Abstract. It has been suggested, and is widely believed, that the anomalous surface warming observed over the Northern Hemisphere continents in the winter following the 1991 eruption of Mt. Pinatubo was, in fact, caused by that eruption, via a stratospheric pathway that involves a strengthening of the polar vortex. However, most studies that have examined multiple, state-of-the-art, coupled climate models report that, in the ensemble mean, the models do not show winter warming after the Mt. Pinatubo eruption. This lack of surface warming in the multi-model mean, concomitant with a frequent lack of strengthening of the polar vortex, is often interpreted as a failure of the models to reproduce the observations. In this paper we show that this interpretation is erroneous, as averaging many simulations from different models, or from the same model, is not expected to yield surface anomalies similar to the observed ones, even if the models were highly accurate, owing to the presence of strong internal variability.

We here analyze three large ensembles of state-of-the-art, coupled climate model simulations and show that, in all three, many individual ensemble members are able to produce post-Pinatubo surface warming in winter that is comparable to the observed one. This establishes that current-generation climate models are perfectly capable of reproducing the observed surface post-eruption warming. We also confirm the bulk of previous studies, and show that the surface anomaly is not statistically different from zero when averaged across ensembles of simulations, which we inter-

pret as the simple fact that the volcanic impact on continental winter temperatures is tiny compared to internal variability.

We also carefully examine the stratospheric pathway in our models and, again confirming previous work, show that any strengthening of the polar vortex caused by the Mt. Pinatubo eruption is very small (of the order of a few meters per second at best). Such minuscule anomalies of the stratospheric circulation are completely overwhelmed by the tropospheric variability at midlatitudes, which is known to be very large: this explains the lack of surface winter warming in the ensemble means.

In summary, our analysis and interpretation offer compelling new evidence that the observed warming of the Northern Hemisphere continents in the winter 1991–1992 was very likely unrelated to the 1991 Mt. Pinatubo eruption.

1 Introduction

Large, low-latitude volcanic eruptions produce considerable, albeit short-lived, natural perturbations to the radiative forcing of the Earth's climate, and thus offer unique opportunities to probe its dynamics. With an estimated peak aerosol loading of 30 Tg (McCormick and Veiga, 1992), the eruption of Mt. Pinatubo in June 1991 was the largest to occur since the advent of satellite observation and, in fact, the second largest over the entire 20th century (after the 1912 Novarupta eruption). Moreover, in terms of dust veil index (Robock, 2000) and stratospheric optical depth (Sato et al., 1993) it

stands unrivaled all the way back to the historic eruption of Mt. Krakatau in 1883, and is therefore the premier candidate for understanding how volcanic aerosols affect the climate system.

After the initial cataclysmic eruption of 14–15 June 1991, the aerosol cloud from Mt. Pinatubo spread rapidly and encircled the globe in a mere 22 d (Bluth et al., 1992), filling the entire tropical belt, both north and south of the Equator, in a couple of months (McCormick and Veiga, 1992) and then spreading to higher latitudes in subsequent months (Long and Stowe, 1994). Since volcanic aerosols are strong scatterers of incoming solar radiation, they act to cool the troposphere and the Earth's surface. By September 1992, the global lower troposphere had cooled by -0.5°C (Dutton and Christy, 1992), with an even larger cooling of -0.7°C in the Northern Hemisphere (NH). Such large cooling values are comparable to the estimates for the epochal Tambora eruption of 1815 (McCormick et al., 1995).

In the context of such widespread cooling, the surface temperature over the NH continents happened to be anomalously warm in the winter immediately following the Mt. Pinatubo eruption (Robock, 2002). In a series of papers, Groisman (1992), Robock and Mao (1992), and later Robock and Mao (1995) and Kelly et al. (1996), argued that continental winter warming also occurred following several other eruptions since 1850, and suggested that the winter NH warming was actually *caused* by the volcanic eruptions. Further observational evidence was offered by Shindell et al. (2004), who expanded the set to a dozen large, low-latitude eruptions, going back to the year 1600. Their additional evidence, however, includes some perplexing facts. For instance, they show that the continental winter warming following both the 1883 Krakatau and the 1815 Mt. Tambora eruptions is, apparently, much smaller than that following the 1982 El Chichón eruption (see Fig. 1 of Shindell et al., 2004): this is difficult to reconcile with the narrative that volcanoes are the major cause of the NH continental winter warming, since those two earlier eruptions are larger in magnitude than the later one. Finally, after analyzing European climate reconstructions over the last half millennium, Fischer et al. (2007) report the somewhat puzzling result that the wintertime surface temperature anomalies following low-latitude eruptions appear to be stronger the second post-eruption year than in the first (recall that only a small fraction of the volcanic aerosols are left in the stratosphere in the second winter after an eruption).

Part of the widespread belief in the existence of a causal link between low-latitude volcanic eruptions and winter warming over the NH continents stems from the fact that a mechanism has been proposed to explain that link. Graf et al. (1993), on the basis of highly¹ idealized numerical experiments, followed by the observational studies of Kodera (1994) and Perlwitz and Graf (1995), and further numerical studies by Kirchner et al. (1999), Stenchikov et al. (2002) and many others thereafter, have advocated for the existence of what we will refer to as a “stratospheric pathway” causally linking low-latitude eruptions in summer with midlatitude surface warming the following winter. The starting point for this mechanism is the well-known fact that sulfate aerosols of volcanic origin are also strong absorbers of infrared radiation: hence powerful, low-latitude eruptions that are able to penetrate sufficiently high into the atmosphere can cause a strong *warming* of the tropical lower stratosphere, in addition to the tropospheric and surface cooling mentioned above. In the case of Mt. Pinatubo a $2\text{--}3^{\circ}\text{C}$ warming² of the tropical lower stratosphere was seen in radiosonde observations (Randel, 2010), in agreement with multiple reanalyses (Fujiwara et al., 2015). Such a perturbation increases the Equator-to-pole temperature gradient in the stratosphere, notably in winter, and induces a strengthening of the stratospheric polar vortex. The stronger polar vortex, it is claimed, then causes a positive phase of the North Atlantic Oscillation (or the Northern Annual Mode), which finally results in warmer surface temperatures over the NH continents, notably over Eurasia.

