Abstract. Over the 21st century changes in both tropospheric and stratospheric ozone are likely to have important consequences for the Earth’s radiative balance. In this study, we investigate the radiative forcing from future ozone changes using the Community Earth System Model (CESM1), with the Whole Atmosphere Community Climate Model (WACCM), and including fully coupled radiation and chemistry schemes. Using year 2100 conditions from the Representative Concentration Pathway 8.5 (RCP8.5) scenario, we quantify the individual contributions to ozone radiative forcing of (1) climate change, (2) reduced concentrations of ozone depleting substances (ODSs), and (3) methane increases. We calculate future ozone radiative forcings and their standard error (SE: associated with inter-annual variability of ozone) relative to year 2000 of (1) 33 ± 104 m W m⁻², (2) 163 ± 109 m W m⁻², and (3) 238 ± 113 m W m⁻² due to climate change, ODSs, and methane, respectively. Our best estimate of net ozone forcing in this set of simulations is 430 ± 130 m W m⁻² relative to year 2000 and 760 ± 230 m W m⁻² relative to year 1750, with the 95 % confidence interval given by ±30 %. We find that the overall long-term tropospheric ozone forcing from methane chemistry–climate feedbacks related to OH and methane lifetime is relatively small (46 m W m⁻²). Ozone radiative forcing associated with climate change and stratospheric ozone recovery are robust with regard to background climate conditions, even though the ozone response is sensitive to both changes in atmospheric composition and climate. Changes in stratospheric-produced ozone account for ~ 50 % of the overall radiative forcing for the 2000–2100 period in this set of simulations, highlighting the key role of the stratosphere in determining future ozone radiative forcing.

1 Introduction

Ozone is an important trace gas that plays a key role in the Earth’s radiative budget, atmospheric chemistry, and air quality. As a radiatively active gas, ozone interacts with both shortwave and longwave radiation. In the troposphere, ozone is an important regulator of the oxidizing capacity (both itself and as the main source of hydroxyl radicals, OH) and an important pollutant with negative effects on vegetation and human health (e.g. Prather et al., 2001; UNEP, 2015). However, approximately 90 % of ozone by mass is found in the stratosphere – protecting the biosphere from harmful ultraviolet solar radiation (WMO, 2014) – and is an important source of ozone in the troposphere and its budget (e.g. Collins et al., 2003; Sudo et al., 2003; Zeng and Pyle, 2003). Therefore, its future evolution in the troposphere and the stratosphere is...
an important concern for climate change and air quality during
the 21st century. Future changes in emissions of ozone
precursors (e.g. methane), ODSs, and climate are thought to
be major drivers of ozone abundances (e.g. Stevenson et al.,
2006; Kawase et al., 2011; Young et al., 2013; Banerjee et al.,
2016).

The stratospheric–tropospheric exchange (STE) of ozone
significantly influences the abundance and distribution of
tropospheric ozone (e.g. Zeng et al., 2010; Banerjee et al.,
2016). The Brewer–Dobson circulation (BDC) governs the
meridional transport of air and trace constituents in the
stratosphere and is characterized by upwelling in the trop-
ics, poleward motion in the stratosphere, and sinking at
middle and high latitudes (Butchart, 2014, and references
therein). The BDC is commonly thought to consist of a shal-
low branch controlling the lower stratosphere region and a
deep branch controlling the middle and upper stratosphere.
The latter presents two cells during the spring and fall sea-
sons and one stronger cell into the winter hemisphere (Birner
and Bönisch, 2011). Although observational estimates and
climate models suggest an acceleration of the stratospheric
mean mass transport via the BDC associated with climate
change (e.g. Oberländer et al., 2013; Ploeger et al., 2013;
Butchart, 2014; Stiller et al., 2017), significant uncertainty
still remains (Engel et al., 2009; Hegglin et al., 2014; Ray et
al., 2014). The tropopause is the boundary that “separates”
the troposphere and the stratosphere, two chemically and
dynamically distinct regions. Defining the tropopause is cru-
ial to diagnose budget terms of trace gases such as the STE of
ozone (e.g. Prather et al., 2011), although the chosen def-
inition may affect the resulting analysis (e.g. Wild, 2007;
Stevenson et al., 2013; Young et al., 2013).

Stratospheric ozone is expected to recover towards pre-
industrial levels during the 21st century due to the imple-
mentation of the Montreal Protocol and its Amendments and
Adjustments (WMO, 2014) as ODS concentrations slowly
decrease in the atmosphere (e.g. Austin and Wilson, 2006;
Eyring et al., 2010). Indeed, the global ozone layer has al-
ready shown the first signs of recovery (WMO, 2014; Chip-
perfield et al., 2017). Future ozone recovery can affect tro-
ospheric composition via enhanced STE of ozone and reduc-
tions in tropospheric photolysis rates, both associated with
higher levels of ozone in the stratosphere. Previous mod-
elling studies that have isolated the impacts of stratospheric
ozone recovery have shown that the increased STE is the
most important driver of changes in the tropospheric ozone
burden (Zeng et al., 2010; Kawase et al., 2011; Banerjee et al.,
2016). However, tropospheric ozone is also signifi-
cantly affected by the change in ultraviolet radiation reach-
ing the troposphere brought about by the thicker strato-
spheric ozone layer. In turn, reductions in ozone photoly-
sis result in lower OH concentrations – i.e. O$_3$ + hν(λ <
320 nm) → O(1D) + O$_2$ – and therefore a longer methane
lifetime with consequences for long-term tropospheric ozone
abundances (e.g. Morgenstern et al., 2013; Zhang et al.,
2014).

The broad impacts of future climate change on the dis-
tribution of ozone are robust across a number of modelling
studies and multi-model activities (Kawase et al., 2011;
Young et al., 2013; Arblaster et al., 2014; Banerjee et al.,
2016; Iglesias-Suarez et al., 2016). Stratospheric cooling
leads to further ozone loss in the polar lower stratosphere
(through enhanced heterogeneous ozone destruction) and
ozone increases in the upper stratosphere (through reduced
NO$_x$ abundances, HO$_x$-catalyzed ozone loss, and enhanced
net oxygen chemistry; Haigh and Pyle, 1982; Rosenfield et
al., 2002). In addition, a projected acceleration of the BDC
leads to an enhanced STE of ozone (e.g. Garcia and Randel,
2008; Butchart et al., 2010), which results in (i) decreases
in tropical lower stratospheric ozone associated with a rela-
tively faster ventilation and reduced ozone production (Aval-
lone and Prather, 1996) and (ii) ozone increases in the upper
troposphere, particularly in the region of the subtropical jets,
linked to the descending branch of the BDC (e.g. Kawase et
al., 2011; Banerjee et al., 2016). On the other hand, a warmer
and wetter climate results in reduced tropospheric ozone lev-
els – i.e. linked to a decrease in net chemical production due
to enhanced ozone chemical loss (e.g. Wild, 2007).

