Abstract. The seasonal evolution of O₃ and its photochemical production regime in a polluted region of eastern China between 2014 and 2017 has been investigated using observations. We used tropospheric ozone (O₃), carbon monoxide (CO), and formaldehyde (HCHO, a marker of VOCs (volatile organic compounds)) partial columns derived from high-resolution Fourier transform spectrometry (FTS); tropospheric nitrogen dioxide (NO₂, a marker of NO_x (nitrogen oxides)) partial column deduced from the Ozone Monitoring Instrument (OMI); surface meteorological data; and a back trajectory cluster analysis technique. A broad O₃ maximum during both spring and summer (MAM/JJA) is observed; the day-to-day variations in MAM/JJA are generally larger than those in autumn and winter (SON/DJF). Tropospheric O₃ columns in June are 1.55×10^{18} molecules cm⁻² (56 DU (Dobson units)), and in December they are 1.05×10^{18} molecules cm⁻² (39 DU). Tropospheric O₃ columns in June were ~ 50 % higher than those in December. Compared with the SON/DJF season, the observed tropospheric O₃ levels in MAM/JJA are more influenced by the transport of air masses from densely populated and industrialized areas, and the high O₃ level and variability in MAM/JJA

is determined by the photochemical O₃ production. The tropospheric-column HCHO/NO₂ ratio is used as a proxy to investigate the photochemical O₃ production rate (PO₃). The results show that the PO₃ is mainly nitrogen oxide (NO_x) limited in MAM/JJA, while it is mainly VOC or mixed VOC–NO_x limited in SON/DJF. Statistics show that NO_x-limited, mixed VOC–NO_x-limited, and VOC-limited PO₃ accounts for 60.1 %, 28.7 %, and 11 % of days, respectively. Considering most of PO₃ is NO_x limited or mixed VOC–NO_x limited, reductions in NO_x would reduce O₃ pollution in eastern China.

1 Introduction

Human health, terrestrial ecosystems, and material degradation are impacted by poor air quality resulting from high photochemical ozone (O₃) levels (Wennberg and Dabdub, 2008; Edwards et al., 2013; Schroeder et al., 2017). In polluted areas, tropospheric O₃ is generated from a series of complex reactions in the presence of sunlight involving carbon monoxide (CO), nitrogen oxides (NO_x ≡ NO (nitric oxide) + NO₂

(nitrogen dioxide)), and volatile organic compounds (VOCs) (Oltmans et al., 2006; Schroeder et al., 2017). Briefly, VOCs first react with the hydroxyl radical (OH) to form a peroxy radical ($\text{HO}_2 + \text{RO}_2$), which increases the rate of catalytic cycling of NO to NO_2 . O_3 is then produced by photolysis of NO_2 . Subsequent reactions between HO_2 or RO_2 and NO lead to radical propagation (via subsequent reformation of OH). Radical termination proceeds via the reaction of OH with NO_x to form nitric acid (HNO_3) (Reaction R1, referred to as LNO_x) or by radical–radical reactions resulting in stable peroxide formation (Reactions R2–R4, referred to as LRO_x , where $\text{RO}_x \equiv \text{RO}_2 + \text{HO}_2$) (Schroeder et al., 2017):

Typically, the relationship between these two competing radical termination processes (referred to as the ratio $\text{LRO}_x/\text{LNO}_x$) can be used to evaluate the photochemical regime. In high-radical, low- NO_x environments, Reactions (R2)–(R4) remove radicals at a faster rate than Reaction (R1) (i.e., $\text{LRO}_x \gg \text{LNO}_x$), and the photochemical regime is regarded as “ NO_x limited”. In low-radical, high- NO_x environments the opposite is true (i.e., $\text{LRO}_x \ll \text{LNO}_x$), and the regime is regarded as “VOC limited”. When the rates of the two loss processes are comparable ($\text{LNO}_x \approx \text{LRO}_x$), the regime is said to be at the photochemical transition/ambiguous point, i.e., mixed VOC– NO_x limited (Kleinman et al., 2005; Sillman et al., 1995a; Schroeder et al., 2017).

Understanding the photochemical regime at local scales is a crucial piece of information for enacting effective policies to mitigate O_3 pollution (Jin et al., 2017; Schroeder et al., 2017). In order to determine the regime, the total reactivity with OH of the myriad of VOCs in the polluted area has to be estimated (Sillman, 1995a; Xing et al., 2017). In the absence of such information, the formaldehyde (HCHO) concentration can be used as a proxy for VOC reactivity because it is a short-lived oxidation product of many VOCs and is positively correlated with peroxy radicals (Schroeder et al., 2017). Sillman (1995a) and Tonnesen and Dennis (2000) found that in situ measurements of the ratio of HCHO (a marker of VOCs) to NO_2 (a marker of NO_x) could be used to diagnose local photochemical regimes. Over polluted areas, both HCHO and tropospheric NO_2 have vertical distributions that are heavily weighted toward the lower troposphere, indicating that tropospheric-column measurements of these gases are fairly representative of near-surface conditions. Many studies have taken advantage of these favorable vertical distributions to investigate surface emissions of NO_x and VOCs from space (Boersma et al., 2009; Martin et al., 2004a; Millet et al., 2008; Streets et al., 2013). Martin et al. (2004a) and Duncan et al. (2010) used satellite measurements of the

column HCHO/ NO_2 ratio to explore tropospheric O_3 sensitivities from space and disclosed that this diagnosis of O_3 production rate (PO_3) is consistent with previous findings of surface photochemistry. Witte et al. (2011) used a similar technique to estimate changes in PO_3 from the strict emission control measures (ECMs) during the Beijing Summer Olympic Games period in 2008. Recent papers have applied the findings of Duncan et al. (2010) to observe O_3 sensitivity in other parts of the world (Choi et al., 2012; Witte et al., 2011; Jin and Holloway, 2015; Mahajan et al., 2015; Jin et al., 2017).