In spite of its simplicity, this proposed mechanism remains unconvincing because it has yet to be properly quantified. For instance, one could ask *how large* is the polar vortex acceleration caused by an eruption comparable to the one of Mt. Pinatubo in 1991? A recent study (Bittner et al., 2016), using a very large ensemble of runs with a well-tested stratosphere-resolving model, reports a polar vortex acceleration of $3\text{--}4\text{ m s}^{-1}$ at 10 hPa around 60°N , but also reports that an ensemble size of 15–20 members is needed to establish that fact at the 95 % confidence level (and twice that size is needed for a 99 % significance; see their Fig. 2a). But, more importantly, Bittner (2015) shows that such a polar vortex acceleration (of a few meters per second) does not result in a statistically significant wintertime continental warming, even with 100 members. This should not be surprising, as the internal variability associated with the North Atlantic Oscillation can easily overwhelm the surface effects of such a small stratospheric perturbation, as it even confounds the forced signal from increasing greenhouse gases over an entire 50-year period (see, for instance, Deser et al., 2017).

¹Their model was run in perpetual January configuration, with prescribed sea surface temperatures and sea ice concentrations, forced with an “externally computed” heating rate, but without interactive aerosols or ozone chemistry modules.

²At levels close to 20 km, taking the 1-year mean after the eruption minus the mean of the preceding 3 years.

In fact, the original stratospheric pathway mechanism has been called into question, even by its original proponents. Stenchikov et al. (2002) suggested that the stratospheric pathway may be part of a more complex mechanism and, on the basis of results from a single model, proposed that an additional tropospheric pathway may be equally important. In addition, Graf et al. (2007) reported that observations actually show *increased* planetary wave activity in the winter following the Mt. Pinatubo eruption, which is at odds with the claim that an anomalously strong polar vortex would cause NH surface warming that winter, and completely invalidates the original mechanism. Thus, they suggest “that the climate effects of volcanic eruptions are *not* being explained by the excitation of inherent zonal mean variability modes such as the strong polar vortex or Northern Annular Mode, but rather is another mode that possibly reflects upon the North Atlantic Oscillation” (Graf et al., 2007).

Furthermore, one can find in the literature many modeling studies whose findings are often diametrically opposite to each other. We will not exhaustively cite all previous papers, but simply limit ourselves to highlighting a few key studies to illustrate the contradictory claims that can be found in the peer-reviewed literature. Let us start by summarizing the findings of Driscoll et al. (2012), who analyzed 13 models from the Climate Model Intercomparison Project, Phase 5 (CMIP5). These models were specifically selected so as to have at least two ensemble members available. Comparing the average across all the models, as well as the averages across all the members of the each model, they concluded that “none of the models manage to simulate a sufficiently strong dynamical response,” given the absence of NH continental warming following the Mt. Pinatubo eruption in the model averages. Their study confirms the earlier conclusion reached with the CMIP3 models (Stenchikov et al., 2006), and many other studies (e.g., Thomas et al., 2009; Marshall et al., 2009; Bittner, 2015; Wunderlich and Mitchell, 2017).

Against this body of evidence, analyzing two versions of the NASA/GISS model, Shindell et al. (2004) have claimed that “driven by solar heating induced by the stratospheric aerosols, these models produce enhanced westerlies from the lower stratosphere all the way to the surface” and a significant wintertime warming over the NH continents, in agreement with Graf et al. (1993) and Kirchner et al. (1999), who also claimed that climate models are able to simulate the continental winter warming following the Mt. Pinatubo eruption via the stratospheric pathway. In fact, Shindell et al. (2004) concluded that their results “provide a further strong indication of the critical role of the stratosphere in the dynamic response to external forcing,” with a suggestion that a well-resolved stratosphere is crucial for capturing the NH winter warming that would be caused by volcanic eruptions. That suggestion, however, would seem soundly refuted by the evidence presented in Charlton-Perez et al. (2013), who separately analyzed models with and without a well-resolved stratosphere, and showed no difference between the two sets

in the forced response of the polar vortex in the winter following volcanic eruptions.

And lastly, Zambri and Robock (2016) reanalyzed the CMIP5 models using a different methodology. Averaging only the largest eruptions, and only the first winter after those eruptions, they concluded that “most models do produce a winter warming signal, with warmer temperatures over NH continents and a stronger polar vortex in the lower stratosphere,” directly contradicting Driscoll et al. (2012).

It is in the context of such multiple inconsistent claims that our paper aims to answer two questions:

1. Are current-generation climate models able to simulate the continental winter warming in the NH following the 1991 Mt. Pinatubo eruption?
2. If so, does the stratospheric pathway proposed by Robock and Mao (1992) and Graf et al. (1993) play any role in simulating that warming?

Analyzing large ensembles of model integrations from three different state-of-the-art coupled climate models over the historical period, we show below that (1) models *are* perfectly capable of simulating NH continental warming in the winter following the Mt. Pinatubo eruption, but (2) the stratospheric pathway – and, more importantly, the Mt. Pinatubo eruption itself – very likely played *no significant role* in the occurrence of that warming.