Climate feedbacks associated with future ozone changes
are surrounded by large uncertainties. Lightning is a major
natural source of nitrogen oxides (LNO$_x$) in the troposphere
(Galloway et al., 2004), with important consequences for at-
mospheric composition in the middle to upper troposphere
and the lower stratosphere. The current best estimate of an-
nual and global mean LNO$_x$ emissions is 5 ± 3 Tg(N) yr$^{-1}$,
with chemistry–climate models suggesting LNO$_x$ emission
sensitivity to climate change of ∼ 4–60 % K$^{-1}$ (Schumann
and Huntrieser, 2007, and references therein). Although
more recent modelling studies find LNO$_x$ emission climate
sensitivity lying at the lower end of the above estimate (Zeng
et al., 2008; Banerjee et al., 2014), results from a multi-
model activity suggest large uncertainty in the magnitude
and even the sign of future projection responses due to dif-
f erent parameterizations (Finney et al., 2016). Most LNO$_x$
emissions occur in the middle to upper tropical troposphere
over the continents, where the photochemical production of
ozone is most efficient in the troposphere – i.e. low back-
ground concentrations and longer lifetimes of NO$_y$,
lower temperatures affecting ozone loss chemistry, and abundant
sunlight (e.g. Williams, 2005; Dahlmann et al., 2011). A
small but significant fraction of lightning-induced NO$_x$
emis-
sions are converted into less photochemically active nitric
acid (HNO$_3$, via HO$_2$ + NO reaction), which can be removed
through wet deposition or transported into the lower strato-
sphere (acting as a reservoir of NO$_y$; e.g. Jacob, 1999; Søvde
et al., 2011). In addition, OH concentrations increase with
LNO$_x$ emissions and the resultant lightning-produced ozone
– i.e. via NO + HO$_2$ and O(1D) + H$_2$O, respectively – with a
corresponding reduction in methane lifetime. This resulting
climate feedback is important because methane is a potent greenhouse gas (GHG) and ozone precursor.

To date, ozone is the third largest contributor to the total tropospheric radiative forcing (RF) since the pre-industrial period, with overall increases in its concentration contributing a global radiative forcing over 1750–2011 of $+0.35 \text{ Wm}^{-2}$ (Myhre et al., 2013). In this study, we use the concept of radiative effect (RE) to diagnose the contribution of ozone changes on the global radiative budget. The ozone RE is the radiative flux imbalance between incoming shortwave solar radiation and outgoing longwave infrared radiation (at the tropopause, after allowing for stratospheric temperatures to readjust to radiative equilibrium), which results from the presence of both anthropogenic and natural ozone (Rap et al., 2015). Note that RF is therefore the change in RE over time (e.g. Myhre et al., 2013). Ozone shows two distinct regimes with regard to its RE, with positive (longwave radiation) and negative (shortwave radiation) effects for increases in stratospheric ozone and positive (for both longwave and shortwave radiation) effects for ozone increases in the troposphere (e.g. Lacis et al., 1990; Forster and Shine, 1997). In addition, changes in the distribution of ozone – i.e. latitudinal and vertical structure – are of a particular interest for its RE due to horizontally varying factors such as surface albedo, clouds, and the thermal structure of the atmosphere (e.g. Lacis et al., 1990; Berntsen et al., 1997; Forster and Shine, 1997; Gauss et al., 2003). Previous studies showed the highest radiative efficiency of ozone in the tropical upper troposphere (e.g. Worden et al., 2011; Riese et al., 2012; Rap et al., 2015), a region greatly influenced by changes in stratospheric influx (e.g. Hegglin and Shepherd, 2009; Zeng et al., 2010; Banerjee et al., 2016) and lightning-produced ozone (e.g. Banerjee et al., 2014; Liaskos et al., 2015) in a warmer climate.

Modelling experiments used in the latest Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) followed the Representative Concentration Pathway (RCP) emission scenarios for short-lived precursors (van Vuuren et al., 2011) and long-lived species (Meinshausen et al., 2011). The RCPs are named according to the total radiative forcing at the end of the 21st century relative to 1750. For example, while the RCP8.5 emissions scenario refers to the total 8.5 W m$^{-2}$ RF by 2100, future tropospheric ozone RF was projected to account for up to $\sim 9\%$ ($0.6 \pm 0.2 \text{ Wm}^{-2}$) of the total RF (Stevenson et al., 2013). Note that the methane concentration in 2100 is more than double that in the year 2000 following the RCP8.5 emissions scenario.

Previous research has investigated impacts on ozone abundances and distributions associated with future changes in climate, ODSs, and ozone precursor emissions in a process-based approach – i.e. imposing one single forcing at a time (Collins et al., 2003; Sudo et al., 2003; Zeng and Pyle, 2003; Zeng et al., 2008, 2010; Kawase et al., 2011; Banerjee et al., 2016). Other modelling studies focused on the radiative effects of tropospheric (e.g. Gauss et al., 2003; Stevenson et al., 2013) and stratospheric (Bekki et al., 2013) ozone changes under future emission scenarios in a non-process-based fashion. One study has recently identified the indirect tropospheric and stratospheric ozone RF between 2000 and 2100 due to individual perturbations (Banerjee et al., 2018). Yet the upper limit of future ozone RF remains poorly constrained. For example, climate models do not necessarily agree on the sign of the indirect ozone forcing resulting from climate change and associated feedbacks (e.g. LNOx). Furthermore, there are uncertainties arising from the interactions and non-linearities between different agents (e.g. combined forcing may differ from the sum of individual forcings due to different background conditions) and long-term changes (e.g. methane feedback associated with changes in lifetimes).