With in situ measurements, Tonnesen and Dennis (2000) observed a radical-limited environment with HCHO/ NO_2 ratios < 0.8 , an NO_x -limited environment with HCHO/ NO_2 ratios > 1.8 , and a transition environment with HCHO/ NO_2 ratios between 0.8 and 1.8. With 3-D chemical model simulations, Sillman (1995a) and Martin et al. (2004b) estimated that the transition between the VOC- and NO_x -limited regimes occurs when the HCHO/ NO_2 ratio is ~ 1.0 . With a combination of regional chemical model simulations and the Ozone Monitoring Instrument (OMI) measurements, Duncan et al. (2010) concluded that O_3 production decreases with reductions in VOCs at a column HCHO/ NO_2 ratio < 1.0 and NO_x at column HCHO/ NO_2 ratio > 2.0 ; both NO_x and VOC reductions decrease O_3 production when the column HCHO/ NO_2 ratio lies in between 1.0 and 2.0. With a 0-D photochemical box model and airborne measurements, Schroeder et al. (2017) presented a thorough analysis of the utility of column HCHO/ NO_2 ratios to indicate surface O_3 sensitivity and found that the transition/ambiguous range estimated via column data is much larger than that indicated by in situ data alone. Furthermore, Schroeder et al. (2017) concluded that many additional sources of uncertainty (regional variability, seasonal variability, variable free-tropospheric contributions, retrieval uncertainty, air pollution levels and meteorological conditions) may cause the transition threshold vary both geographically and temporally, and thus the results from one region are not likely to be applicable globally.

With the rapid increase in fossil fuel consumption in China over the past 3 decades, the emission of chemical precursors of O_3 (NO_x and VOCs) has increased dramatically, surpassing that of North America and Europe and raising concerns about worsening O_3 pollution in China (Tang et al., 2012; Wang et al., 2017; Xing et al., 2017). Tropospheric O_3 was already included in the new air quality standard as a routine monitoring component (<http://www.mep.gov.cn>; last access: 23 May 2018), where the limit for the maximum daily 8 h average (MDA8) O_3 in urban and industrial areas is $160 \mu\text{g m}^{-3}$ (~ 75 ppbv at 273 K, 101.3 kPa). According to air quality data released by the Chinese Ministry of Environmental Protection, tropospheric O_3 has replaced $\text{PM}_{2.5}$ as the primary pollutant in many cities during summer (<http://www.mep.gov.cn/>; last access: 23 May 2018). A precise knowledge of O_3 evolution and photochemical pro-

duction regime in the polluted troposphere in China has important policy implications for O₃ pollution controls (Tang et al., 2011; Xing et al., 2017; Wang et al., 2017).

In this study, we investigate the O₃ seasonal evolution and photochemical production regime in the polluted troposphere in eastern China with tropospheric O₃, CO, and HCHO derived from ground-based high-resolution Fourier transform spectrometry (FTS) in Hefei, China, tropospheric NO₂ deduced from the OMI satellite (<https://aura.gsfc.nasa.gov/omi.html>; last access: 23 May 2018), surface meteorological data, and a back trajectory cluster analysis technique. Considering the fact that most NDACC (Network for Detection of Atmospheric Composition Change) FTS sites are located in Europe and Northern America, whereas the number of sites in Asia, Africa, and South America is very sparse, and there is still no official NDACC FTS station that covers China (<http://www.ndacc.org/>; last access: 23 May 2018), this study can not only improve our understanding of regional photochemical O₃ production regime but also contributes to the evaluation of O₃ pollution controls.

This study concentrates on measurements recorded during midday, when the mixing layer has largely been dissolved. All FTS retrievals are selected within ± 30 min of OMI overpass time (13:30 local time (LT)). While the FTS instrument can measure throughout the whole day, unless cloudy, OMI measures only during midday. For Hefei, this coincidence criterion is a balance between the accuracy and the number of data points.

2 Site description and instrumentation

The FTS observation site (117°10' E, 31°54' N; 30 m a.s.l. (above sea level)) is located in the western suburbs of Hefei city (the capital of Anhui Province, population of 8 million) in central-eastern China (Fig. S1 in the Supplement). A detailed description of this site and its typical observation scenario can be found in Tian et al. (2018). Similar to other Chinese megacities, serious air pollution is common in Hefei throughout the whole year (<http://mep.gov.cn/>; last access: 23 May 2018).

Our observation system consists of a high-resolution FTS spectrometer (IFS125HR, Bruker GmbH, Germany), a solar tracker (Tracker-A Solar 547, Bruker GmbH, Germany), and a weather station (ZENO-3200, Coastal Environmental Systems, Inc., USA). The near-infrared (NIR) and middle infrared (MIR) solar spectra were alternately acquired in routine observations (Wang et al., 2017). The MIR spectra used in this study are recorded over a wide spectral range (about 600–4500 cm⁻¹) with a spectral resolution of 0.005 cm⁻¹. The instrument is equipped with a KBr beam splitter and MCT detector for O₃ measurements and a KBr beam splitter and InSb detector for other gases. The weather station includes sensors for air pressure (± 0.1 hpa), air temperature (± 0.3 °C), relative humidity (± 3 %), solar radiation (± 5 %),

wind speed (± 0.2 m s⁻¹), wind direction ($\pm 5^\circ$), and the presence of rain.

