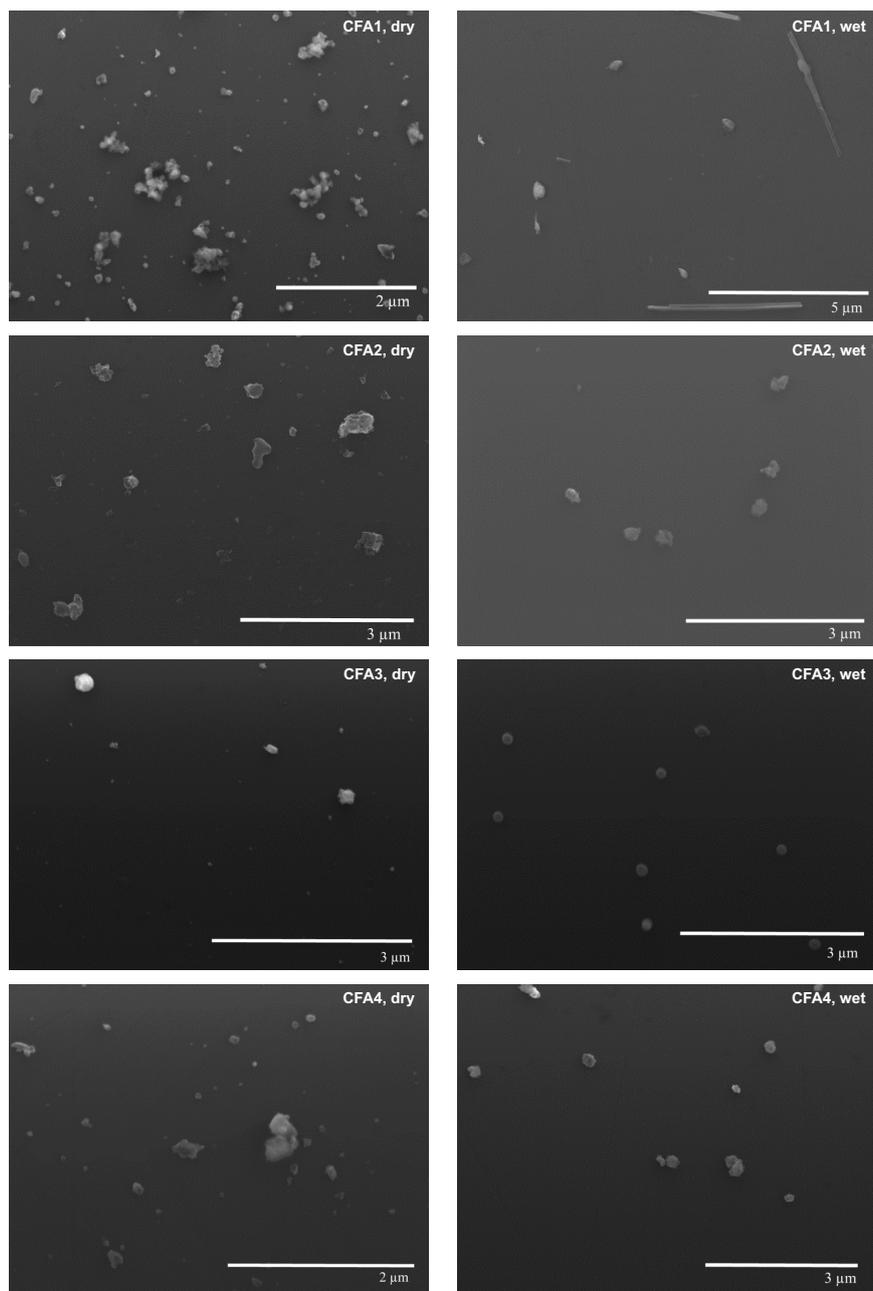

**Table S1.** Chemical composition of CFA particles from dry and wet particle generation as determined by EDX measurements. The number of investigated particles is given in parentheses. Elements in parentheses have only been detected in some of the particles.

CFA sample	Dry particle generation	Wet particle generation	Difference wet/dry
1	O, Ca, Si, S (16) Si, O (10)	O, Ca, Al, (Fe, Si) (15) O, Al, (Fe, Si) (12)	- S +Fe, Al
2	O, Fe, Al, Si, S, Ca (9) O, Fe, Al, Si, S, Ca, Mg (7) O, Si, Ca, Fe (1)	O, Ca, Al, Si, S (16) O, Ca, Al, Si, S, Fe (3) O, Si, Ca (1)	-Mg
3	Si, O, Al, Fe, Ca, (Mg, S) (9) Si, O (3) O, S, (Al, Fe, Si) (3) O, Ca, Si (1) O, Ca (1)	Si, O, Al, Fe, Ca, (Mg, S, K) (5) Si, O, (Al, Fe) (19) O, Ca, Si, S, (Fe, Mg) (3)	
4	Si, O (5) O, C, Si, Ca, Al, (Fe, S, Mg) (11) Si, O, Al (5) C, O (2)	Si, O (11) O, Ca, Si, Al, S, (Fe) (8) O, Si, (Al, Fe) (2)	- C