Here we aim to narrow this gap by assessing how key factors drive net ozone radiative forcing and providing an estimate of the uncertainty arising from non-linearities and long-term feedbacks. We use the Community Earth System Model (CESM1) in its “high-top” (up to 140 km) atmosphere version – the Whole Atmosphere Community Climate Model (WACCM) – and a series of sensitivity simulations to quantify the radiative effects of ozone due to (1) climate change, (2) lightning-induced NOx emissions, (3) stratospheric ozone recovery, and (4) methane emissions between 2000 and 2100 following the RCP8.5 emissions scenario. We explore the robustness of the ozone radiative forcings associated with the above drivers under different background conditions due to non-linearities in ozone responses. Moreover, here we use a synthetic ozone tracer to unambiguously identify stratospheric- and tropospheric-produced ozone forcing. Note that this study does not address reductions in anthropogenic NOx and non-methane volatile organic compounds emissions, since they play a marginal role in future ozone RF under the RCP8.5 scenario (based on an additional simulation not presented here).

The CESM1–WACCM model, sensitivity simulations, and ozone radiative effect calculations are described in Sect. 2. A present-day model evaluation, future projected ozone changes, and associated radiative effects are presented in Sect. 3. Different sources of uncertainties are discussed and accounted for in Sect. 4. Finally, a summary and concluding remarks are presented in Sect. 5.

2 Methodology

2.1 Model description

We use the CESM (version 1.1.1) chemistry–climate model with a configuration that fully couples the atmosphere and land components. A comprehensive description of the model is given by Marsh et al. (2013, and references therein).

The atmosphere component of CESM is WACCM version 4, a high-top model that extends from the surface to approximately 140 km in the lower thermosphere, with a
vertical resolution ranging from 1.2 km near the tropopause to $\sim 2$ km near the stratopause and a horizontal resolution of $1.9^\circ \times 2.5^\circ$ (latitude by longitude). The chemical scheme is the Model for Ozone and Related Chemical Tracers (MOZART) for the troposphere (Emmons et al., 2010) and the stratosphere (Kinnison et al., 2007), including recent updates (Lamarque et al., 2012; Tilmes et al., 2015). It includes 169 chemical species with detailed photolysis, gas-phase, and heterogeneous reactions (see Tables A1 and A2 in Tilmes et al., 2016). Recent updates in the orographic gravity wave forcing that reduce the cold bias in Antarctic polar temperatures (Calvo et al., 2017; Garcia et al., 2017) and the polar stratospheric chemistry (Wegner et al., 2013; Solomon et al., 2015) are included in the model. Concentrations of radiatively active gas-phase compounds such as ozone, nitrous oxide ($\text{N}_2\text{O}$), methane ($\text{CH}_4$), and halogenated ODSs are coupled to the model radiation scheme. Lightning-induced NO$_x$ emissions are parameterized using the cloud top height method (Price and Vaughan, 1993), and annual global mean LNO$_x$ emissions are scaled to simulate present-day values of 3–5 Tg N yr$^{-1}$.

A stratospheric ozone tracer (O3S) is implemented to represent the abundance and distribution of stratospheric-produced ozone in the troposphere (Roelofs and Lelieveld, 1997). O3S is equivalent to ozone in the stratosphere. In the troposphere it undergoes the same chemical loss processes as ozone, but does not undergo dry deposition, following the recommendations for the Chemistry–Climate Model Initiative (CCMI; Eyring et al., 2013; Morgenstern et al., 2017). To account for dry deposition of O3S, we apply an annual global correction factor based on an additional model simulation (not used in the main results). This correction factor is approximately linear, ranging from 0.7 at the surface to 0.95 around 250 hPa.

The land component is the Community Land Model version 4, which has the same horizontal resolution as the atmosphere component and interactively calculates dry deposition for trace gases in the atmosphere (Val Martin et al., 2014) and biogenic emissions using the Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1 (Guenther et al., 2012).

### 2.2 Experimental set-up

This modelling set-up uses time slice simulations driven by sea surface temperatures (SSTs) and sea ice climatologies from previous CESM1–WACCM fully coupled simulations performed as part of the CCMI (SENC2-8.5; see Morgenstern et al., 2017). An average over 1990–2009 is used to represent the year 2000; since the existing model simulation did not cover the period 2090–2109, an average over 2080–2099 is used to represent conditions at the end of the 21st century (nominally 2100). Note, however, that the perturbed concentrations of atmospheric gases are taken from year 2100 in the RCP8.5 scenario, and hence these experiments are labelled as 2100 in the paper. Each time slice experiment is integrated for 20 years, with the last 10 years analysed in this study (i.e. the spin-up period covered the first 10 years). Seasonally varying boundary conditions are specified for carbon dioxide ($\text{CO}_2$), $\text{N}_2\text{O}$, $\text{CH}_4$, and ODSs (halogen-containing compounds), as recommended for CCMI (Eyring et al., 2013). Changes in ozone precursors other than $\text{CH}_4$ and land-use changes are not explored here (i.e. these are fixed at year 2000 levels in all experiments). Volcanic eruptions are not included in the experiments, and the incoming solar radiation is fixed at 1361 W m$^{-2}$. The quasi-biennial oscillation is imposed by the relaxation of equatorial winds (90–3 hPa) with an approximate 28-month period between eastward and westward phases (Marsh et al., 2013).

Table 1 lists the simulations used in this study. The control simulation (Cnt) had all boundary conditions set to the year 2000. Then each sensitivity simulation added one single driver (i.e. boundary condition changed to the year 2100) at a time. For example, while the climate-related ozone RF (with fixed LNO$_x$ emission) is explored comparing the Clim–Cnt simulations, the forcing associated with changes in lightning-induced NO$_x$ emissions is quantified comparing the Ltn–Clim simulations, and so forth. This method provides a different estimate of the overall net ozone RF compared to exploring the impact of the individual drivers alone (e.g. it accounts for non-linear effects that may be neglected by exploring each perturbation compared to the reference simulation). However, since the attribution of forcings to individual drivers may be sensitive to different background conditions, we also evaluate the robustness of the experimental design (see Sect. 3.5).

Here we provide specific details of the boundary conditions. The simulations can be classified into three main groups.