3 FTS retrievals of O₃, CO, and HCHO

3.1 Retrieval strategy

The SFIT4 (version 0.9.4.4) algorithm is used in the profile retrieval (Supplement Sect. S1; <https://www2.acom.ucar.edu/irwg/links>; last access: 23 May 2018). The retrieval settings for O₃, CO, and HCHO are listed in Table 1. All spectroscopic line parameters are adopted from HITRAN 2008 (Rothman et al., 2009). A priori profiles of all gases except H₂O are from a dedicated WACCM (Whole Atmosphere Community Climate Model) run. A priori profiles of pressure, temperature, and H₂O are interpolated from the National Centers for Environmental Protection and National Center for Atmospheric Research (NCEP/NCAR) reanalysis (Kalnay et al., 1996). For O₃ and CO, we follow the NDACC standard convention with respect to micro-window (MW) selection and interfering gas consideration (<https://www2.acom.ucar.edu/irwg/links>; last access: 23 May 2018). HCHO is not yet an official NDACC species but has been retrieved at a few stations with different retrieval settings (Albrecht et al., 2002; Vigouroux et al., 2009; Jones et al., 2009; Viatte et al., 2014; Franco et al., 2015). The four MWs used in the current study are chosen from a harmonization project taking place in view of future satellite validation (Vigouroux et al., 2018). They are centered at around 2770 cm⁻¹, and the interfering gases are CH₄, O₃, N₂O, and HDO.

We assume measurement noise covariance matrices S_e to be diagonal and set their diagonal elements to the inverse square of the signal-to-noise ratio (SNR) of the fitted spectra and the non-diagonal elements of S_e to zero. For all gases, the diagonal elements of a priori profile covariance matrices S_a are set to the standard deviation of a dedicated WACCM run from 1980 to 2020, and its non-diagonal elements are set to zero.

We regularly used a low-pressure HBr cell to monitor the instrument line shape (ILS) and included the measured ILS in the retrieval (Hase, 2012; Sun et al., 2018).

3.2 Profile information in the FTS retrievals

The sensitive range for CO and HCHO is mainly tropospheric, and for O₃ it is both tropospheric and stratospheric (Fig. S2). The typical degrees of freedom (DOFS) over the total atmosphere obtained at Hefei for each gas are included in Table 2: they are about 4.8, 3.5, and 1.2 for O₃, CO, and HCHO, respectively. In order to separate independent partial column amounts in the retrieved profiles, we have chosen the altitude limit for each independent layer such that the DOFS in each associated partial column is not less than 1.0. The retrieved profiles of O₃, CO, and HCHO can be divided into four, three, and one independent layers, respec-

Error analysis	Systematic error – smoothing error (smoothing) – errors from other parameters: background curvature (curvature), optical path difference (max_opd), field of view (omega), solar line strength (solstrnth), background slope (slope), solar line shift (solshft), phase (phase), solar zenith angle(sza), line temperature broadening (linetair_gas), line pressure broadening (linepair_gas), line intensity(lineint_gas) <hr/> Random error – interference errors: retrieval parameters (retrieval_parameters), interfering species (interfering_species) – Measurement error (measurement) – errors from other parameters: temperature (temperature), zero level (zshift)		

tively (Fig. S3). The troposphere is well resolved by O₃, CO, and HCHO, where CO exhibits the best vertical resolution with more than two independent layers in the troposphere.

In this study, we have chosen the same upper limit (12 km) for the tropospheric columns for all gases (Table 2), which is about 3 km lower than the mean value of the tropopause (~ 15.1 km). In this way we ensured the accuracies for the tropospheric O₃, CO, and HCHO retrievals and minimized the influence of transport from the stratosphere, i.e., the so-called STE process (stratosphere–troposphere exchange).

3.3 Error analysis

The results of the error analysis presented here are based on the average of all measurements that fulfill the screening scheme, which is used to minimize the impacts of sig-

nificant weather events or instrument problems (Supplement Sect. S2). In the troposphere, the dominant systematic error for O₃ and CO is the smoothing error, and for HCHO it is the line intensity error (Fig. S4). The dominant random error for O₃ and HCHO is the measurement error, and for CO it is the zero baseline level error (Fig. S5). Taking all error items into account, the summarized errors in O₃, CO, and HCHO for the 0–12 km tropospheric partial column and for the total column are listed in Table 3. The total errors in the tropospheric partial columns for O₃, CO, and HCHO have been evaluated to be 8.7 %, 6.8 %, and 10.2 %, respectively.

Table 2. Typical degrees of freedom for signal (DOFs) and sensitive range of the retrieved O₃, CO, and HCHO profiles at Hefei site.

Gas	Total column DOFs	Sensitive range (km)	Tropospheric partial column (km)	Tropospheric DOFs
O ₃	4.8	Ground – 44	Ground – 12	1.3
CO	3.5	Ground – 27	Ground – 12	2.7
HCHO	1.2	Ground – 18	Ground – 12	1.1

Total errors	8.7	5.0	6.8	3.95	10.2	5.8

4 Tropospheric O₃ seasonal evolution

4.1 Tropospheric O₃ seasonal variability

Figure 1a shows the tropospheric O₃ column time series recorded by the FTS from 2014 to 2017, where we followed Gardiner's method and used a second-order Fourier series plus a linear component to determine the annual variability (Gardiner et al., 2008). The analysis did not indicate a significant secular trend of tropospheric O₃ column probably because the time series is much shorter than those in Gardiner et al. (2008); the observed seasonal cycle of tropospheric O₃ variations is well captured by the bootstrap resampling method (Gardiner et al., 2008). As commonly observed, high levels of tropospheric O₃ occur in spring and summer (hereafter MAM/JJA). Low levels of tropospheric O₃ occur in autumn and winter (hereafter SON/DJF). Day-to-day variations in MAM/JJA are generally larger than those in SON/DJF (Fig. 1b). At the same time, the tropospheric O₃ column roughly increases over time in the first half of the year and reaches the maximum in June and then decreases during the second half of the year. Tropospheric O₃ columns in June are 1.55×10^{18} molecules cm⁻² (56 DU (Dobson units)) and in December are 1.05×10^{18} molecules cm⁻² (39 DU). Tropospheric O₃ columns in June were $\sim 50\%$ higher than those in December.