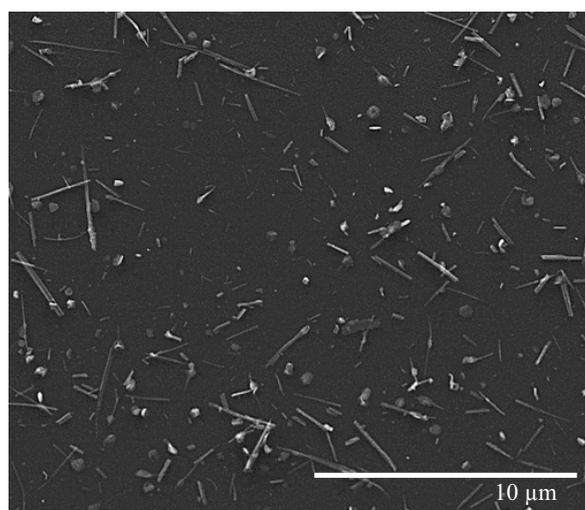

## S2 ESEM/EDX

Fig. S5 shows the ESEM images of dry- and wet-generated quasi-monodisperse CFA particles. Spherical particles, often described as the main particle type in CFA in literature (e.g., Davison et al., 1974; Ramsden and Shibaoka, 1982; Flanders, 1999; Zhang et al., 2011), were rarely detected in the dry-generated samples. Spherical shapes are thought to originate from combustion of organic substances and melting of mineral inclusions in the coal, leading to the formation of spherical ash droplets (Damle et al., 1982; Flagan and Seinfeld, 1988). The spherical shape is often retained as the particles cool and solidify, however, particles can also be deformed. Seames (2003) reported CFA particles in the size range between 0.1 and 1  $\mu\text{m}$  with irregular shapes, comparable to the morphology shown in Fig. S5 and argued that this deviation from the sphere could be the result of particle inflation, cracking, or shedding due to expanding gases, partial melting, and/or agglomeration. The latter is a probable mechanism in the case of CFA1, where many particles consisting of aggregates of small spherules can be seen. Gieré et al. (2003) who performed transmission electron microscopy of class F CFA particles found both smooth spherical particles and irregularly shaped particles in the size range of several hundred nanometers. The irregularly shaped particles were made up of crushed glass, or glassy spheres with small crystals attached to their surface which concealed the spherical shape. Differences in morphology between the different CFA samples can be explained by differences in coal composition and combustion conditions (Zhang et al., 2006). In general, the wet-generated CFA particles feature a more uniform and compact shape than the dry-generated ones, maybe because irregularities are covered by a layer of dissolved and redistributed material during suspension and subsequent atomization (Herich et al., 2009). An exception are wet-generated CFA1 particles, which, in addition to spheroidal particles, occur as needle-shaped particles (see Fig. S6 and Appendix B).

The results of the EDX chemical composition analysis are summarized in Table S1. EDX was performed for each sample for both dry- and wet-generated particles. Elements that were detected in all samples, either from dry or wet particle generation are O, Ca, and Si, which is in agreement with the ALABAMA mass spectra. However, characteristic trace elements (Ti, Co, V, Ba, Sr, Zn, and Pb), that are present in the CFA samples according to ALABAMA, were not detected by EDX. Differences between dry- and wet-generated particles were identified and, for the most part, agree with the mass spectra. However, EDX results should be treated with caution from a statistical point of view: Due to the time-consuming analysis and the, in parts, non-ideal loading of the substrates, ~20 particles were characterized in each case. Hence, a more detailed comparison between samples, particle generation methods, and to the ALABAMA mass spectra cannot be provided.

**Figure S5.** ESEM images of quasi-monodisperse (300 nm) CFA particles sampled onto B substrates with the multi-MINI. Left: Dry particle generation, right: wet particle generation. Note the different magnification.

**Figure S6.** ESEM image of quasi-monodisperse (300 nm) CFA1 particles from wet particle generation.

### S3 XRD

XRD patterns (see Figs. S7 to S10) were measured for the original samples and for the samples after being suspended in water which then was evaporated. This was done to identify major crystalline phases and processes taking place during the interaction of CFA with water. Note that this is a bulk investigation, i.e., a direct connection may not be drawn between XRD and the LACIS, ALABAMA, and EDX results. Amounts of the identified phases are given in each plot but must be treated cautiously, as the CFA powder is quite inhomogeneous and only ~0.5 g were used for an XRD measurement. Table S2 gives an overview of phases identified in the CFA samples.