- Sensitivity simulations that explore the impacts of climate change are performed. Here SSTs, sea ice, and
main GHGs (i.e. CO$_2$ and N$_2$O) are specified to year 2100 levels (see above for an explanation of SST and sea ice fields). The upper end emission scenario of the RCP family is explored (RCP8.5). Natural biogenic emissions (e.g. isoprene) are calculated online, which are mainly governed by changes in CO$_2$, climate, and land use (Squire et al., 2014). The indirect ozone radiative effect resulting from this climate feedback is implicitly contained in the climate signal. However, unlike LNO$_x$ emissions it mainly impacts ozone in the lower troposphere where ozone shows relatively small radiative efficiency (Rap et al., 2015). To isolate the impacts of lightning-produced ozone, additional experiments are performed with year 2000 levels for LNO$_x$ emissions (fLNOx). Fixed LNO$_x$ simulations follow the approach of Banerjee et al. (2014), imposing the monthly mean LNO$_x$ emissions climatology from the Cnt run and switching off its interactive calculation in the model. To justify this method, we compared temperature and tropospheric ozone fields between the Cnt and Cnt+fLNOx simulations and found negligible differences (not shown).

- Stratospheric ozone recovery due to the slow decrease in ODS concentrations (referring to the total organic chlorine and bromine species) regulated under the framework of the Montreal Protocol is investigated. Based on the CCMI recommendations, halogen species (CFC11, CFC12, CFC113, CFC114, CFC115, CC14, HCFC22, HCFC141b, HCFC142b, C$_2$F$_2$ClBr, C$_3$F$_3$Br, CH$_3$Br, CH$_3$CCl$_3$, CH$_3$Cl, H1202, H2402, CH$_2$Br$_2$, and CHBr$_3$) are specified to year 2100 levels for the halogen scenario A1 (WMO, 2011), which includes the early phase-out of hydrochlorofluorocarbons agreed in 2007. Note that two brominated short-lived species (CH$_2$Br$_2$ and CHBr$_3$) were included in these experiments to accurately represent bromine loading and thus the associated ozone depletion, providing an additional bromine surface mixing ratio of ∼ 6 ppt on top of that from the longer-lived bromine compounds.

- Future levels of methane and its impacts on ozone are investigated. Concentrations of CH$_4$ are imposed to year 2100 levels from the RCP8.5 pathway – i.e. approximately double concentrations compared to year 2000. Note that methane levels were kept at year 2000 levels for the sensitivity simulations described above that explore climate change impacts.

2.3 Radiative transfer calculations

To calculate the resulting all-sky REs of ozone we use the ozone radiative kernel (O$_3$ RK) technique based on Rap et al. (2015), updated for the whole atmosphere (Fig. 1). The O$_3$ RK, defined as the derivative of the radiative flux relative to small perturbations in ozone, was calculated using the offline version of the SOCRATES radiative transfer model with nine longwave (LW) and six shortwave (SW) bands, which is based on Edwards and Slingo (1996). Radiative flux calculations employed a monthly mean climatology of temperature, water vapour, and ozone from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim and year 2000 surface albedo and clouds from the International Satellite Cloud Climatology Project (Rossow and Schiffer, 1999). Stratospherically adjusted REs of ozone were computed using the fixed dynamical heating approximation (Fels et al., 1980), which assumes that the atmosphere adjusts to a new equilibrium state via radiative process only – i.e. without dynamical feedbacks – in a relatively short period (∼ few months). A 1 ppb perturbation in ozone is added to each layer in turn, and temperatures above 200 hPa are adjusted iteratively until they converge to a new local radiative–dynamical equilibrium and the change in net flux at the 200 hPa level is diagnosed. The O$_3$ RK is then constructed from the changes in net flux resulting from the ozone perturbations applied to all atmospheric layers. The 200 hPa level is used for the stratospheric temperature adjustment as an approximation for the level at which the transition to local radiative–dynamical equilibrium in the stratosphere occurs. The net O$_3$ RK (Fig. 1a) illustrates the importance of the upper troposphere and lower stratosphere, particularly at low latitudes where changes in ozone are very efficient in affecting the radiative flux of the Earth. The LW component (Fig. 1b) is positive throughout the atmosphere and dominates the net O$_3$ RK, although the SW component (Fig. 1c) outweighs the former in the upper stratosphere (i.e. negative sensitivity).

We compared the ozone RF calculated using the O$_3$ RK technique (i.e. by multiplying the simulated ozone change with the net O$_3$ RK interpolated to the model grid) with the corresponding RF calculated directly with the SOCRATES radiative transfer model (see the Supplement, Fig. S1). The good agreement between the two methods (global mean difference of 0.01 W m$^{-2}$) is consistent with the Rap et al. (2015) findings, in which the O$_3$ RK was proposed as an efficient and accurate method to estimate ozone RFs, and it is particularly well suited for multi-model intercomparison activities.

A chemical tropopause definition (Prather et al., 2001), using the 150 ppb ozone level of the Cnt simulation, is employed to differentiate ozone changes and associated RFs occurring in the troposphere and the stratosphere. Compared to the latter, we found a negligible difference in the partitioning of tropospheric–stratospheric forcing using a consistent chemical tropopause definition for the driver investigated (i.e. higher tropopause associated with climate change).
3 Results

3.1 Present-day ozone radiative effects and model validation

A detailed present-day ozone evaluation of a similar model and experimental set-up was presented by Tilmes et al. (2016). In summary, simulated monthly mean ozone shows good agreement with observational estimates within a 25% range in spring and summer. Zonal and annual mean tropospheric ozone shows the best agreement with observations at low and mid-latitudes (±5 DU), a key region for its radiative effect (e.g. Rap et al., 2015). Likewise, the zonal and annual mean stratospheric ozone agrees fairly well with satellite estimates in the Southern Hemisphere (SH) and low latitudes (±30 DU), but larger deviations are found at middle and high latitudes in the Northern Hemisphere (NH), a discrepancy also apparent in the models of the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP; Iglesias-Suarez et al., 2016). The tropospheric ozone budget (production, loss, dry deposition, stratospheric input), burden, and lifetime for the Cnt simulation (see Table 2 and Fig. S2) are within previous multi-model estimates (Stevenson et al., 2013; Young et al., 2013, 2018).