Vigouroux et al. (2015) studied the O₃ trends and variabilities at eight NDACC FTS stations that have a long-term time series of O₃ measurements, namely, Ny-Ålesund (79° N), Thule (77° N), Kiruna (68° N), Harestua (60° N), Jungfraujoch (47° N), Izaña (28° N), Wollongong (34° S), and Lauder (45° S). All these stations were located in non-polluted or relatively clean areas. The tropospheric columns at these stations are of the order of 0.7×10^{18} to $1.1 \times$

10^{18} molecules cm⁻². The results showed a maximum tropospheric O₃ column in spring at all these stations except at the high-altitude stations Jungfraujoch and Izaña, where it extended into early summer. This is because the STE process is most effective during late winter and spring (Vigouroux et al., 2015). In contrast, we observed a broader maximum at Hefei which extends over the MAM/JJA season, and the values are $\sim 35\%$ higher than those studied in Vigouroux et al. (2015). This is because the observed tropospheric O₃ levels in MAM/JJA are more influenced by air masses originating from densely populated and industrialized areas (see Sect. 4.2), and the MAM/JJA meteorological conditions are more favorable to photochemical O₃ production (see Sect. 5.1). The selection of tropospheric limits 3 km below the tropopause minimized but cannot avoid the influence of transport from the stratosphere; the STE process may also contribute to high level of tropospheric O₃ column in spring.

4.2 Regional contribution to tropospheric O₃ levels

In order to determine where the air masses came from and thus contributed to the observed tropospheric O₃ levels, we have used the HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) model to calculate the three-dimensional kinematic back trajectories that coincide with the FTS measurements from 2014 to 2017 (Draxler et al., 2009). In the calculation, the GDAS (University of Alaska Fairbanks GDAS Archive) meteorological fields were used with a spatial resolution of $0.25^\circ \times 0.25^\circ$, a time resolution of 6 h, and 22 vertical levels from the surface to 250 mbar. All daily back trajectories at 12:00 UTC, with a 24 h pathway arriving at Hefei site at 1500 m a.s.l., have been grouped into clusters and divided into MAM/JJA and SON/DJF seasons (Stunder, 1996). The results showed that air masses in

Figure 1. (a) FTS measured and bootstrap resampled tropospheric O₃ columns at Hefei site. The linear trend and the residual are also shown. Detailed description of the bootstrap method can be found in Gardiner et al. (2008). (b) Tropospheric O₃ column monthly means derived from (a).

Jiangsu and Anhui provinces in eastern China; Hebei and Shandong provinces in northern China; Shaanxi, Henan, and Shanxi provinces in northwestern China; and Hunan and Hubei provinces in central China contributed to the observed tropospheric O₃ levels.

In the MAM/JJA season (Fig. 2a), 28.8 % of air masses are of eastern origin and arrived at Hefei through the southeast of Jiangsu Province and east of Anhui Province; 41.0 % are of southwestern origin and arrived at Hefei through the northeast of Hunan and Hubei provinces, and southwest of Anhui Province; 10.1 % are of northwestern origin and arrived at Hefei through the southeast of Shanxi and Henan provinces, and northwest of Anhui Province; 10.1 % are of

northern origin and arrived at Hefei through the south of Shandong Province and north of Anhui Province; 10.1 % are of local origin generated in the south of Anhui Province. As a result, air pollution from megacities such as Shanghai, Nanjing, Hangzhou, and Hefei in eastern China; Changsha and Wuhan in central-southern China; Zhenzhou and Taiyuan in northwest China; and Jinan in north China could contribute to the observed tropospheric O₃ levels.

In the SON/DJF season, trajectories are generally longer and originated in the northwest of the MAM/JJA ones (Fig. 2b). The direction of air masses originating in the eastern sector shifts from the southeast to the northeast of Jiangsu Province, and that of local air masses shifts from the south