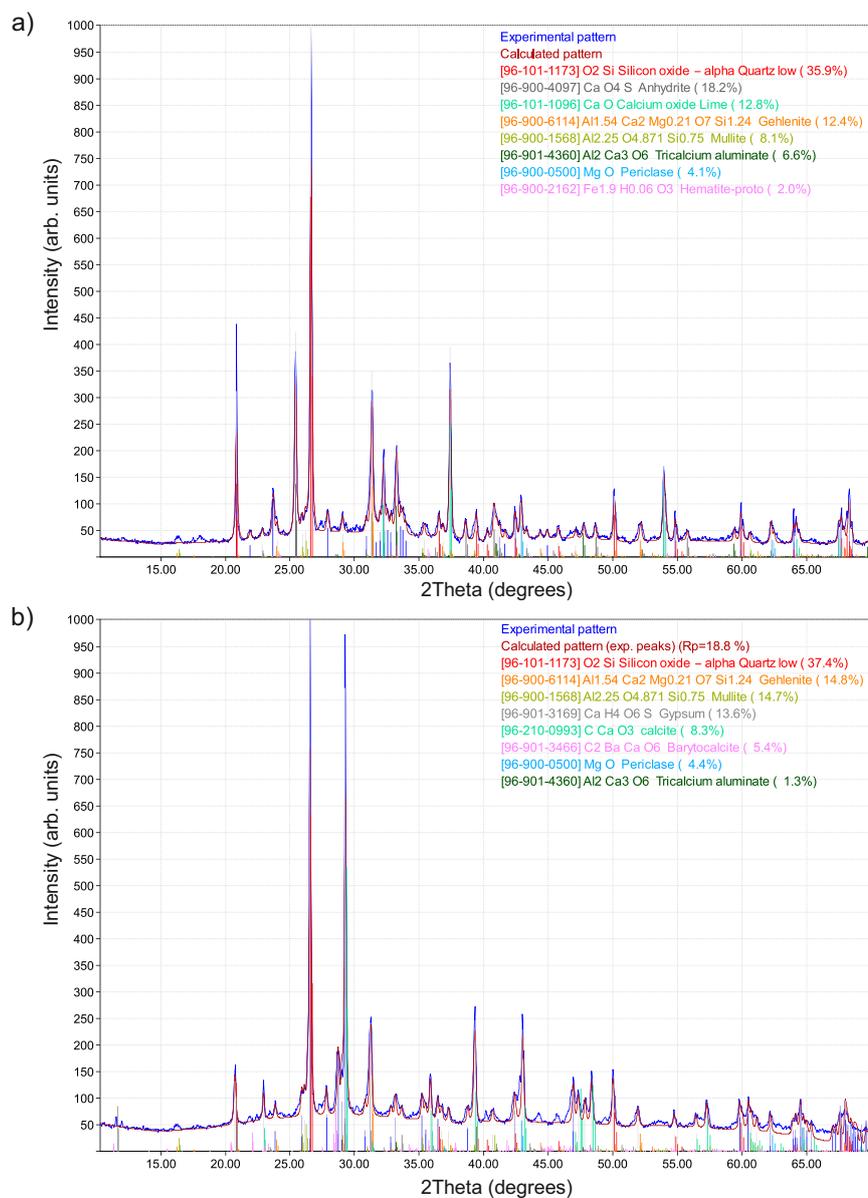

Quartz ( $\text{SiO}_2$ ) is the major crystalline phase in all of the samples, either dry or after suspension. Anhydrite ( $\text{CaSO}_4$ ) and quicklime ( $\text{CaO}$ ) occur in all of the dry samples, however, prominent peaks can only be seen for CFA1 (Fig. S7). Minor crystalline phases in the dry samples include mullite ( $\text{Al}_6\text{Si}_2\text{O}_{13}$ ), gehlenite ( $\text{Ca}_2\text{Al}[\text{AlSiO}_7]$ ), hematite ( $\text{Fe}_2\text{O}_3$ ), magnetite ( $\text{Fe}^{2+}/\text{Fe}^{3+}\text{O}_4$ ), periclase ( $\text{MgO}$ ), rutile ( $\text{TiO}_2$ ), anatase ( $\text{TiO}_2$ ), and tricalcium-aluminate ( $3\text{CaO}\cdot\text{Al}_2\text{O}_3$ ), all of which have been identified previously in CFA samples of different geographical origin (e.g., McCarthy et al., 1984; Querol et al., 1996; Nathan et al., 1999; Shoumkova et al., 2005; Ward and French, 2006; Liang et al., 2010; Nyambura et al., 2011).

Distinct changes in the XRD pattern of dry particles and particles that have been suspended in water can be seen for CFA1. Here, the hydration of anhydrite ( $\text{CaSO}_4$ ) to gypsum ( $\text{CaSO}_4\cdot 2\text{H}_2\text{O}$ , see R1 of the main text) can be observed. This is a process which is also relevant for submicron CFA particles, as those are likely to be coated with anhydrite (Enders, 1996). Also, the patterns indicate that quicklime ( $\text{CaO}$ ) is converted into calcite ( $\text{CaCO}_3$ ) via hydration and carbonation (see R2 and R3 of the main text). Only minor changes between dry bulk and bulk after suspension can be seen for the other CFA samples, probably because they contain much less anhydrite and quicklime than CFA1 (see Sect. S4). The decrease of the magnetite fraction in suspension particles of CFA2 and CFA3 in comparison to the dry bulk could be due to the suspension preparation routine. Ferromagnetic magnetite particles stick to the magnetic agitator while stirring. When removing the agitator from the suspension, those particles are depleted. However, we do not expect the removal of magnetic material from the CFA suspensions to cause the observed decrease in immersion freezing efficiency because a decrease was also observed for CFA suspensions which were not in contact with the magnetic agitator (see Fig. 5 of the main text).