2 Methods

2.1 The models

Three large ensembles of integrations with state-of-the-art, comprehensive climate models are analyzed in this paper. All our models include atmosphere, land, ocean and sea ice components, fully coupled³ to accurately simulate the climate system response to the Mt. Pinatubo eruption. Here are, in brief, the specifications of our three models: WACCM4, CAM5-LE and CanESM2.

- WACCM4 is the Whole Atmosphere Community Climate Model, version 4, developed by the Community Earth System Model (CESM) project. WACCM4 is a high-top model, with a lid at 140 km and 66 vertical levels and a horizontal resolution of $\sim 2^\circ$. Its climate over the 20th century has been thoroughly evaluated by Marsh et al. (2013), who present further details about this model. We emphasize that WACCM4 also includes interactive stratosphere ozone chemistry and, therefore, has the most realistic representation of stratospheric dynamics and chemistry of the three models analyzed here.

³Note that was mostly not the case in the earlier studies. Graf et al. (1993), Kirchner et al. (1999), Stenchikov et al. (2002) and Shindell et al. (2004) did not use fully coupled climate models.

- CAM5-LE was also developed under the CESM project, with ocean and sea ice components similar to those of WACCM4. However, the atmospheric component of CAM5-LE is very different: it is a low-top model with only 30 vertical levels but with a higher horizontal resolution ($\sim 1^\circ$) and, most importantly, employs very different physical parameterizations than those in WACCM4 (Neale et al., 2010) and, in fact, has a considerably different climate sensitivity (Gettelman et al., 2013). CAM5-LE has been at the heart of the CESM Large Ensemble Project (see Kay et al., 2015, for details) and its performance, therefore, has been thoroughly tested in dozens of studies which have analyzed its output.
- CanESM2 is the second-generation Canadian Earth System Model, developed at the Canadian Centre for Climate Modelling and Analysis (CCCma). The atmospheric component of CanESM2 is a spectral model with an approximate horizontal resolution of 2.8° and with 35 unevenly spaced vertical levels and a model top near 0.1 hPa. For more details the reader may consult von Salzen et al. (2013). Again, this is a well-tested model which has contributed a whole suite of runs to the CMIP5 project, and it has been widely used in many climate studies (e.g., Swart et al., 2015).

We note that all three models were previously used to study the climatic effects of volcanic eruptions (English et al., 2013; Lehner et al., 2016; Gagné et al., 2017). More importantly, for all three models we have available a *large ensemble* of integrations which cover the second half of the 20th century. For these integrations, the models include all known natural and anthropogenic forcings, as per the so-called “historical” specifications of the CMIP5 protocol (Taylor et al., 2012). Specifically, we have analyzed 13 runs with WACCM4, 42 runs with CAM5-LE, and 50 runs with CanESM2. We stress that the model forcings are *identical for all members* of the same ensemble. The differences among members of the same ensemble arise uniquely from minuscule perturbations imposed on the models’ atmospheric initial conditions: the differences allow us to explore the internal variability of the system which, in many cases, can be much larger than the response to an external forcing, be it natural or anthropogenic. The reader is referred to Deser et al. (2012) for the seminal exposition of this methodology.

2.2 The analysis

We here discuss three key methodological choices we made in designing the best strategy to determine whether current-generation climate models are able to capture the wintertime NH continental warming following volcanic eruptions.

1. *Choice of eruption.* Although the model runs available to us cover the 1963 Agung and 1982 El Chichón eruption, we will here focus solely on the 1991 eruption

of Mt. Pinatubo end, in view of the following. First, as already noted, that eruption is the best observed of all known eruptions, and thus offers the best opportunity to contrasting models and observations. Second, one can easily argue that every eruption is unique: for instance, while the aerosol cloud from Pinatubo spread out in both hemispheres, the cloud of Mt. Agung spread primarily into the Southern Hemisphere (Viebrock and Flowers, 1968). So, combining these seems inappropriate. Third, and most importantly, since we are seeking to isolate and quantify the *forced response* to volcanic eruptions, it makes no sense to average eruptions of different magnitudes. This would be tantamount to trying to estimate the Earth’s climate sensitivity by averaging together $2\times\text{CO}_2$ and $4\times\text{CO}_2$ model runs. And we do not know whether the forced response varies linearly with the magnitude of an eruption. Other recent studies have also argued against averaging stronger and weaker eruptions when seeking to isolate their climatic impacts (Bittner et al., 2016; Zambri and Robock, 2016).

2. *Choice of winters.* We will here analyze only the *first* winter following the June 1991 eruption, i.e., the 3-month period from December 1991 to February 1992. Many (if not most) of the earlier studies assumed that the effect of volcanic eruptions can be felt for several years, and averaged together the first and second winters after each eruption. We see no cogent reason for doing so: the Mt. Pinatubo volcanic aerosols were removed from the atmosphere with an *e*-folding timescale of about 12 months (Barnes and Hofmann, 1997), so that the aerosol optical depth in January 1993 is much smaller than in January 1992 (see also Long and Stowe, 1994). Furthermore, if indeed the stratospheric pathway is crucial to carrying the response down to the surface at higher latitudes, it is difficult to imagine what memory the stratosphere would possess in the winter of 1993 of an eruption that occurred in June 1991. The recent study of Zambri and Robock (2016) also argues that only the first winter should be used since “averaging the first two winters after each eruption may have had a damping effect.”
3. *Choice of reference period.* Here we follow the methodology of Stenchikov et al. (2006) and Driscoll et al. (2012), and define the wintertime anomalies after the Mt. Pinatubo eruption as the difference between 1991/1992 winter and the mean of the winters in the 1985–1990 reference period. While this need not be the best way to quantify the post-eruption anomalies, we nonetheless adopt it in order to be consistent with recent studies that analyzed models similar to ours (Bittner et al., 2016; Zambri and Robock, 2016). As we will show below, our conclusions differ significantly from those of previous studies, and we want to make it clear

that the choice of reference period is not at the root of those differences.