Figure 2a and b show the annual mean ozone RE calculated for the Cnt simulation (year 2000 or “present day” hereafter) and the Tropospheric Emission Spectrometer (TES) from July 2005 until June 2008 (05–08). TES is the first product providing tropospheric ozone profiles suitable for RE studies and has been previously evaluated against other observational estimates (e.g. Osterman et al., 2008), showing a small bias in the troposphere and the stratosphere of approximately 3–4 DU. The annual and global ozone RE in the Cnt simulation is 2.26 ± 0.14 Wm$^{-2}$ (1 SE associated with inter-annual variability), which is within the TES range of 2.21–2.26 Wm$^{-2}$. The spatial distribution of simulated and observed ozone REs are fairly well correlated ($r = 0.6$, $p < 0.01$), although note that the noisier TES signal is largely the result of averaging only 3 years. Both the simulated and observed present-day ozone REs reveal a positive poleward gradient, with a minimum in tropical regions (approximately 20° N–20° S) that is associated with the relatively low ozone levels found in the upper troposphere and lower stratosphere (see Fig. S2). A peak is found at high latitudes in the NH, driven by the transport of relatively rich tropospheric ozone air from mid-latitudes coupled with only moderate ozone depletion in the NH stratosphere. This is in contrast with lower RE values within the SH polar vortex, driven by the larger stratospheric ozone depletion over Antarctica (Solomon et al., 2015). Figure 2c compares the Cnt annual mean ozone RE against the TES data set. Compared to TES, the simulated annual mean tends to overestimate the RE in the NH and underestimate it in the SH, which is consistent with the bias in ozone distribution (Tilmes et al., 2016). Significant biases are mainly confined to the tropical and subtropical regions – i.e. bias is defined here when the simulated RE ± 1.96 SE
3.2 Ozone changes

Table 2. Tropospheric ozone budget including the following: ozone production (P) and loss (L) terms based on the gas-phase reaction rates of the O3 family (O3, O, O3D, and NO2); net chemical production of ozone defined as the residual of the production and loss terms (N = P – L); dry deposition of ozone (D) term; stratospheric–tropospheric exchange (S; i.e. influx from the stratosphere) term as the residual of the dry deposition and net chemistry production terms (S = D – N); ozone burden (B) term; ozone and methane lifetimes (τO3 and τCH4, respectively) as the ratio between the burden and total losses (τ = burden / total loss); τCH4 including loss with respect to OH and adjusted for soil uptake (160 years) and stratospheric sink (120 years; Prather et al., 2012); burden for the stratospheric ozone tracer (B03S).

¹ Offline lightning-induced NOx emissions imposed by applying a monthly mean climatology of the Cnt simulation.

(~ 95% confidence interval) is outside the observed range. Although tropical and subtropical regions are of particular interest for future changes in ozone and its resulting radiative forcing (i.e. highest radiative efficiency), there is a large NH / SH compensation as shown by the annual and global mean forcings. Note the RE is the radiative flux imbalance at a given time due to a radiatively active species (e.g. with and without ozone), whereas the RF refers to the change in RE over time.

Future lightning (Lnt–Clm; Fig. 3b) shows an increase in LNOx emissions by ~ 33%, which results in ozone increases mainly in the tropical and subtropical upper troposphere. However, present-day LNOx emissions have significant uncertainties and climate models do not agree on the sign of the change due to different lightning parameterizations (Finney et al., 2016). Nevertheless, the simulated present-day LNOx emissions of 4.8 ± 1.6 Tg(N) yr⁻¹ are within observationally derived estimates, and the model LNOx sensitivity to climate of 10.8 ± 1.6 K⁻¹ is at the upper end of the 2 standard deviation climate model range (8.8 ± 2 % K⁻¹; Finney et al., 2016). The net global tropospheric ozone responses to climate will be largely determined by the interplay between (non-lightning) climate-induced ozone losses and lightning-induced ozone production.

Reductions in inorganic chlorine and bromine abundances (O3r–Ln; Fig. 3c) result in stratospheric ozone increases. Upper stratospheric ozone recovers largely due to decreases in ClOx – catalyzed ozone destruction. Due to reduced heterogeneous ozone loss chemistry, the largest changes are found in polar regions in the lower stratosphere, with increases of ~ 450 % over the Antarctic (November) and ~ 45 % over the Arctic (April). Greater abundances of stratospheric ozone result in an approximately 20 % increase in the STE (Table 2) driving higher levels of tropospheric ozone, particularly at middle and high latitudes in the SH (related to ozone hole recovery) and tropical and subtropical upper troposphere (the descending region of the BDC), which is consistent with previous model estimates (Banerjee et al., 2016). The BDC-driven increases are somewhat offset by the large overhead ozone column reducing actinic fluxes and therefore ozone photochemical production (Table 2; Banerjee et al., 2016).
Methane is a greenhouse gas and an ozone precursor in the troposphere that plays various roles in the stratosphere, and these processes are difficult to isolate from the rest. Future methane (Mth–O3r; Fig. 3d) emissions show a widespread increase in ozone in the troposphere, with an annual and global tropospheric column ozone increase of 15 ± 8 % (Table S1). Previous modelling studies reported similar increases of 10–13 % (Brasseur et al., 2006; Kawase et al., 2011). Compensation between ozone decreases in the upper stratosphere (enhanced HOx-catalyzed chemistry) and increases in the lower stratosphere (smog-like chemistry and the partitioning of active–inactive chlorine; Randeniya et al., 2002; Stenke and Grewe, 2005; Portmann and Solomon, 2007; Fleming et al., 2011; Revell et al., 2012) results in small changes of 2 ± 5 % for the annual and global stratospheric column ozone.

3.3 Ozone radiative forcing

Figure 4 shows maps of annual mean radiative forcing between 2000 and 2100 due to changes in ozone for the whole atmosphere, along with zonal mean forcings associated with changes in the troposphere and the stratosphere for single perturbation simulations. Note that zonal mean forcings are weighted by latitudinal area (i.e. cosine–latitude), allowing for direct comparison with the total forcing. Annual and global mean forcing values and their SE (i.e. due to ozone changes only) are listed in Table 3. Ozone radiative forcing shows strong dependence on the vertical distribution of the change (e.g. Lacis et al., 1990; Forster and Shine, 1997; Rap et al., 2015) and to a lesser extent on the horizontal distribution (e.g. Berntsen et al., 1997). Differences can be seen in both the geographical pattern of the forcing and in the magnitude related to the drivers.

The global forcing associated with climate (Clm–Cnt; Fig. 4a) of −70 ± 102 mWm⁻² is relatively small and not highly statistically significant (errors denote 1 SE associated with the 10-year inter-annual variability of ozone change unless otherwise specified). The geographical pattern shows a relatively strong and significant forcing at high latitudes in the NH related to ozone increases in the lower stratosphere (transport from enhanced BDC) and upper stratosphere (reduced chemical loss due to cooling). However, this is outweighed by a negative tropospheric forcing in the tropics and a negative stratospheric forcing in the SH extra-tropical region. The latter is largely due to additional ozone depletion in the lower stratosphere (i.e. reduction of STE; not shown).