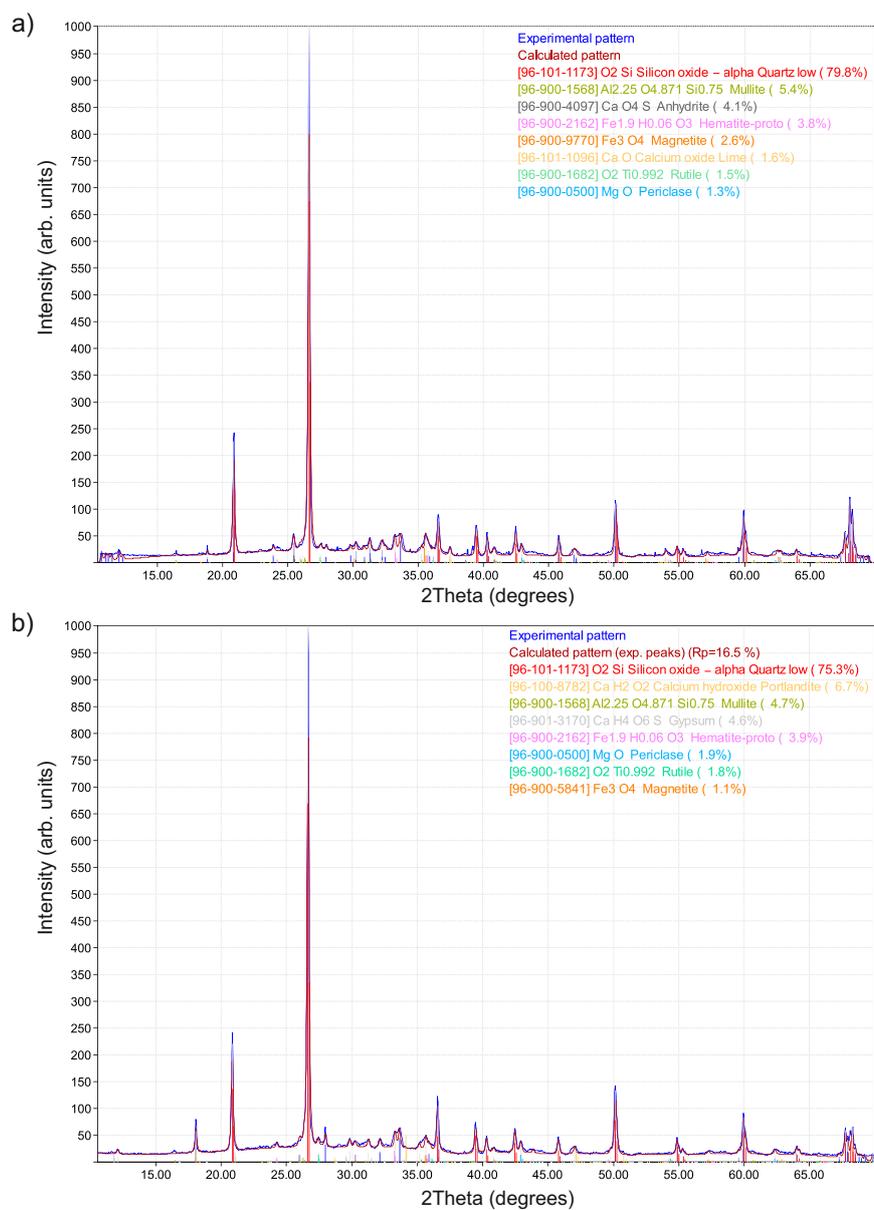

It has been argued previously that the amorphous, i.e., non-crystalline, fraction may play an important role for the immersion freezing behavior of CFA particles (Umo et al., 2015). Even though the amorphous fraction was not quantitatively determined here, the broad "hump", which occurs in the region up to  $\sim 40^\circ$  and is most prominent in the CFA3 pattern (Fig. S9), indicates that this sample contains the highest amount of amorphous material in bulk. This is in accordance with findings by Ward and French (2006) who investigated the amorphous fraction of different CFA samples and showed that CFA from black coal combustion contains more amorphous material than CFA from brown coal combustion. Matsunaga et al. (2002) described an increase of the amorphous fraction towards smaller particle sizes due to the fast cooling rates of small particles, i.e., CFA3 likely contains the highest amount of amorphous material in 300 nm particles. From this, we can conclude that amorphous material in CFA does not seem to have a promoting effect on the immersion freezing efficiency, as CFA3 was the least efficient of the four dry-dispersed samples.

**Table S2.** Identified crystalline phases from XRD measurements of dry CFA and CFA after suspension and evaporation. Checkmarks in parentheses indicate minor phases (< 5 %).

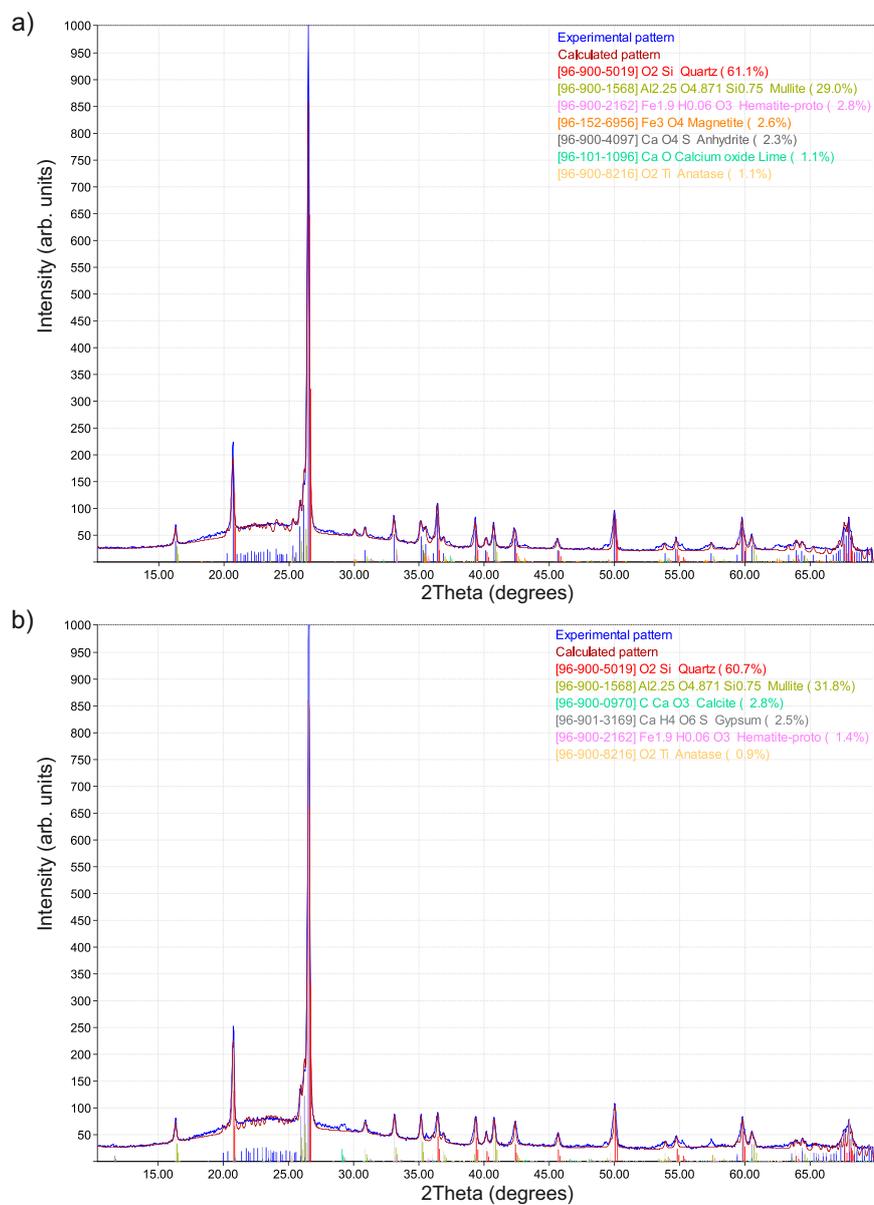

Crystalline phase	Chemical formula	CFA1		CFA2		CFA3		CFA4	
		dry	wet	dry	wet	dry	wet	dry	wet

Numbers in parentheses indicate the identified amount of the crystalline phase but should be treated cautiously.

**Figure S9.** XRD patterns of a) dry bulk CFA3 and b) CFA3 after suspension and evaporation. Numbers in brackets in the legend indicate reference pattern IDs from the Crystallography Open Database. Numbers in parentheses indicate the identified amount of the crystalline phase but should be treated cautiously.