In summary, for all quantities in all figures below (except Fig. 2) we will be showing and discussing anomalies defined as the difference between the first winter following the June 1991 Mt. Pinatubo eruption and the reference period defined in Driscoll et al. (2012). We will refer to these as the “post-Pinatubo anomalies,” or just “the anomalies” for short, and, for simplicity, denote them with a prime (e.g., T'_s for the surface temperature anomalies).

3 Can climate models simulate the observed NH continental warming following the 1991 Mt. Pinatubo eruption?

It is useful to start by recalling what the observed wintertime, post-Pinatubo, surface temperature anomalies over the NH continents actually look like. They are shown in Fig. 1, from four different datasets: two observational ones, GIS-TEMP (Hansen et al., 2010) and HadCRUT4 (Morice et al., 2012), and two reanalyses, NCEP/NCAR (Kalnay et al., 1996) and ERA-Interim (Dee et al., 2011). Note the excellent agreement between these four data products, which all show warming over both North America and the Eurasian continent. The fact that *both* continental masses were anomalously warm is of relevance for the stratospheric pathway mechanism to be discussed in the next section. These anomalies are also in excellent agreement with the lower tropospheric temperature anomalies from the Microwave Sounding Unit, Channel 2 (MSU2) satellite observations shown by Robock (2002), albeit for a slightly different reference period.

We now turn to analyzing the models. Before showing the simulated surface temperatures, however, we wish to illustrate the models' response to the Mt. Pinatubo eruption in the stratosphere, as the warming of the tropical stratosphere is an essential component of the stratospheric pathway mechanism. The global top-of-the-atmosphere (TOA) net outgoing shortwave radiation anomalies are shown in Fig. 2a, b, c, for WACCM4, CAM5-LE and CanESM2, from left to right. These panels may be contrasted directly with Fig. 2 of Driscoll et al. (2012), as they demonstrate that our three models are comparable to most CMIP5 models.

The resulting warming of the tropical lower stratosphere (30° S–30° N) is shown in Fig. 2d, e, f. The ERA-Interim reanalyses are also shown for comparison (black curves in each panel). While the CanESM2 model appears to be in good agreement with the observations, both WACCM4 and CAM5-LE greatly overestimate the post-eruption warming in the lower stratosphere. Reanalyses show an anomaly of roughly 2 °C, but those models show ensemble mean anomalies closer to 6 and 9 °C, respectively. This is not exceptional, as Driscoll et al. (2012) reports that most CMIP5 models simulate a much stronger anomaly than was observed (see their Fig. 3). The interesting point, however, is that this model bias

can be turned to our advantage: as will become clear below, the fact that models simulate an unrealistically strong warming of the tropical lower stratosphere after the Mt. Pinatubo eruption greatly strengthens our interpretation and conclusion.

With this in mind, we now proceed to examine the surface temperature anomalies simulated by our three models following the Mt. Pinatubo eruption, shown in Fig. 3. It is important to keep in mind that for each ensemble member the post-Pinatubo anomalies arise from two distinct sources: the external forcing and internal variability. The former is computed by averaging together all the members of each ensemble, as that procedure nearly eliminates the internal variability. For WACCM4, CAM5-LE and CanESM2, Fig. 3a, d and g show that forced response. In the winter following the Mt. Pinatubo eruption, all three models show *no statistically significant response* in NH continental surface temperatures.

We stress that this result is in agreement with most of the literature on this subject, notably the multi-model studies with the CMIP3 and CMIP5 models (Stenchikov et al., 2006; Driscoll et al., 2012; Wunderlich and Mitchell, 2017), which have shown that the forced post-Pinatubo anomalies in those models are not statistically significant. Moreover, it has been validated with an even larger ensemble size: Bitner (2015), employing a fully coupled stratosphere resolving model, concluded that after Mt. Pinatubo “the continental winter warming over Northern Europe and Siberia is not significantly different from zero even with 100 ensemble members” (as shown in Fig. 6.4 of that doctoral dissertation).

However, and this is perhaps the key point of our paper, from the fact that the ensemble mean (i.e., the forced) anomalies are not significant, it is *erroneous* to conclude that the models are unable to simulate the NH continental winter warming following the eruption. Recall that the observed anomalies are not expected to resemble the ensemble mean of any set of simulation, as internal variability is superimposed on any forced response in the observations. The correct question to ask is do any individual simulations resemble the observations? Or, more precisely, do the observed anomalies fall within the range, over the ensemble, of the simulated anomalies? The answer to that question is a resounding yes, as we show next.