Future lightning-induced NOx emissions (Ltn–Clm; Fig. 4b) show relatively large though not significant global ozone forcing of 104 ± 108 mWm⁻², mainly the result of simulated tropospheric ozone changes of 2.1 ± 2.3 DU. Two distinct peak regions are evident around the subtropical belts where large ozone changes are coincident with relatively cloud-free areas, higher temperature, and a low solar zenith angle. The strongest positive forcing is found over the Sahara and Middle East deserts, associated with greater surface albedo.

Ozone recovery (O3r–Ltn; Fig. 4c) drives a significant forcing of 163 ± 109 mWm⁻². This forcing is largely confined to the middle and high latitudes, particularly in the SH (due to ozone hole recovery), and is mainly linked to the stratosphere. Extra-tropical STE is especially important in the SH. This is demonstrated by tropospheric forcing of about ∼ 100 mWm⁻² in this region, which is largely the re-
Methane emissions show a large positive forcing around the subtropical belts (Mth–O3r; Fig. 4d), which is principally confined to the troposphere as there is a compensation between changes in the lower and upper stratosphere (Fig. 3d). In the tropical and subtropical troposphere, methane is more readily oxidized as partly associated with higher OH levels, which results in relatively large ozone increases (Fig. 3d). In addition, significant forcings at high latitudes, particularly over the Arctic, are linked to the stratosphere (i.e. reduced ozone loss via decreased active–inactive chlorine partitioning).

Figure 5 shows maps of annual mean normalized tropospheric ozone radiative forcing (NRF) between 2000 and 2100 for the four sensitivity simulations. The NRF – defined here as the tropospheric ozone radiative forcing divided by the tropospheric column ozone – is a useful diagnostic to gain insight into the radiative effects of ozone changes. Very similar global NRFs of ~ 39 m Wm$^{-2}$ DU$^{-1}$ due to (non-lightning) climate and methane indicate relatively evenly distributed ozone changes in the troposphere. In contrast, more localized lightning-produced ozone results in a higher global NRF of 46 m Wm$^{-2}$ DU$^{-1}$, whereas ozone increases at high latitudes due to ozone recovery result in a smaller NRF of 35 m Wm$^{-2}$ DU$^{-1}$. This highlights the dependence of the resulting forcings on the vertical and horizontal distribution of changes in ozone.

Previous studies have shown that the radiative forcings from tropospheric and stratospheric ozone do not have distinct drivers (Søvde et al., 2011; Shindell et al., 2013). Our results support this and show that climate change, ODSs, and methane have consequences for both tropospheric and stratospheric ozone radiative forcing (Table 3). In this set of simulations, changes in ozone occurring in the troposphere and the stratosphere respectively contribute ~ 70 and 30 % to the total annual and global forcing of 435 ± 108 m Wm$^{-2}$.

Further insight can be gained by attributing ozone forcing based on its origin in the stratosphere or the troposphere. In these simulations, we used a stratospheric ozone tracer (see Sect. 2) to unambiguously differentiate ozone with tropospheric origin (O3T) from that with stratospheric origin.
(O3S). Table 3 shows such “source-classified” ozone radiative forcings using the “O3S/ozone” and “O3T/ozone” ratios for tropospheric and stratospheric forcings, respectively. Stratospheric-produced ozone contributes to ∼50% of the annual and global future ozone forcing in this set of simulations, which strongly reinforces the importance of stratospheric–tropospheric interactions.

### 3.4 Methane feedback and resulting ozone forcing

Future climate change and emissions of ODSs and methane will affect the oxidizing capacity of the atmosphere (e.g. via hydroxyl radicals, OH), which influences the methane lifetime (τCH₄) and its concentration. In turn, changes in methane concentrations result in a “long-term” response of tropospheric ozone at decadal timescales (e.g. Fuglestvedt et al., 1999; Wild and Prather, 2000; Holmes et al., 2013).
The simulations considered here neglect this feedback by imposing fixed and uniform lower boundary conditions for methane. However, we can estimate how methane concentrations would have adjusted if they were free to evolve, as well as the associated ozone response and radiative forcing. Using the method described by Fiore et al. (2009, and references therein), we calculate global mean equilibrium methane abundances, [CH4]eq, by using

$$[\text{CH}_4]_{\text{eq}} = [\text{CH}_4]_{\text{Cnt}} \times \left( \frac{\tau_{\text{CH}_4}(p)}{\tau_{\text{CH}_4}(r)} \right)^f,$$

where Cnt represents the fixed boundary conditions for year 2000, (p) and (r) refer to the perturbation and reference simulations, respectively, and f is a feedback factor which accounts for the response of methane to its own lifetime. The feedback factor is explicitly calculated for WACCM using the O3r “(a)” and Mth “(b)” simulations as follows:

$$f = \frac{1}{(1 - s)},$$

where s is calculated by using

$$s = \frac{[\ln (\tau_{\text{CH}_4}(b)) - \ln (\tau_{\text{CH}_4}(a))]}{[\ln (\text{BCH}_4(b)) - \ln (\text{BCH}_4(a))]},$$

and where BCH4 is the annual global mean methane burden. We calculate a value of f of 1.43, which is at the upper end of the literature range (1.19–1.53; Prather et al., 2001; Stevenson et al., 2013; Voulgarakis et al., 2013) but within 7% of the observationally constrained best estimate of 1.34 (Holmes et al., 2013).

The ozone response to this methane feedback is estimated by linear interpolation:

$$\Delta O_3 (\text{eq-Cnt}) = \left[ \frac{\Delta \text{CH}_4 (\text{eq-Cnt})}{\Delta \text{CH}_4 (b-a)} \right] \times \Delta O_3 (b-a), \quad (4)$$

where $$\Delta O_3$$ is the change in the annual global mean of the tropospheric column ozone (Table S1). Assuming the relationships between changes in methane, ozone, and radiative forcings are linear, the associated tropospheric ozone forcings with methane feedback are given by the product of $$\Delta O_3$$ and the NRF due to methane perturbation (39 m W m$$^{-2}$$ DU$$^{-1}$$; Fig. 5d) and are shown in Table 3. The overall long-term tropospheric ozone forcing related to the methane feedback in this set of simulations is a moderate increase of $$\sim$$ 15%. Climate change (Clm and Ltn simulations) enhances the oxidizing capacity of the atmosphere, which results in a small negative forcing of $$-19$$ m W m$$^{-2}$$ due to the methane feedback. In the Mth simulation, OH concentrations are strongly reduced and the associated forcing of 63 m W m$$^{-2}$$ outweighs the climate forcing. This forcing is within the range of $$\sim$$ 40–120 m W m$$^{-2}$$ (mean value of 60) from the ACCMIP ensemble (Table 8 in Stevenson et al.,

www.atmos-chem-phys.net/18/6121/2018/
when considering the same change in methane concentrations (note their values have been linearly extrapolated).