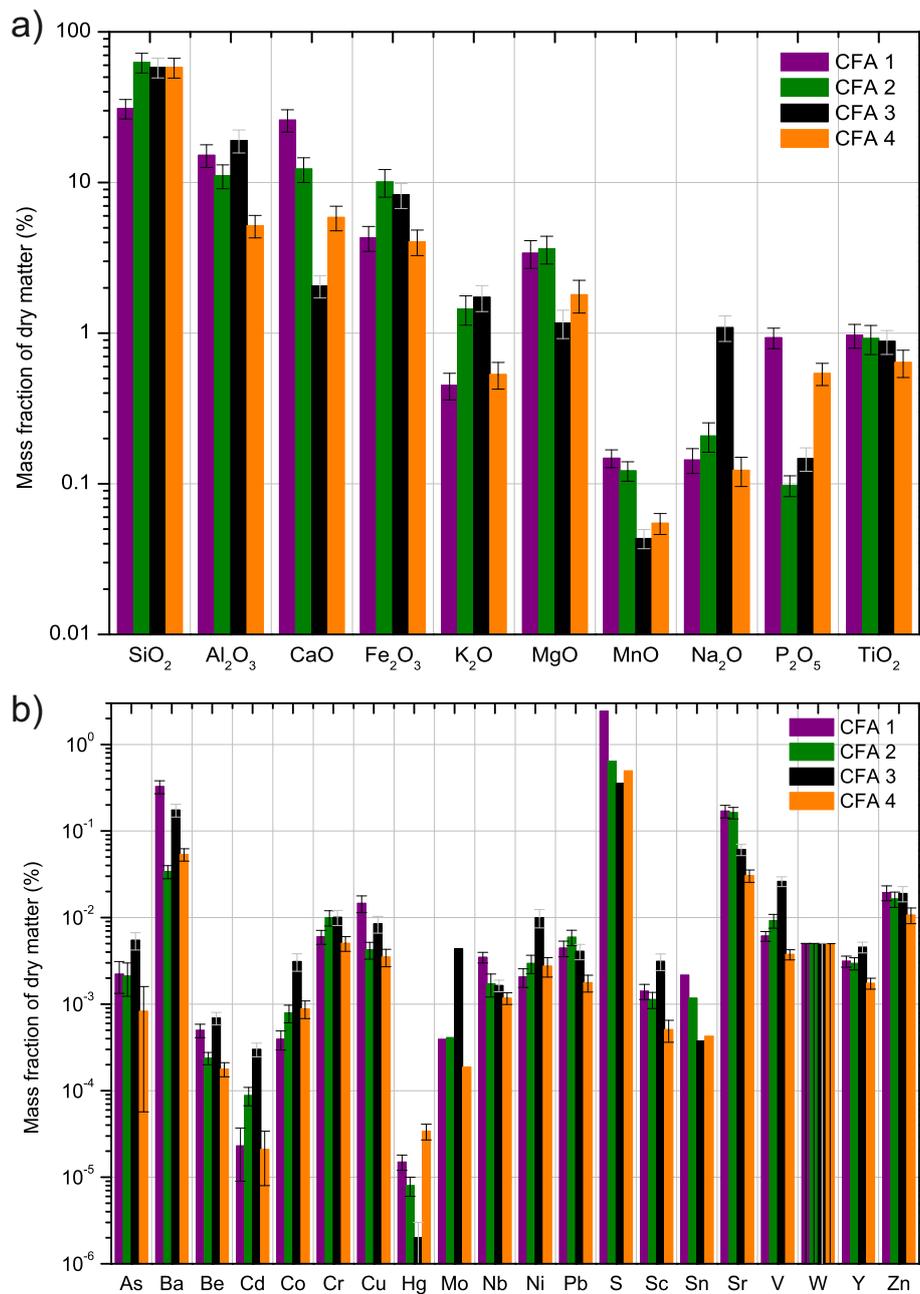

**Figure S10.** XRD patterns of a) dry bulk CFA4 and b) CFA4 after suspension and evaporation. Numbers in brackets in the legend indicate reference pattern IDs from the Crystallography Open Database. Numbers in parentheses indicate the identified amount of the crystalline phase but should be treated cautiously.

#### S4 Bulk chemical composition analysis

It is known that the chemical composition of CFA is dependent on particle size (e.g., Davison et al., 1974). Consequently, the bulk chemical composition is of limited value for identifying species influencing the immersion freezing behavior of 300 nm particles. However, the results can be used to classify the CFA samples according to the American Society for Testing Materials (ASTM, standard C618, 2015). Traditionally, this classification is used to estimate which and how much CFA should be added to cement, because different classes of CFA have different effects on cement hardening and durability (Canpolat et al., 2004).

CFA is defined as class F when the combined content of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{Fe}_2\text{O}_3$  exceeds 70 wt%. CFA is of class C when the combined content of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{Fe}_2\text{O}_3$  is between 50 and 70 wt%. Class C CFA typically has a CaO content  $\geq 20\%$  causing cementitious (self-hardening when reacted with water) properties. Class F, with a typical CaO content of 1 to 12 wt%, is of pozzolanic nature (self-hardening when reacted with water and portlandite; Ahmaruzzaman, 2010). The combined contents of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{Fe}_2\text{O}_3$  of CFA1, CFA2, CFA3, and CFA4 are  $51 \pm 8$ ,  $84 \pm 13$ ,  $85 \pm 14$ , and  $67 \pm 10$  wt%, respectively. The CaO contents of CFA1, CFA2, CFA3, and CFA4 are  $26 \pm 4$ ,  $12 \pm 2$ ,  $2 \pm 0.4$ , and  $6 \pm 1$  wt%, respectively. Consequently, CFA1 is of class C and CFA2, CFA3, and CFA4 are of class F, within measurement uncertainty.