Since that answer crucially depends on the range of anomalies that any one model is able to simulate, we start by illustrating that range. In Fig. 3b, e, h we show the extreme members, i.e., the members with the largest warming anomalies, for each of the three models we have analyzed. Noting that the color bar is identical to the one in Fig. 1, it is clear that the models are able to simulate much stronger warming anomalies than the observed ones. Even more, different ensemble members of the same models, with *an identical volcanic forcing*, are able to simulate equally strong *cooling* over the northern continents, as shown in Fig. 3c, f, i, where the coldest members can be seen. The point of this figure is to illustrate how large the internal variability is (in

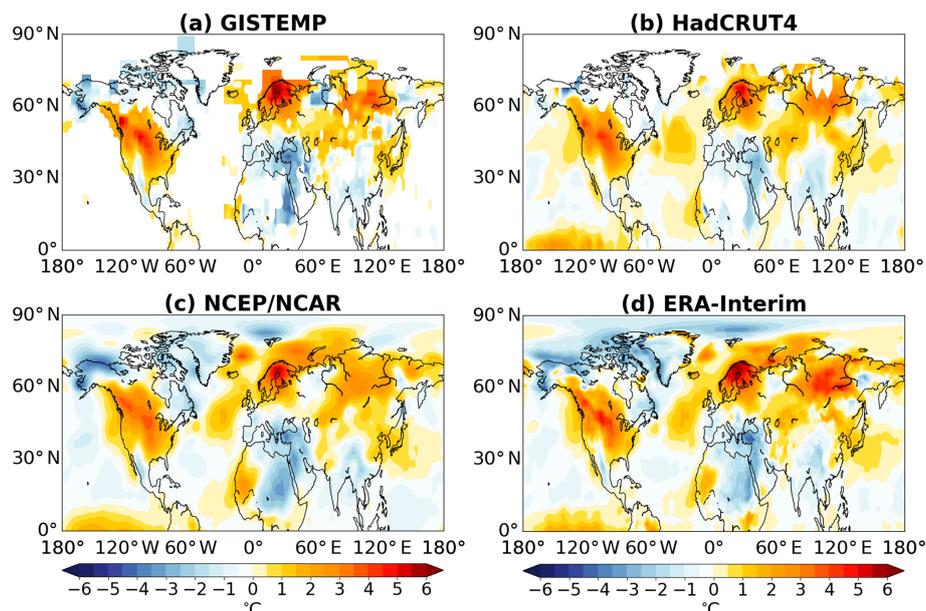

Figure 1. Surface air temperature anomalies ($^{\circ}\text{C}$) for the post-Pinatubo winter of 1991–1992 relative to the reference period (1985–1990) in observations (a) GISTEMP and (b) HadCRUT4 and in reanalyses (c) NCEP/NCAR and (d) ERA-Interim.

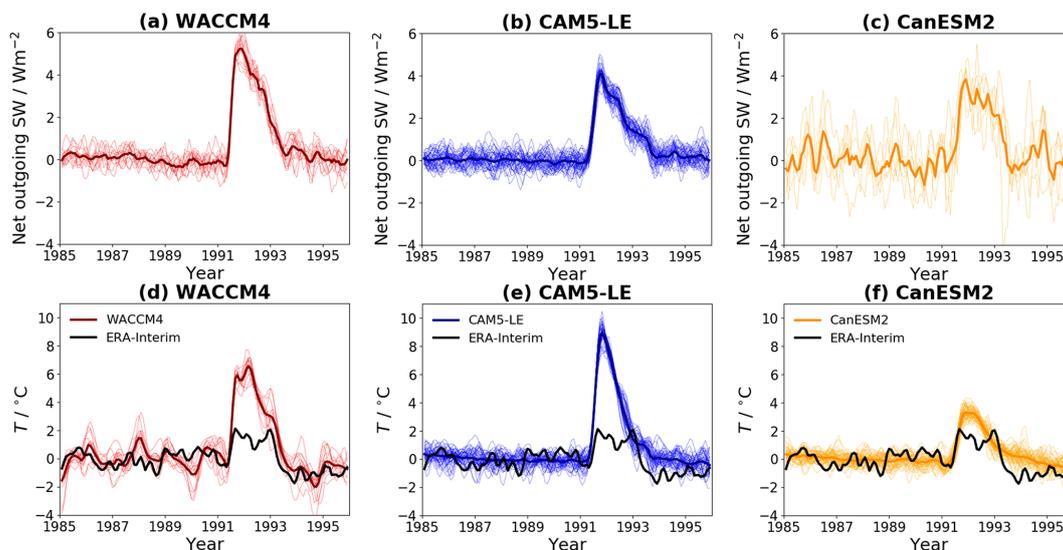

Figure 2. (a, b, c) Globally averaged, deseasonalized, net, outgoing SW radiation at the top of the atmosphere (W m^{-2}). (d, e, f) Tropically averaged (30°S – 30°N), deseasonalized temperature ($^{\circ}\text{C}$) at 50 hPa. (a, d) WACCM4 (red lines). (b, e) CAM5-LE-LE (blue lines). (c, f) CanESM2 (yellow lines). In each panel, the time series for each ensemble member (thin lines) and for the ensemble mean (bold line) are shown. In the bottom row, ERA-Interim values are also shown for comparison (black). All time series are anomalies from the 1985–1990 mean, and are smoothed with a 3-month running average, for direct comparison with Figs. 2 and 3 of Driscoll et al. (2012).

these models) and how tiny the forced response is in comparison. For completeness, the surface temperature anomalies for each member of each ensemble are shown in Figs. S1–S5 in the Supplement.