3.5 Background conditions and forcing

Since the ozone response to a given perturbation is dependent on the background conditions (e.g., temperature, radiative heating, trace gas levels), the resulting forcing associated with individual drivers may be sensitive to the experimental design. For example, lightning-induced ozone forcing due to climate change may differ significantly under present-day or doubled methane concentrations (i.e., year 2000 or year 2100 RCP8.5 abundances). In the present study, we imposed single perturbations successively. Therefore, the total ozone forcing calculated from this set of simulations includes chemistry–climate feedbacks arising from the interactions between the various perturbations. Yet the attribution of indirect ozone forcings to individual drivers may be sensitive to the order considered (Table 1).

We also completed an additional set of simulations (Table S2) to assess the robustness of the calculated RF to the order the perturbations were applied (Table 3). Lightning-induced net ozone forcing (104 ± 108 m Wm$^{-2}$ from Table 3) is not significantly different at the 95% confidence interval (due to inter-annual variability only unless otherwise specified) compared to that calculated under approximately doubled methane concentrations (Ltn_Mth–Ltn Mth). Although the reported lightning net ozone forcing is 50 m Wm$^{-2}$ lower relative to the latter, both lie within the inter-annual uncertainty (~100 m Wm$^{-2}$). The forcing associated with ozone recovery (163 ± 109 m Wm$^{-2}$) is calculated under climate change (i.e., including lightning feedbacks) and present-day methane concentrations, though it also can be derived under present-day climate (O3r_Ods–Cnt) or doubled methane concentrations (Mth–Ltn Mth). We find no significant differences between the forcings associated with these background conditions, although the reported mean forcing resulting from ozone recovery is greater by ~30 m Wm$^{-2}$. Finally, methane-induced net ozone forcing due to doubling its concentrations relative to the present day under ozone recovery conditions (238 ± 113 m Wm$^{-2}$) is not significantly different to that under present-day ODS concentrations (Ltn Mth–Ltn) or without lightning feedbacks (Clm Mth–Clm). The reported forcing associated with methane lies within the latter forcings (i.e., 50 m Wm$^{-2}$ range). Therefore, we conclude that future ozone forcings due to lightning, ozone recovery, and methane concentrations as presented in Table 3 are robust with regard to background conditions.

The fact that global and annual ozone forcings associated with single perturbations are not significantly different with regard to background conditions is perhaps somewhat surprising given that, for instance, ozone production is sensitive to the relative abundances of volatile organic compounds and NO$_x$ (e.g., Sillman, 1999). However, while the globally averaged forcing is not significantly affected by the order in which the perturbations are considered, there are significant differences in budget terms (e.g., ozone burden differences due to lightning can be as large as 4.5 ± 1.4 Tg) and ozone levels in particular regions of the atmosphere. Therefore, the non-linear additivity of the perturbations is important when considering their impacts on quantities such as ozone profiles and surface air quality (not shown).

4 Uncertainties and outlook

We calculate a net ozone radiative forcing of 435 ± 108 m Wm$^{-2}$ corresponding to the year 2100 under the RCP8.5 emissions scenario compared to the present day, with the 1SE of uncertainty arising from variability in ozone between the years of the time slice simulations. This variability indicates a ±25% uncertainty, which is slightly larger than the spread across the ACCMIP ensemble of approximately ±20% (Stevenson et al., 2013). However, additional sources of uncertainty exist in the ozone forcing. Previously, uncertainties arising from the tropopause definition (±3%), the radiation scheme or forcing calculation (±10%), and the extent to which clouds and stratospheric temperature adjustment influence ozone forcing (±7 and ±3%, respectively) have been estimated (Stevenson et al., 2013). Climate feedbacks, land-use change, natural ozone precursor emissions, and future changes in the structure of the tropopause (Wilcox et al., 2012) may introduce at least an additional ±20% uncertainty (Stevenson et al., 2013). Following Stevenson et al. (2013), we assume that the above individual uncertainties are independent and combine them to estimate an overall uncertainty of ±30%, which represents the 95% confidence interval. We note that Skeie et al. (2011) estimated the same overall uncertainty in an independent analysis.

Figure 6 summarizes the global and annual net ozone forcing as well as the forcings by driver and region. Overall, our annual global mean best estimate for the net ozone radiative forcing between 2000 and 2100 is 430 ± 130 m Wm$^{-2}$, with tropospheric and stratospheric forcings of 300 ± 90 and 130 ± 40 m Wm$^{-2}$, respectively. Current estimates for tropospheric and stratospheric ozone forcings from 1750 to 2011 are 400 ± 20 and −50 ± 100 m Wm$^{-2}$, respectively (Myhre et al., 2013). An increase of 0.5 DU in tropospheric ozone was estimated in Skeie et al. (2011) from 2000 to 2010, and a tropospheric ozone normalized radiative forcing of 42 m Wm$^{-2}$ DU$^{-1}$ was calculated from the ACCMIP ensemble (Stevenson et al., 2013). Therefore, we estimate a net ozone forcing of 760 ± 230 m Wm$^{-2}$ from 1750 to 2100 based on our simulations, which is the result of the forcings in the troposphere and the stratosphere (690 ± 210 and 70 ± 20 m Wm$^{-2}$, respectively). Our tropospheric forcing is within the range estimated from the ACCMIP models of 600 ± 120 m Wm$^{-2}$ (Table 12 in Stevenson et al., 2013).
Figure 6. Ozone radiative forcings by drivers (2000–2100; m Wm$^{-2}$). Tropospheric (brown), stratospheric (blue), and net (whole atmosphere, red) forcings are shown. Associated ozone forcings with methane feedback (square hatched) are shown along with the net forcings. The overall ozone forcing (total) is the sum of the individual forcings (climate, lightning, O$_3$ recovery, and methane from Table 3) scaled to 1750 (star hatched). Dots and error bars indicate the mean and the 95% confidence intervals of the forcings, respectively. The information on pre-industrial ozone forcing (1750–2000) and sources of uncertainty are detailed in Sect. 4.