In addition to the bulk chemical composition analysis, Loss On Ignition (LOI) values were determined. The LOI value is a measure of the amount of unburnt fuel, presumably carbonaceous particles, in the CFA samples and hence useful to assess the completeness of combustion in the power plant. The LOI values of the four CFA samples are  $-0.8 \pm 5\%$  for CFA1,  $0.2 \pm 5\%$  for CFA2,  $0.8 \pm 5\%$  for CFA3, and  $8.1 \pm 5\%$  for CFA4, i.e., apparently only CFA4 still contains a relevant amount of unburnt fuel after combustion in the power plant. Particles with high C content tend to form irregular structures because of enhanced aggregation (Hiranuma et al., 2008). The specific surface area of CFA4, which is more than one order of magnitude higher than that of the other samples (see Sect. S8), could hence be in line with the comparably large LOI value. The fact that CFA4 has the lowest immersion freezing efficiency of all samples in the LINA experiments might be related to the amount of unburnt fuel in this sample. Carbonaceous particles, such as soot, have previously been shown to possess limited ice nucleation efficiency in the immersion mode (e.g., Chen et al., 2018).

**Figure S11.** Mass fractions of a) major oxides (calculated from elemental mass fractions) and b) minor elements in CFA dry bulk material.

**Table S3.** Mean  $\mu$  and standard deviation  $\sigma$  of the bi-modal normal distribution fits to size distributions of wet-generated CFA particles.

Sample	Mode	$\mu$	$\sigma$
CFA1	1	74.27	1.76
	2	182.03	1.34
CFA2	1	45.50	1.56
	2	128.03	1.52
CFA3	1	39.45	1.46
	2	96.38	1.50
CFA4	1	39.94	1.30
	2	97.85	1.67

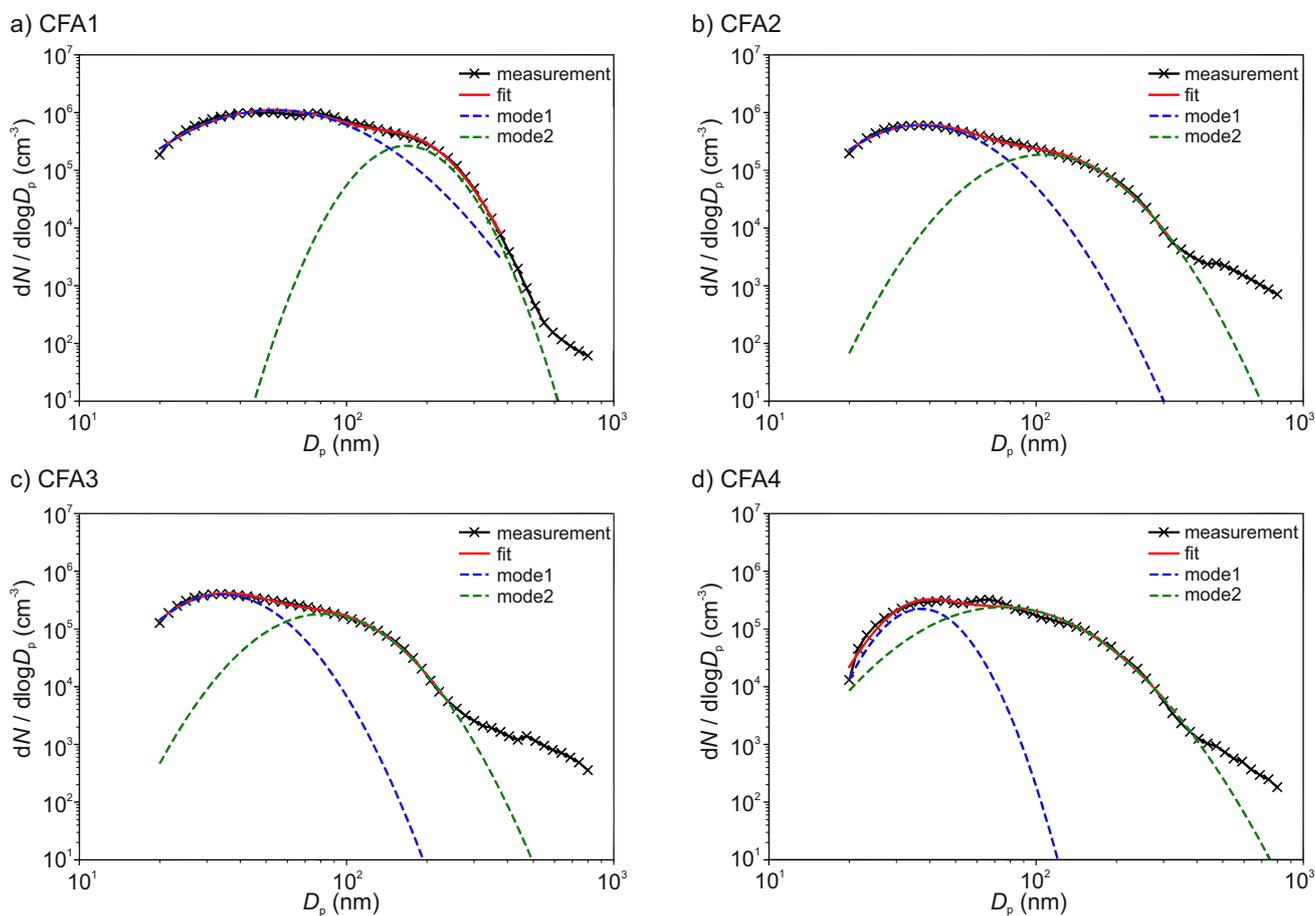

## S5 Size Distributions

Mobility size distributions of CFA aerosol from wet-particle generation were measured with a Differential Mobility Particle Spectrometer (DMPS). An inversion routine (similar to Stratmann and Wiedensohler, 1996) was used to obtain size distributions (see Fig. S12). This was done to exclude the possibility that the investigated 300 nm particles consist of purely water-soluble material which would bias the LACIS measurements. Water-soluble particles would dissolve when being activated to cloud droplets and freezing would occur due to homogeneous nucleation only. In this case,  $f_{\text{ice}}$  would be underestimated and a correction would be necessary.