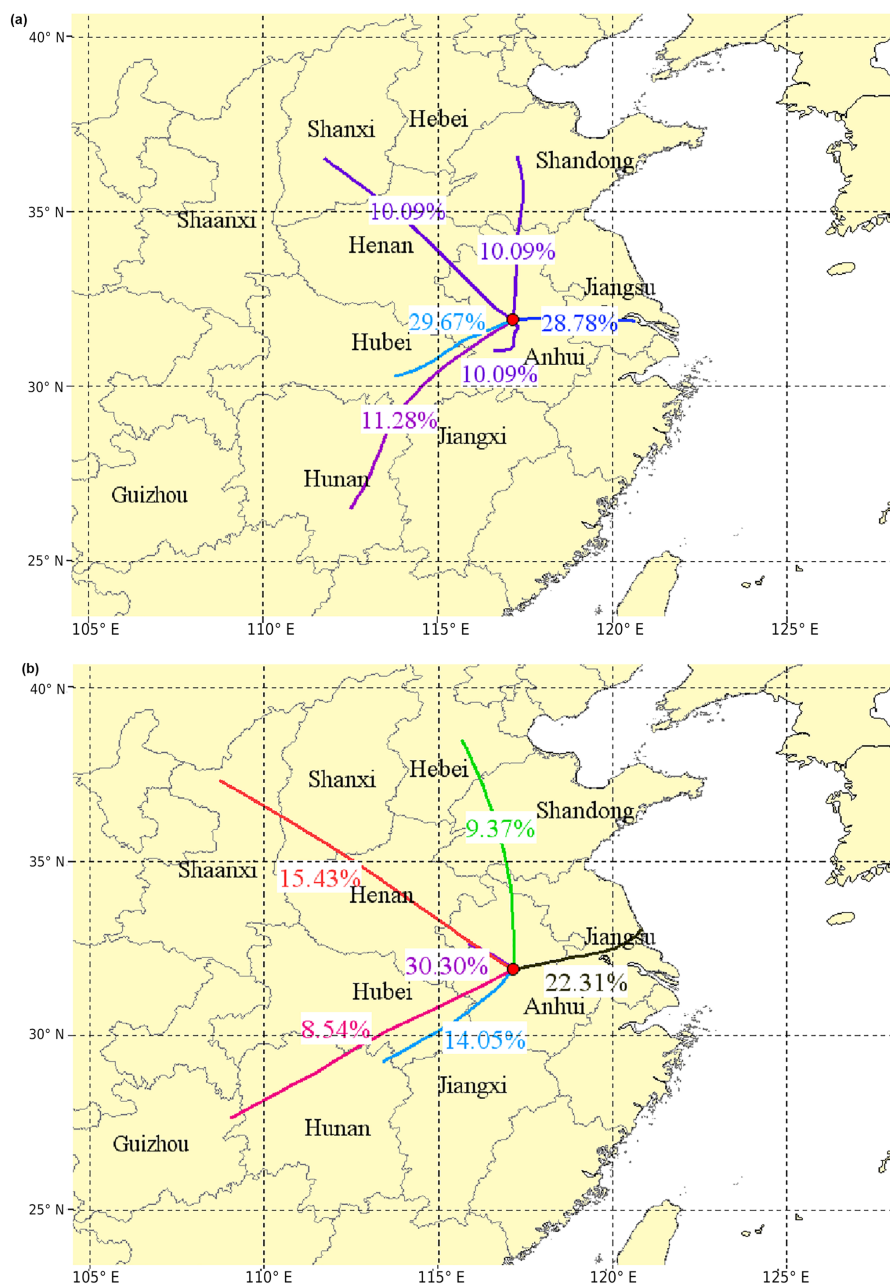

Figure 2. One-day HYSPLIT back trajectory clusters arriving at Hefei at 1500 m a.s.l that are coincident with the FTS measurements from 2014 to 2017. (a) Spring and summer (MAM/JJA) and (b) Autumn and winter (SON/DJF) season. The base map was generated using the TrajStat 1.2.2 software (<http://www.meteothinker.com>, last access: 23 May 2018).

to the northwest of Anhui province. Trajectories of eastern-origin, western-origin, and northern-origin air masses in SON/DJF are 6.5 %, 13.1 %, and 0.7 % less frequent than the MAM/JJA ones, respectively. As a result, the air masses outside Anhui province have a 20.2 % smaller contribution to the observed tropospheric O₃ levels in SON/DJF than in MAM/JJA. In contrast, trajectories of local-origin air masses in SON/DJF are 20.2 % more frequent than the MAM/JJA

ones, indicating a more significant contribution of air masses in Anhui province in SON/DJF.

The majority of the Chinese population lives in the eastern part of China, especially in the three most developed regions, the Jing–Jin–Ji (Beijing–Tianjin–Hebei), the Yangtze River Delta (YRD; including Shanghai–Jiangsu–Zhejiang–Anhui), and the Pearl River Delta (PRD; including Guangzhou, Shenzhen, and Hong Kong). These regions consistently have the highest emissions of anthropogenic precursors (Fig. S6),

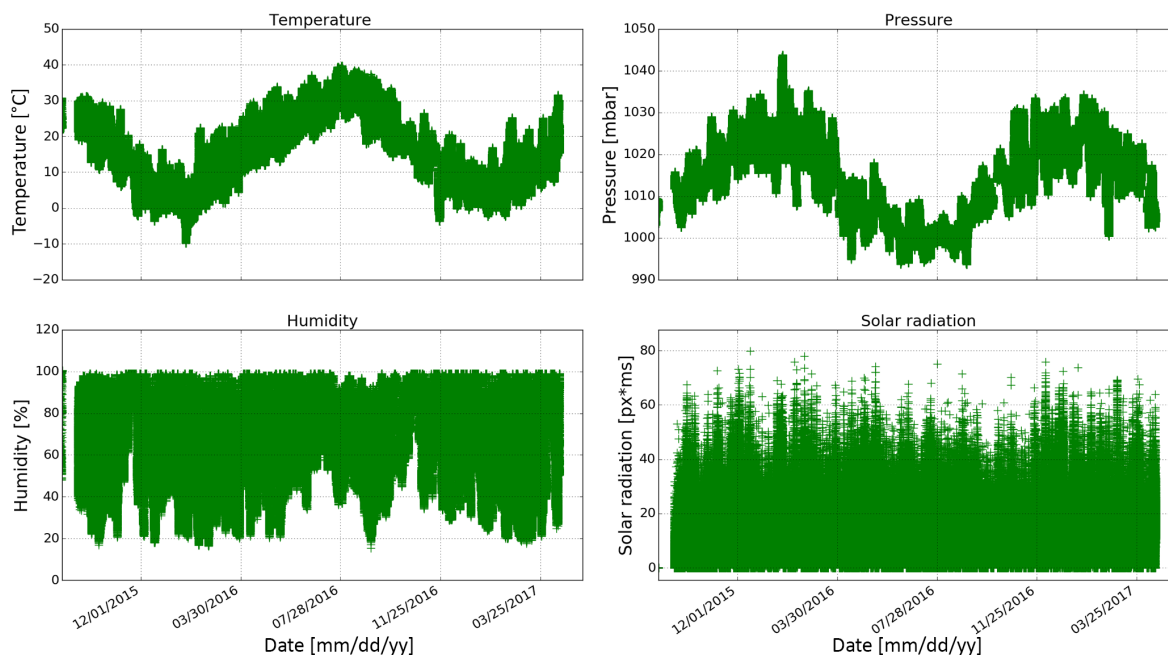

Figure 3. Minutely averaged time series of temperature, pressure, humidity, and solar radiation recorded by the surface weather station.