Previous work has shown that NRF is an appropriate tool for estimating annual and global tropospheric forcings derived from changes in the tropospheric column ozone, which in turn reduces the multi-model uncertainty (Gauss et al., 2003). The NRF in our analysis of 43 m Wm$^{-2}$ DU$^{-1}$ is similar to that from the ACCMIP models between the 1850s and 2000s, but larger compared to that in Gauss et al. (2003). This supports the future tropospheric ozone forcings and their uncertainties during the 21st century derived from the ACCMIP ensemble (calculated using the NRF) and may be used as a benchmark for individual studies.

Although previous studies have examined key drivers of ozone during the 21st century and future changes are relatively well understood (e.g. Kawase et al., 2011; Banerjee et al., 2014, 2016), the resulting forcings have been explored in less detail (e.g. Gauss et al., 2003; Bekki et al., 2013; Stevenson et al., 2013). Following a process-based approach that includes chemistry–climate feedbacks, we calculate that climate-only, lightning, ozone recovery, and methane emissions respectively contribute $-16 \pm 24$, $24 \pm 25$, $38 \pm 25$, and $55 \pm 26$ % to the net ozone RF between 2000 and 2100 (Table 3 and Fig. 6). Further uncertainties arise from the long-term ozone response to methane changes, which could increase the overall tropospheric forcing by $\sim 15$ %. Climate change (including lightning feedbacks) alone produces a relatively small tropospheric ozone forcing of $64 \pm 44$ m Wm$^{-2}$. A subset of eight models from the ACCMIP activity shows a small negative but not significant tropospheric forcing of $-33 \pm 42$ m Wm$^{-2}$, with few models reporting positive forcings (Table 12 in Stevenson et al., 2013). The impact of climate change on ozone forcing is surrounded by large uncertainties, which are associated with chemistry–climate feedbacks and the lack of confidence in the LNO$_x$ sensitivity to global mean surface temperature due to different parameterizations and the vertical distributions of the emissions (Banerjee et al., 2014; Finney et al., 2016), as well as changes in the BDC (Butchart, 2014). For example, the climate-change-induced net ozone forcing between 2000 and 2100 – following the future emission scenario RCP8.5 in an independent chemistry–climate model – is of the same order of magnitude but different sign ($-70$ m Wm$^{-2}$; Banerjee et al., 2018). While Banerjee et al. (2018) found a similar tropospheric ozone forcing of 70 m Wm$^{-2}$, their negative stratospheric ozone forcing outweighs the latter ($-150$ m Wm$^{-2}$). Methane- and ODSs-induced ozone forcings respectively have a substantial contribution from the stratosphere ($\sim 14$ %) and the troposphere ($\sim 34$ %) recently shown in modelling studies (Søvde et al., 2011; Shindell et al., 2013; Banerjee et al., 2018). A striking result, however, is the contribution of the stratospheric-produced ozone to the net forcing of $\sim 30 \pm 20$ and $\sim 99 \pm 50$ % due to methane and ODS concentrations, respectively, which is consistent with the findings from an independent chemistry–climate model (Banerjee et al., 2016, 2018). This reflects the roles that methane plays in stratospheric ozone chemistry (i.e. particularly in the lower stratosphere) and the fact that ozone recovery principally occurs in the stratosphere.

5 Summary and conclusions

This study has explored future changes in ozone by the end of the 21st century and the resulting radiative forcing following a process-based approach by imposing one forcing at a time. We have used the RCP8.5 emissions scenario to represent an upper limit on these responses. This is a different approach to previous studies, which typically have either explored future changes in ozone concentrations or ozone forcing. The methane feedback (due to the changing oxidizing capacity of the atmosphere and due to the long-term tropospheric ozone response) and its forcing have also been accounted for. In addition, non-linearities arising from chemistry–climate interactions have been investigated.

The simulated present-day ozone radiative effect (RE) is in good agreement with estimates based on observed ozone from TES, particularly in terms of its spatial distribution. However, there are systematic biases: RE is overestimated in the NH and underestimated in the SH, with significant biases in the subtropics. These RE biases are mostly consistent with the biases in tropospheric ozone in current global chemistry–climate models (Young et al., 2018), although the simu-
lated annual global present-day tropospheric column ozone (28.9 ± 1.5 DU) is within the observed inter-annual variability of 28.1–34.1 DU (Young et al., 2013). The fact that similar spatial distribution biases are apparent in many climate models suggests a common deficiency, and emissions data have been proposed as a likely candidate (Young et al., 2013, 2018).

Our analysis shows that the net ozone radiative forcing arising from climate-driven changes is relatively small and not significant (33 ± 104 m Wm$^{-2}$), which is largely the result of the interplay between lightning-produced ozone and enhanced ozone destruction (via increased temperatures and humidity). Higher methane concentrations and reduced ODS levels also have consequences for ozone forcing in the stratosphere (45 ± 39 m Wm$^{-2}$) and the troposphere (46 ± 47 m Wm$^{-2}$), respectively. We have demonstrated the importance of both stratospheric–tropospheric interactions and the stratosphere as a key region controlling a large fraction of the tropospheric ozone forcing (i.e. from the source point of view compared to the more common division by recipient region).

Future annual and global tropospheric and stratospheric column ozone changes from year 2000 to 2100 in this set of simulations (7.0 and 21.3 DU, respectively) are mainly driven by methane and ODS emissions, respectively (Table S1). These changes lead to a net ozone radiative forcing of 430 ± 130 m Wm$^{-2}$ compared to the present day, with an overall uncertainty of ±30 % (i.e. representing the 95 % confidence interval). Relative to the pre-industrial period (year 1750), our best estimate for the year 2100 net ozone radiative forcing is 760 ± 230 m Wm$^{-2}$.

This study highlights the key role of the stratosphere in determining future ozone radiative forcing in spite of the fact that the impacts largely take place in the troposphere. Increasing confidence in present-day observations of the Brewer–Dobson circulation and the stratospheric–tropospheric exchange will therefore play a crucial role in improving chemistry–climate models and better constraining ozone radiative forcing. A future study will address the importance of the stratosphere on future air quality commitments, which may better inform emission regulations.

Data availability. The model output used here is available upon request from the corresponding author (figlesias@iqfr.csic.es). The whole atmosphere ozone radiative kernel is also available upon request from Alexandru Rap (a.rap@leeds.ac.uk).

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/acp-18-6121-2018-supplement.