We quantify the relative magnitude of the forced response and the internal variability in Fig. 4 with box-and-whisker plots for the quantity T'_s , defined as the surface temperature

anomaly averaged over the landmasses in the region (40 – 70°N , 0 – 150°W), roughly corresponding to the Eurasian continent. First note that the mean of each ensemble is very near zero (a few tens of degrees at most, and not statistically significant), confirming the results of many previous studies that the forced response in the NH midlatitudes in the winter following the Mt. Pinatubo eruption is basically nonexistent

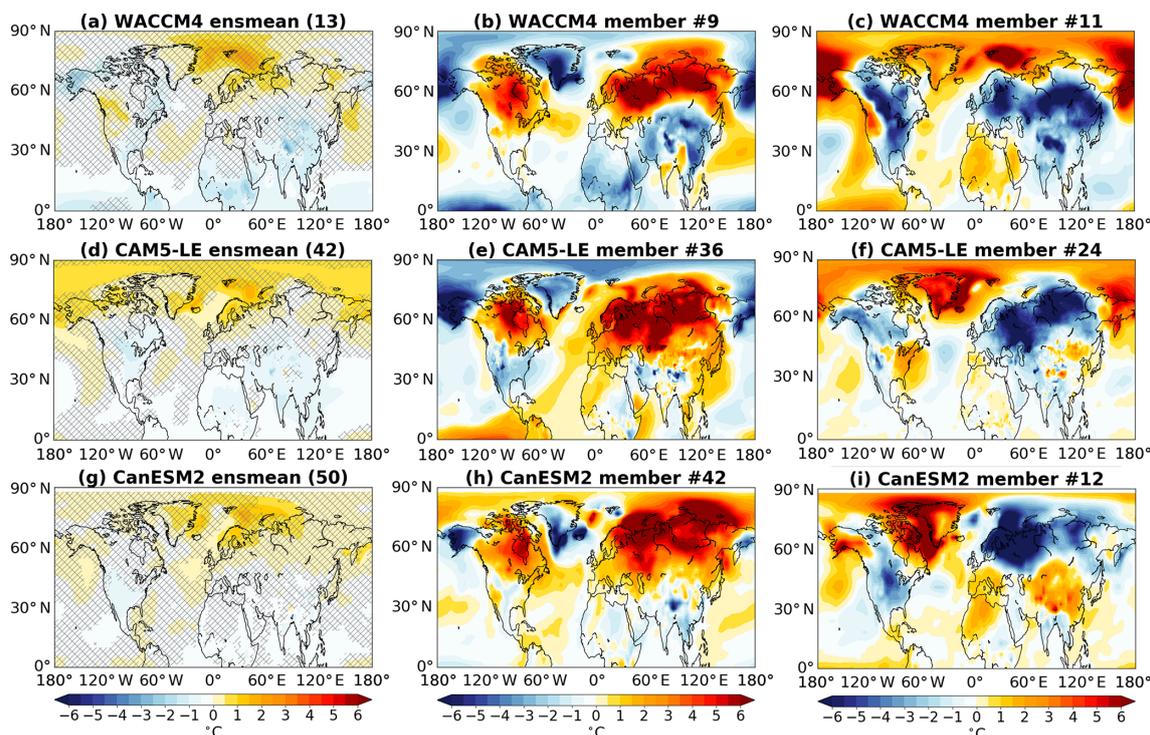

Figure 3. Wintertime surface air temperature anomalies ($^{\circ}\text{C}$) as simulated by WACCM4 (a, b, c), CAM5-LE (d, e, f) and CanESM2 (g, h, i) following the 1991 Mt. Pinatubo eruption. (a, d, g) The ensemble mean for each model (with the number of ensemble members in parentheses), and hatching over areas where the anomalies not significant at the 95 % confidence level. (b, e, h) Individual members exhibiting extreme warming over the NH continents for each model. (c, f, i) Individual members exhibiting extreme cooling.

in the models. Second, the models are in reasonably good agreement about the internal variability, showing a warming–cooling range of 2 to 4 $^{\circ}\text{C}$ on each side of zero, which is much larger than the forced response. Third, and most importantly, the reanalysis (red dot) falls well within the simulated range, indicating that the models are perfectly capable of capturing the post-Pinatubo winter anomalies in the NH.

4 Does the stratospheric pathway play a role in simulating the NH winter warming following the Pinatubo eruption?

Having established that our three models are able to simulate the observed NH continental warming after the Mt. Pinatubo eruption, we now turn to examining the stratospheric pathway mechanism proposed by Robock and Mao (1992), Graf et al. (1993), and others. In a nutshell, that mechanism involves two steps: (1) a strengthening of the stratospheric polar vortex caused by the enhanced Equator-to-pole lower stratospheric temperature gradient following the Mt. Pinatubo eruption, which, in turn, causes (2) an anomalous atmospheric circulation resulting in a warming anomaly over the Eurasian continent.

To carefully investigate the existence of a possible stratospheric pathway, we will limit ourselves to the WACCM4

model, as the other two do not have an accurate representation of the stratosphere and, more importantly, of its variability. We recognize that 13 members may perhaps not qualify as a “large” ensemble but, as we will show, the results presented below are in excellent agreement with those of Bittner et al. (2016), who analyzed a much larger⁴ 100-member ensemble.

Now, to quantify the strength of the polar vortex we compute the quantity U'_{10} , defined as the anomaly in the zonal mean, zonal wind at 10 hPa and 60° N. This quantity is widely used for the detection of stratospheric sudden warmings (see, e.g., Charlton and Polvani, 2007; Butler and Gerber, 2018). To quantify the meridional lower stratospheric temperature gradient we compute the quantity $\nabla T'_{50}$, defined as the difference in zonal mean temperature between

⁴The WACCM4 simulations analyzed here are a lot more computationally expensive than those in Bittner et al. (2016), as they involve interactive ozone chemistry. In fact, we are aware of no other study with a coupled atmosphere–ocean–chemistry model which has analyzed ensembles with more than a handful of members. Just to cite a few recent studies, McLandress et al. (2011) analyze three members, Solomon et al. (2015) six members and Li et al. (2018) four members. So, we maintain that a 13-member ensemble with interactive chemistry, and coupled ocean and sea ice components, represents a substantial step forward.