which have led to severe region-wide air pollution. This is particularly the case for the Hefei site, located in the central-western corner of the YRD, where the population in the southeastern area is typically denser than the northwestern area. Specifically, the southeast of Jiangsu province and the south of Anhui province are two of the most developed areas in YRD, and human activities therein are very intense. Therefore, when the air masses originated from these two areas, the O_3 level is usually very high. Overall, compared with the SON/DJF season, the more southeastern air masses transportation in MAM/JJA indicated that the observed tropospheric O_3 levels could be more influenced by the densely populated and industrialized areas, broadly accounting for the higher O_3 level and variability in MAM/JJA.

5 Tropospheric O_3 production regime

5.1 Meteorological dependency

Photochemistry in polluted atmospheres, particularly the formation of O_3 , depends not only on pollutant emissions but also on meteorological conditions (Lei et al., 2008; Wang et al., 2017; Coates et al., 2016). In order to investigate the meteorological dependency of the O_3 production regime in the observed area, we analyzed the correlation of the tropospheric O_3 with the coincident surface meteorological data. Figure 3 shows time series of temperature, pressure, humidity, and solar radiation recorded by the surface weather station. The seasonal dependencies of all these coincident meteorological elements show no clear dependencies except for

the temperature and pressure, which show clear reverse seasonal cycles. Generally, the temperatures are higher and the pressures are lower in MAM/JJA than those in SON/DJF. The correlation plots between the FTS tropospheric O_3 column and each meteorological element are shown in Fig. 4. The tropospheric O_3 column shows positive correlations with solar radiation, temperature, and humidity, and negative correlations with pressure.

High temperature and strong sunlight primarily affects O_3 production in Hefei in two ways: by speeding up the rates of many chemical reactions and by increasing emissions of VOCs from biogenic sources (BVOCs) (Sillman and Samson, 1995b). While emissions of anthropogenic VOCs (AVOCs) are generally not dependent on temperature, evaporative emissions of some AVOCs do increase with temperature (Rubin et al., 2006; Coates et al., 2016). Elevated O_3 concentration generally occurs on days with wet conditions and low pressure in Hefei, probably because these conditions favor the accumulation of O_3 and its precursors. Overall, MAM/JJA meteorological conditions are more favorable to O_3 production (higher sun intensity, higher temperature, wetter condition, and lower pressure) than SON/DJF, which supports the fact that tropospheric O_3 in MAM/JJA is larger than that in SON/DJF.

5.2 PO_3 relative to CO, HCHO, and NO_2 changes

In order to determine the relationship between tropospheric O_3 production and its precursors, the chemical sensitivity of PO_3 relative to tropospheric CO, HCHO, and NO_2 changes was investigated. Figure 5 shows time series of tropospheric

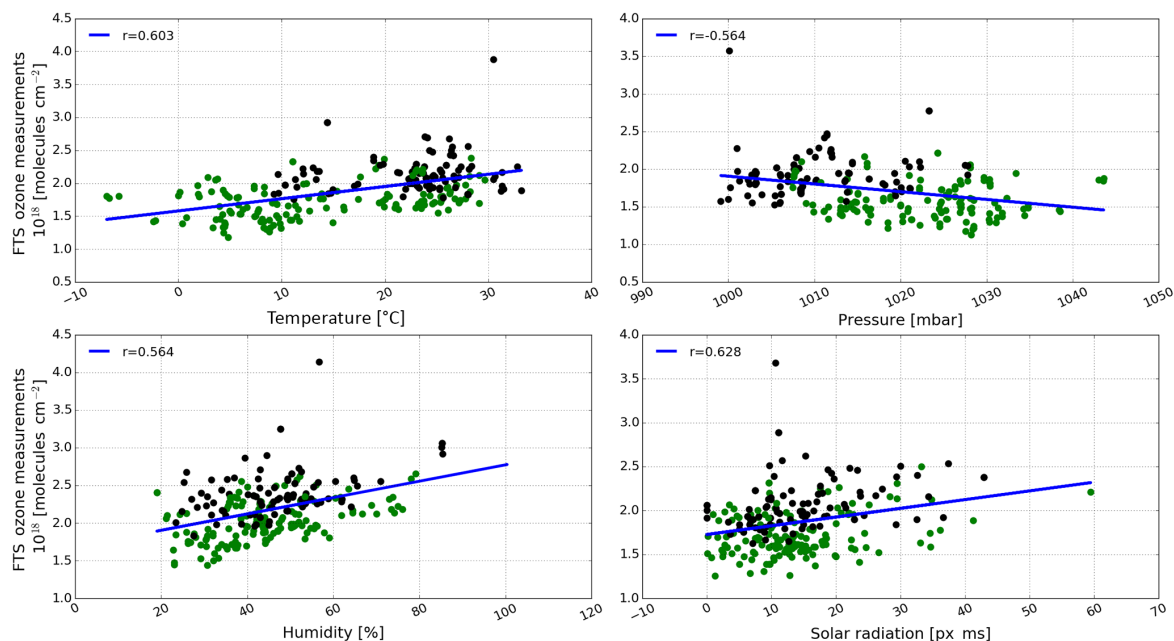

Figure 4. Correlation plot between the FTS tropospheric O_3 column and the coincident surface meteorological data. Black dots are data pairs within the MAM/JJA season and green dots are data pairs within the SON/DJF season.