The size distributions appear to be tri-modal. However, a bi-modal normal distribution fit was applied, as only part of the third mode was captured. Table S3 shows the fit parameters, i.e., mean  $\mu$  and standard deviation  $\sigma$  of both normal distribution modes for each sample. The fitting was performed to identify the size range of the different occurring modes. In contrast to earlier publications (Damle et al., 1982; Flagan and Seinfeld, 1988), where CFA size distributions were characterized as bi-modal, with the first submicron mode representing particles formed from the gas phase by nucleation/condensation and the second supermicron mode representing residual ash particles, Linak et al. (2002) describe a tri-modal size distribution with an additional mode enclosed between nucleation/condensation mode and residual ash mode. This "fine fragmentation" mode could be equal to mode 2 in the shown CFA size distributions. Mode 1 at smaller sizes originates from water-soluble substances in the suspension and conceals the nucleation/condensation mode.

In case of CFA2, CFA3, and CFA4, suspensions were prepared in the same way as for LACIS measurements, i.e., by suspending 0.5 g CFA in 100 mL distilled water, 10 min of ultrasonification, and 24 h of stirring. For these samples, the ratio of concentrations of the two modes clearly shows that 300 nm particles almost exclusively consist of water-insoluble material. Mode 1, i.e., water-soluble material, does not contribute to the measured number concentrations of CFA2, CFA3, and CFA4 at 300 nm, meaning that no correction of  $f_{\text{ice}}$  is needed.

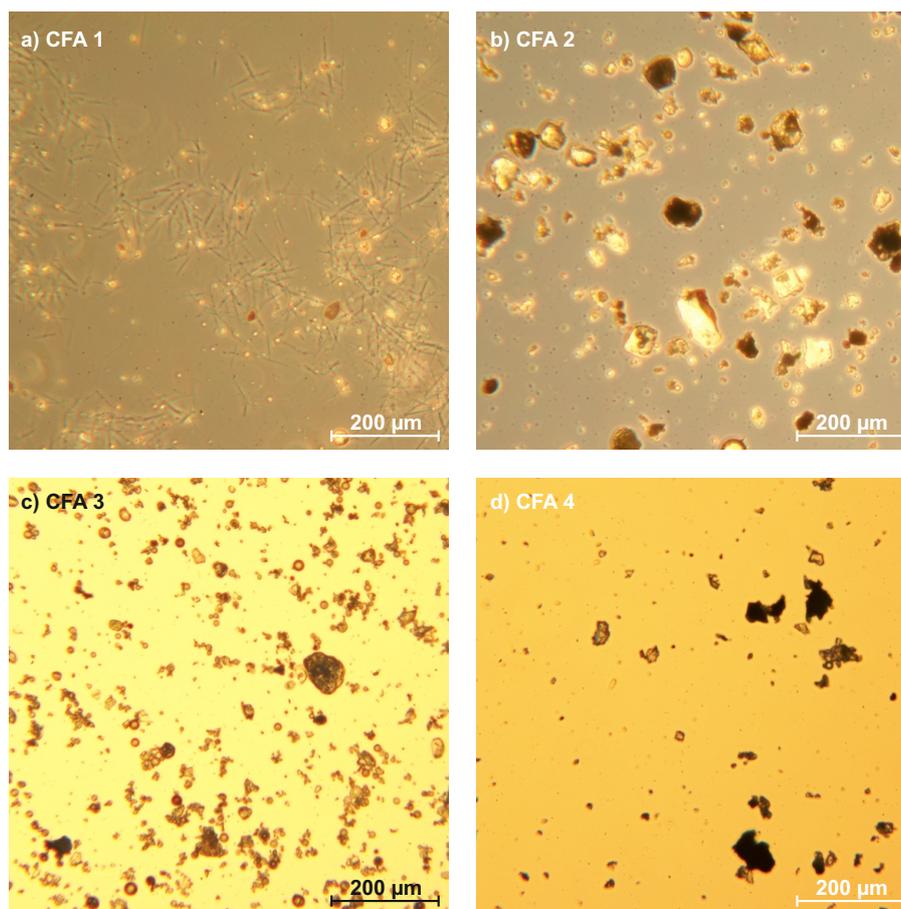

In case of CFA1, a fresh suspension was prepared to minimize the occurrence of needle-shaped particles which would bias the size distribution. However, we suspect that needle-shaped particles already started forming during the size distribution measurement, which takes ~15 min. In fact, we observed a fresh CFA1 suspension droplet under an optical microscope and saw the formation of needle-shaped particles within ~10 min. This would also explain, why the size distribution of CFA1 differs from those of the other samples: The mean of mode 1 is at ~74 nm for CFA1, while it is close to 40 nm for the other three CFA samples (see Table S3). Also, mode 1 is much broader for CFA1 in comparison to the others. This suggests that we measured the size distribution of an external mixture of needle-shaped particles and spheroidal particles which cannot be separated from one another. Hence, no conclusion can be drawn about the occurrence of purely water-soluble particles at 300 nm for CFA1.

**Figure S12.** Size distributions from DMPS measurements with wet-generated CFA particles. a) Size distribution of particles generated from a freshly prepared CFA1 suspension. b), c), and d) Size distributions of aerosol generated from suspensions of CFA2, CFA3, and CFA4 that were ultrasonicated for 10 min and stirred for 24 h.

## S6 Light Microscope

Images of liquid CFA suspension droplets were taken with a digital camera coupled to an optical microscope (Primovert, Carl Zeiss Microscopy GmbH, Jena, Germany). The magnification is 200x and unpolarized light was used. The suspensions were prepared in the same way as for the LACIS measurements and pipetted onto a glass microscope slide. A second slide was put on top of the liquid droplet to increase the amount of particles in focus and to avoid evaporation. Figure S13 a shows that needle-shaped particles are present in the aqueous environment of the CFA1 suspension, suggesting that they precipitate in the suspension and are not only weakly water-soluble. The needle-shaped particles are several tens of microns long. In addition to the needle-shaped particles, smaller spherical and irregularly shaped particles can be seen. Droplets from the CFA2, CFA3, and CFA4 suspensions do not contain needle-shaped particles, only irregular and spherical particles. Generally, the number of irregularly shaped particles visible in Fig. S13 is much higher than the number of spherical particles for all samples. Coagulation of particles can be observed to some extent for all samples and might affect the surface area available for triggering immersion freezing in the cold stage experiments as described by Emersic et al. (2015).