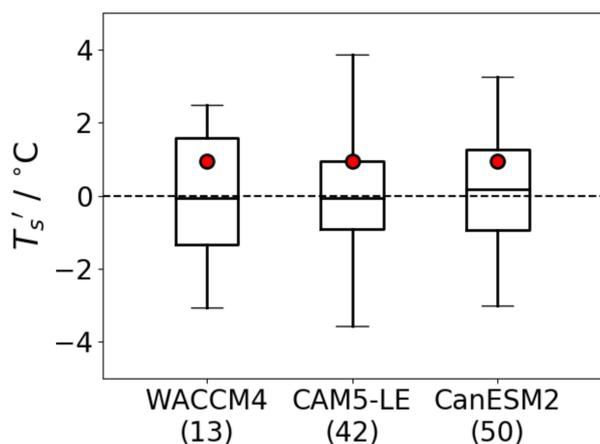

Figure 4. Box-and-whisker plots of simulated surface temperature anomaly ($^{\circ}\text{C}$) over Eurasia ($40\text{--}70^{\circ}\text{N}$, $0\text{--}150^{\circ}\text{W}$) in the first post-Pinatubo winter (1991–1992) relative to the reference period (1985–1990). The horizontal line inside each box denotes the ensemble mean; the lower and upper limits of each box denote the 25th and 75th percentile values, respectively; the whiskers span the full range of the ensemble members. For comparison, the red circles denote the value calculated from the ERA-Interim reanalyses.

the tropics ($30^{\circ}\text{S}\text{--}30^{\circ}\text{N}$) and the polar cap ($60\text{--}90^{\circ}\text{N}$) at 50 hPa: that level is chosen so as to capture the maximum amplitude of the stratospheric warming from Mt. Pinatubo at low latitudes. The relationship between the U'_{10} and $\nabla T'_{50}$ is shown in Fig. 5a: their correlation is exceedingly high (with an r^2 value of 0.89). From the ensemble mean value (black dot) one can see that, indeed, a warming of the tropical lower stratosphere by a potent low-latitude eruption does result in a stronger⁵ wintertime polar vortex in our model.

The key question, however, is, how much stronger? In the case of the Mt. Pinatubo eruption, this is given by the black circles in Fig. 5a, which indicate the ensemble mean value of 3.5 m s^{-1} for our WACCM4 simulation. This is in excellent agreement with the findings of Bittner et al. (2016), who also reported $3\text{--}4\text{ m s}^{-1}$ acceleration of the polar vortex following large low-latitude eruptions, and emphasized that 15–20 ensemble members are need to establish this result in a statistically significant way (at 95 %). One cannot overemphasize how minuscule this forced response is when contrasted with the unforced, internal variability of the wintertime polar vortex, whose strength can vary by many tens of meters per second over a period as short as a week (e.g., during a stratospheric sudden warming event, which occurs roughly every other year; see Charlton and Polvani, 2007).

⁵Although we do not believe that it is appropriate to analyze the CAM5-LE and CanESM models for possible evidence of a stratospheric pathway – as those are low-top models with a poorly resolved stratosphere and thus unrealistic stratospheric variability – we nonetheless include in Fig. S6 the same scatter plots as in Fig. 5, to satisfy the request of one anonymous referee. The reader can see that those two other models confirm the WACCM results.

With this in mind, we now proceed to examining the second step of the proposed mechanism, the relationship between the polar vortex anomaly U'_{10} and the Eurasian surface temperature anomaly T'_s . We find no meaningful correlation between the two, as evident from Fig. 5b (the r^2 value is 0.06), the ensemble mean temperature anomaly is indistinguishable from zero. It is widely appreciated that the variability of the midlatitude tropospheric circulation is very large, so that it can easily overwhelm polar vortex anomalies of tens of meters per second. In fact, even stratospheric sudden warmings – which correspond to massive perturbations of the stratospheric polar vortex and result in a wind reversal at 10 hPa, from westerlies to easterlies – are not always able to produce a significant surface signal (see the sudden warming compendium; Butler et al., 2017).

Another way of illustrating the weakness of the connection between polar vortex strength and Eurasian surface temperature anomalies is to contrast two WACCM4 ensemble members – specifically no. 2 and no. 12 – for which T'_s is shown in Fig. 6a, b. We have chosen these two particular members as they simulate very similar Eurasian surface warming anomalies, not unlike the ones in the observations. In spite of those surface similarities, the corresponding stratospheric temperature gradients are completely different (see Fig. 6c, d). The tropical lower stratosphere is anomalously warm in both members, owing to the direct radiative effect of the volcanic aerosols, which is robust. In contrast the polar stratosphere is anomalously warm for one case (no. 2) but cold for the other (no. 12). The corresponding temperature gradients $\nabla T'_{50}$ are thus of opposite sign and, predictably, the polar vortex is anomalously weak for the former and strong for the latter member, as seen in Fig. 6e, f, where we show the zonal mean zonal wind at 10 hPa. Note that these opposite-signed polar vortex anomalies have an amplitude of about 10 m s^{-1} , which is 3 times larger than the forced response documented above. In spite of such large and opposite-signed polar vortex anomalies, both members exhibit very similar surface temperature anomalies over Eurasia, as seen in the top row: this demonstrates that polar vortex anomalies do not *necessarily* determine the surface anomalies.

For completeness, the full vertical structure of the ensemble mean temperature anomalies for the WACCM4 model is shown in Fig. 7a. The only statistically significant signal is found in the tropics, where WACCM4 greatly overestimates the post-Pinatubo warming, yielding a temperature gradient in the lower stratosphere that is considerably larger than the observed one: as seen in Fig. 5a, the ensemble-mean simulated value of $\nabla T'_{50}$ is 5.3°C , whereas the observed value is 0.4°C . In spite of a much larger temperature gradient anomaly than the observed one, we find little statistically significant response in the polar stratospheric winds, as seen in Fig. 7b. There is an overall acceleration of the polar vortex, as one might expect, but the area of significance is quite small, and the grid point at 10 hPa and 60°N (the canonical metric for the polar vortex strength) is not statistically significant.