CO , HCHO , and NO_2 columns that are coincident with O_3 counterparts. The tropospheric NO_2 was deduced from the OMI product selected within the $\pm 0.7^\circ$ latitude/longitude rectangular area around the Hefei site. The retrieval uncertainty for the tropospheric column is less than 30% (https://disc.gsfc.nasa.gov/datasets/OMNO2_V003/ last access: 23 May 2018). Tropospheric HCHO and NO_2 show clear reverse seasonal cycles. Generally, tropospheric HCHO is higher and tropospheric NO_2 is lower in MAM/JJA than in SON/DJF. Pronounced tropospheric CO was observed, but the seasonal cycle is not evident, probably because CO emission is not constant over the season or season dependent.

Figure 6 shows the correlation plot between the FTS tropospheric O_3 column and the coincident tropospheric CO , HCHO , and NO_2 columns. The tropospheric O_3 column shows positive correlations with tropospheric CO , HCHO , and NO_2 columns. Generally, the higher the tropospheric CO concentration, the higher the tropospheric O_3 , and both VOCs and NO_x reductions decrease O_3 production. As an indicator of regional air pollution, the good correlation between O_3 and CO (Fig. 6a) indicates that the enhancement of tropospheric O_3 is highly associated with the photochemical reactions which occurred in polluted conditions rather than due to the STE process. The relatively weaker overall correlations of O_3 with HCHO (Fig. 6b) and NO_2 (Fig. 6c) are partly explained by different lifetimes of these gases, i.e., several hours to 1 day in summer for NO_2 and HCHO and several days to weeks for O_3 . So older O_3 -enhanced air masses easily loose traces of NO_2 or HCHO . Since the sensitivity of PO_3 to VOCs and NO_x is different under different

limitation regimes, the relatively flat overall slopes indicate that the O_3 pollution in Hefei can be fully attributed neither to NO_x pollution nor to VOC pollution.

5.3 O_3 – NO_x – VOC sensitivities

5.3.1 Transition/ambiguous range estimation

Referring to previous studies, the chemical sensitivity of PO_3 in Hefei was investigated using the column HCHO/NO_2 ratio (Martin et al., 2004; Duncan et al., 2010; Witte et al., 2011; Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al., 2015; Schroeder et al., 2017; Jin et al., 2017). The methods have been adapted to the particular conditions in Hefei. In particular the findings of Schroeder et al. (2017) have been taken into account.

Since the measurement tools for O_3 and HCHO , the pollution characteristic, and the meteorological condition in this study were not the same as those of previous studies, the transition thresholds estimated in previous studies were not applied here (Martin et al., 2004a; Duncan et al., 2010; Witte et al., 2011; Choi et al., 2012; Jin and Holloway, 2015; Mahajan et al., 2015; Schroeder et al., 2017; Jin et al., 2017). In order to determine transition thresholds applicable in Hefei, China, we iteratively altered the column HCHO/NO_2 ratio threshold and judged whether the sensitivities of tropospheric O_3 to HCHO or NO_2 changed abruptly. For example, in order to estimate the VOC -limited threshold, we first fitted tropospheric O_3 to HCHO that lies within column HCHO/NO_2 ratios < 2 (an empirical starting point) to obtain the corre-

Figure 5. Time series of tropospheric CO, HCHO, and NO₂. Tropospheric CO and HCHO were derived from FTS observations, which is the same as tropospheric O₃, and tropospheric NO₂ is derived from OMI data.

sponding slope and then we decreased the threshold by 0.1 (an empirical step size) and repeated the fit, i.e., only fitted the data pairs with column HCHO/NO₂ ratios < 1.9. This was done iteratively. Finally, we sorted out the transition ratio which shows an abrupt change in slope, and regarded this as the VOC-limited threshold. Similarly, the NO_x-limited threshold was determined by iteratively increasing the column HCHO/NO₂ ratio threshold until the sensitivity of tropospheric O₃ to NO₂ changed abruptly.

The transition threshold estimation with this scheme exploits the fact that O₃ production is more sensitive to VOCs if it is VOC-limited and is more sensitive to NO_x if it is NO_x limited, and there exists a transition point near the threshold (Martin et al., 2004a). Su et al. (2017) used this scheme to investigate the O₃–NO_x–VOC sensitivities during the 2016 G20 conference in Hangzhou, China, and argued that this diagnosis of PO₃ could reflect the overall O₃ production conditions.

5.3.2 PO₃ limitations in Hefei

Through the above empirical iterative calculation, we observed a VOC-limited regime with column HCHO/NO₂ ratios < 1.3, an NO_x-limited regime with column HCHO/NO₂ ratios > 2.8, and a mixed VOC–NO_x-limited regime with column HCHO/NO₂ ratios between 1.3 and 2.8. Column measurements sample a larger portion of the atmosphere, and thus their spatial coverage is larger than in situ measurements. So the photochemical scene disclosed by column measurements is larger than the in situ measurement. Specifically, this study reflects the mean photochemical condition of the troposphere.

Schroeder et al. (2017) argued that the column measurements from space have to be used with care because of the high uncertainty and the inhomogeneity of the satellite measurements. This has been mitigated in this study by the following.

The FTS measurements have a much smaller footprint than the satellite measurements. Also, we concentrate on measurements recorded during midday, when the mixing layer has largely been dissolved.

The measurements are more sensitive to the lower parts of the troposphere, which can be inferred from the normalized averaging kernels (AVKs). The reason is simply that the AVKs show the sensitivity to the column, but the column per altitude decreases with altitude.