**Figure S13.** Optical microscope images of CFA suspension droplets. a) CFA1, where needle-shaped particles are present in the aqueous environment. b), c), and d) CFA2, CFA3, and CFA4, where no needle-shaped particles were observed.

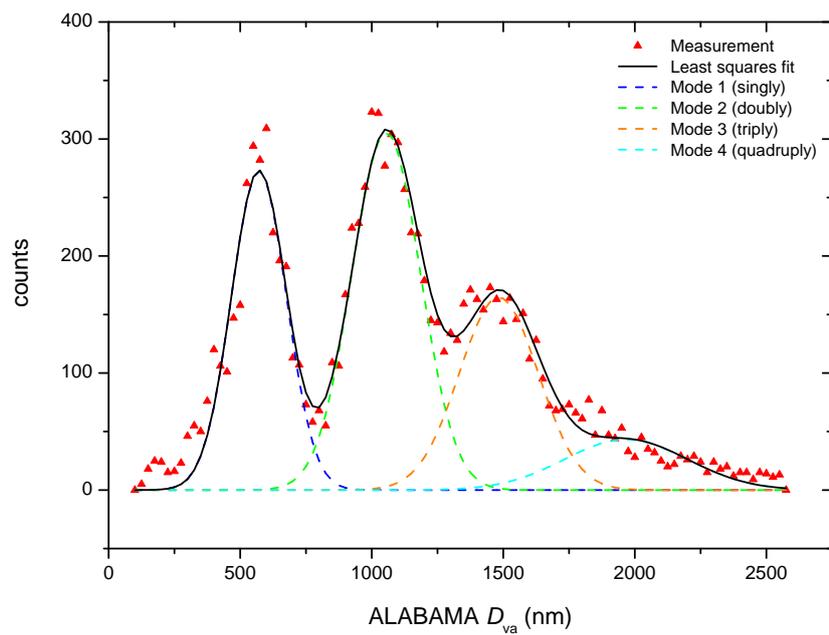

## S7 Multiple charge correction

Multiple charge fractions were determined from ALABAMA size distribution measurements of the quasi-monodisperse aerosol (see Fig. S14). The black line represents the result of a least-squares fit assuming a four-modal normal distribution. The multiply-charged fractions were determined by dividing the number of counts below the separate modes by the total number of counts. The multiple charge correction of the measured  $f_{ice}$  values was performed according to Hartmann et al. (2016) and Burkert-Kohn et al. (2017).

Note that multiply-charged fractions differ substantially for the different samples and particle generation methods, and, in case of dry particle generation, also increase with duration of the experiment. On the one hand, this increase could be caused by a decreasing efficiency of the cyclone due to accumulated material within. On the other hand, there is a temporal shift in size distribution of particles in the reservoir of the aerosol generator. Hence, multiply-charged fractions of dry-generated CFA were determined specifically for those points in time when LACIS measurements took place. Multiply-charged fractions given in Table S4 are averaged values for a time frame starting ~1 hour after particle generation was turned on and lasting ~20 minutes, which is when most LACIS measurements took place. LACIS data acquired at an earlier point in time were corrected with the respective multiply-charged fractions (not shown).

**Table S4.** Multiply-charged fractions as determined from ALABAMA size distribution measurements.

$n$	1	2	3	4	5
$D_p$ (nm)	300	507	706	902	1097
<b>CFA 1 dry</b>	0.81	0.19	-	-	
<b>CFA 2 dry</b>	0.59	0.29	0.09	0.03	
<b>CFA 3 dry</b>	0.28	0.38	0.24	0.1	
<b>CFA 4 dry</b>	0.67	0.21	0.07	0.05	
<b>CFA 1 wet</b>	0.59	0.33	0.05	0.03	
<b>CFA 2 wet</b>	0.58	0.36	0.04	0.02	
<b>CFA 3 wet</b>	0.34	0.40	0.09	0.09	0.08
<b>CFA 4 wet</b>	0.6	0.29	0.06	0.05	

**Figure S14.** Average size distribution of dry-generated CFA3 particles measured with ALABAMA.  $D_{va}$  is the vacuum aerodynamic diameter.

## S8 BET specific surface area

The specific surface area of the four CFA samples was determined by 11-point BET measurements using  $N_2$  gas. The detection limit of the instrument (Nova 2200e, Quantachrome Instruments, Boynton Beach, FL, USA) is  $0.01 \text{ m}^2 \text{ g}^{-1}$ . Samples were degassed for 3 to 4 hours at  $80 \text{ }^\circ\text{C}$  prior to the measurements. The results shown in Table S5 are average values of fits ( $R^2 = 0.999$ ) to three measurements with each sample. The given errors correspond to the standard deviation of the three results of each sample. Measurements with CFA1, CFA2, and CFA3 yielded results which are quite close to the detection limit. Independent measurements with bulk CFA at a different laboratory showed very similar results (CFA1:  $1.7 \text{ m}^2 \text{ g}^{-1}$ , CFA2:  $4 \text{ m}^2 \text{ g}^{-1}$ , CFA3:  $1 \text{ m}^2 \text{ g}^{-1}$ , CFA4:  $52 \text{ m}^2 \text{ g}^{-1}$ ), indicating that the low values given in Table S5 are trustworthy. Determination of the pore volume fraction showed that CFA1, CFA2, and CFA3 are non-porous, CFA4 has low porosity.

**Table S5.** BET specific surface area of bulk (used for LINA  $n_s$  calculations) and fine CFA (used for WISDOM  $n_s$  calculations).

CFA sample	BET specific surface area ( $\text{m}^2 \text{ g}^{-1}$ )
1 bulk	$1.4 \pm 0.3$
1 fine	$1.2 \pm 0.2$
2 bulk	$5.9 \pm 0.6$
3 bulk	$1.5 \pm 0.3$
4 bulk	$49.4 \pm 0.7$