Figure 7 shows time series of column HCHO/NO₂ ratios which varied over a wide range from 1.0 to 9.0. The column HCHO/NO₂ ratios in summer are typically larger than those in winter, indicating that the PO₃ is mainly NO_x limited in summer and mainly VOC limited or mixed VOC–NO_x limited in winter. Based on the calculated transition criteria, 106 days of observations that have coincident O₃, HCHO, and NO₂ counterparts in the reported period are classified, where 57 days (53.8 %) are in the MAM/JJA season and 49 days (46.2 %) are in the SON/DJF season. Table 4 lists the statistics for the 106 days of observations, which shows that NO_x-limited, mixed VOC–NO_x-limited, and VOC-limited PO₃ accounts for 60.3 % (64 days), 28.3 % (30 days), and 11.4 % (12 days), respectively. The majority of NO_x-limited (70.3 %) PO₃ lies in the MAM/JJA season, while the majority of mixed VOC–NO_x-limited (70 %) and VOC-limited (75 %) PO₃ lies in the SON/DJF season. As a result, reductions in NO_x and VOC could be more effective to mitigate

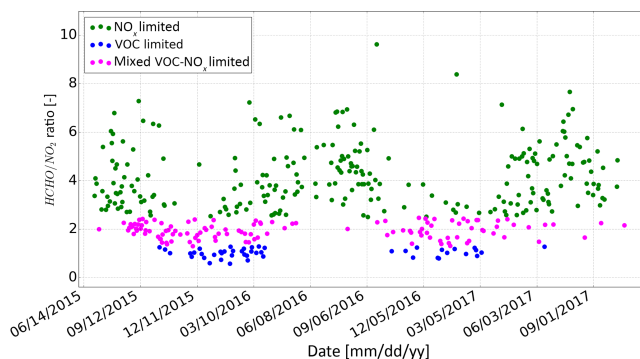

Figure 6. Correlation plot between the FTS tropospheric O₃ column and coincident tropospheric CO (a), HCHO (b), and NO₂ (c) columns. The CO and HCHO data are retrieved from FTS observations, and the NO₂ data were deduced from the OMI product.

Table 4. Chemical sensitivities of PO₃ for the selected 106 days of observations that have coincident O₃, HCHO, and NO₂ counterparts.

Items	Proportion		Autumn and winter		Spring and summer	
	days	percentage	days	percentage	days	percentage
NO _x limited	64	60.3 %	19	29.7 %	45	70.3 %
Mixed VOC–NO _x limited	30	28.3 %	21	70 %	9	30 %
VOC limited	12	11.4 %	9	75 %	3	25 %
Sum	106	100 %	49	46.2 %	57	53.8 %

**Figure 7.** Time series of column HCHO/NO₂ ratios.

O₃ pollution in the MAM/JJA and SON/DJF seasons, respectively. Furthermore, considering most of PO₃ is NO_x limited or mixed VOC–NO_x limited, reductions in NO_x would reduce O₃ pollution in eastern China.

6 Conclusions

We investigated the seasonal evolution and photochemical production regime of tropospheric O₃ in eastern China from 2014 to 2017 by using tropospheric O₃, CO, and HCHO columns derived from Fourier transform infrared spectrometry (FTS), the tropospheric NO₂ column deduced from the Ozone Monitoring Instrument (OMI), the surface meteorological data, and a back trajectory cluster analysis technique. A pronounced seasonal cycle for tropospheric O₃ is captured by the FTS, which roughly increases over time in the first half year and reaches the maximum in June, and then it decreases over time in the second half year. Tropospheric O₃ columns in June are 1.55×10^{18} molecules cm⁻² (56 DU (Dobson units)), and in December they are 1.05×10^{18} molecules cm⁻² (39 DU). Tropospheric O₃ columns in June were $\sim 50\%$ higher than those in December. A broad maximum within both spring and summer (MAM/JJA) is observed, and the day-to-day variations in MAM/JJA are generally larger than those in autumn and winter (SON/DJF). This differs from tropospheric O₃ measurements in Vigouroux et al. (2015). However, Vigouroux et al. (2015) used measurements at relatively clean sites.

Back trajectory analysis showed that air pollution in Jiangsu and Anhui provinces in eastern China; Hebei and Shandong provinces in northern China; Shaanxi, Henan, and Shanxi provinces in northwest China; and Hunan and Hubei provinces in central China contributed to the observed tropospheric O₃ levels. Compared with the SON/DJF season, the observed tropospheric O₃ levels in MAM/JJA are more influenced by the transport of air masses from densely populated and industrialized areas, and the high O₃ level and variability in MAM/JJA is determined by the photochemical O₃ production. The tropospheric-column HCHO/NO₂ ratio is used as a proxy to investigate the chemical sensitivity of the O₃ production rate (PO₃). The results show that PO₃ is mainly nitrogen oxide (NO_x) limited in MAM/JJA, while it is mainly VOC or mixed VOC–NO_x limited in SON/DJF. Reductions in NO_x and VOC could be more effective to mitigate O₃ pollution in the MAM/JJA and SON/DJF seasons, respectively. Considering most of PO₃ is NO_x limited or mixed VOC–NO_x limited, reductions in NO_x would reduce O₃ pollution in eastern China.

Data availability. The SFIT4 software can be found via <https://www2.acom.ucar.edu/irwg/links> (last access: 23 May 2018). The data used in this paper are available on request.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/acp-18-14569-2018-supplement>.

Author contributions. The first two authors contributed equally to this work. YS and CL prepared the paper with inputs from all coauthors. MP, CV, JN, NJ, and MDM designed the retrieval and optimized the content. QH and WS conceived ozone production regime study. WZ provided the OMI NO₂ product. WW, CS, YT, XX, MZ, and JL carried out the experiments and performed back trajectory cluster analysis.

Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue “Quadrennial Ozone Symposium 2016 – Status and trends of atmospheric ozone (ACP/AMT inter-journal SI)”. It is a result of the Quadrennial Ozone Symposium 2016, Edinburgh, United Kingdom, 4–9 September 2016.