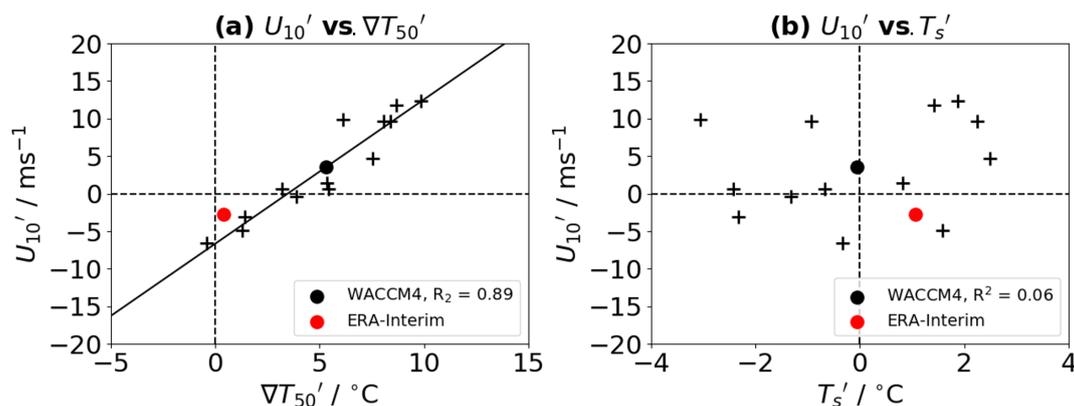

Figure 5. Scatter plots showing the relationship between U'_{10} , the anomalies in the zonal mean zonal wind at 10 hPa and 60°N (m s^{-1}) and the anomalies in (a) the NH meridional temperature gradient $\nabla T'_{50}$ between the tropics (30°S – 30°N) and the pole (60 – 90°N) ($^\circ$), and (b) the Eurasian surface air temperature T'_s ($^\circ\text{C}$). Crosses show individual ensemble members, and the black dot shows the ensemble mean value. The red dot shows the ERA-Interim reanalysis.

This conclusion does not contradict the findings of Bittner et al. (2016), who reported a statistically significant response of the stratospheric polar vortex after the Mt. Pinatubo eruption in their model. We have only 13 members at our disposal here, and this is why we are unable to establish clear significance with WACCM4. To appreciate how difficult it is to obtain a statistically significant response in the polar vortex, we show the U'_{10} anomalies for each of the 13 members in Fig. 8: there is a wide scatter across the 13 members, yielding an ensemble mean which is much smaller than most individual members. Nonetheless, the fact that only four members show a vortex weakening and the remaining nine show a vortex strengthening is suggestive of polar vortex acceleration. Using a different high-top model, Bittner et al. (2016) found that 15–20 ensemble members were needed to obtain a statistically significant strengthening of the polar vortex, and our ensemble size is not too far below that threshold.

More important, however, is the red line in Fig. 8, showing the ERA-Interim anomalies: it indicates that the polar vortex was, actually, anomalously weak in the winter following the Mt. Pinatubo eruption. For clarity, we show the entire latitude–pressure profiles of the ERA-Interim temperature and wind anomalies in Fig. 7c, d. Amazingly⁶ enough, the polar stratosphere was anomalously warm (not cold) after the eruption (panel c), and the polar vortex was anomalously weak (not strong): note, in panel d, the negative zonal wind

⁶This crucial fact seems to have gone largely unnoticed in the literature. It is reported in the doctoral dissertation of Thomas (2008, see her Figs. 4.16 and 4.17), and tangentially noted by Mitchell et al. (2011, see their Fig. 8, and the accompanying text), who employed so-called “elliptical” diagnostics for the polar vortex. It is also briefly discussed in Toohey et al. (2014, see their Fig. 1), who argue that wintertime stratospheric state in the first winter after Mt. Pinatubo may not be representative of the “pure response” to the volcanic aerosols owing to confounding factors (e.g., the Quasi-Biennial Oscillation).

between 10 and 1 hPa, and between 50 and 60°N , where the climatological polar vortex is located. So we conclude by asking, how can the stratospheric pathway mechanism be invoked as an explanation for the observed warming over the NH continents, as one can read in Robock (2002), if the polar stratosphere was actually *warmer* and the polar vortex was actually *weaker* in the winter that followed the 1991 eruption of Mt. Pinatubo?

5 Summary and discussion

The aim of this paper has been to understand the cause of the warm anomalies that were observed over the NH continents following the Mt. Pinatubo eruption in June 1991. More specifically, referring back to the introduction, we have addressed two related but distinct questions: the ability of the models to simulate the observations and the importance of the stratospheric pathway.

First, we have demonstrated that the current generation of coupled climate models is eminently capable of simulating such anomalies. Unlike previous studies, our conclusion follows from comparing the observed anomalies to *individual* model simulations, not to the *average* of multiple simulations. We have shown that climate models, when forced with an identical volcanic perturbation, can actually simulate a much larger surface warming than observed and, in fact, an equally large cooling. Furthermore, confirming many previous studies, we have shown that averaging across model simulations results in statistically insignificant surface temperature anomalies in the NH following the eruption. Taken together, and assuming climate models are not fundamentally flawed, these facts are here interpreted as follows: the internal variability of the climate system in the NH in wintertime is much larger than any impact from the Mt. Pinatubo eruption. As a consequence, it is hard to imagine that any substantial

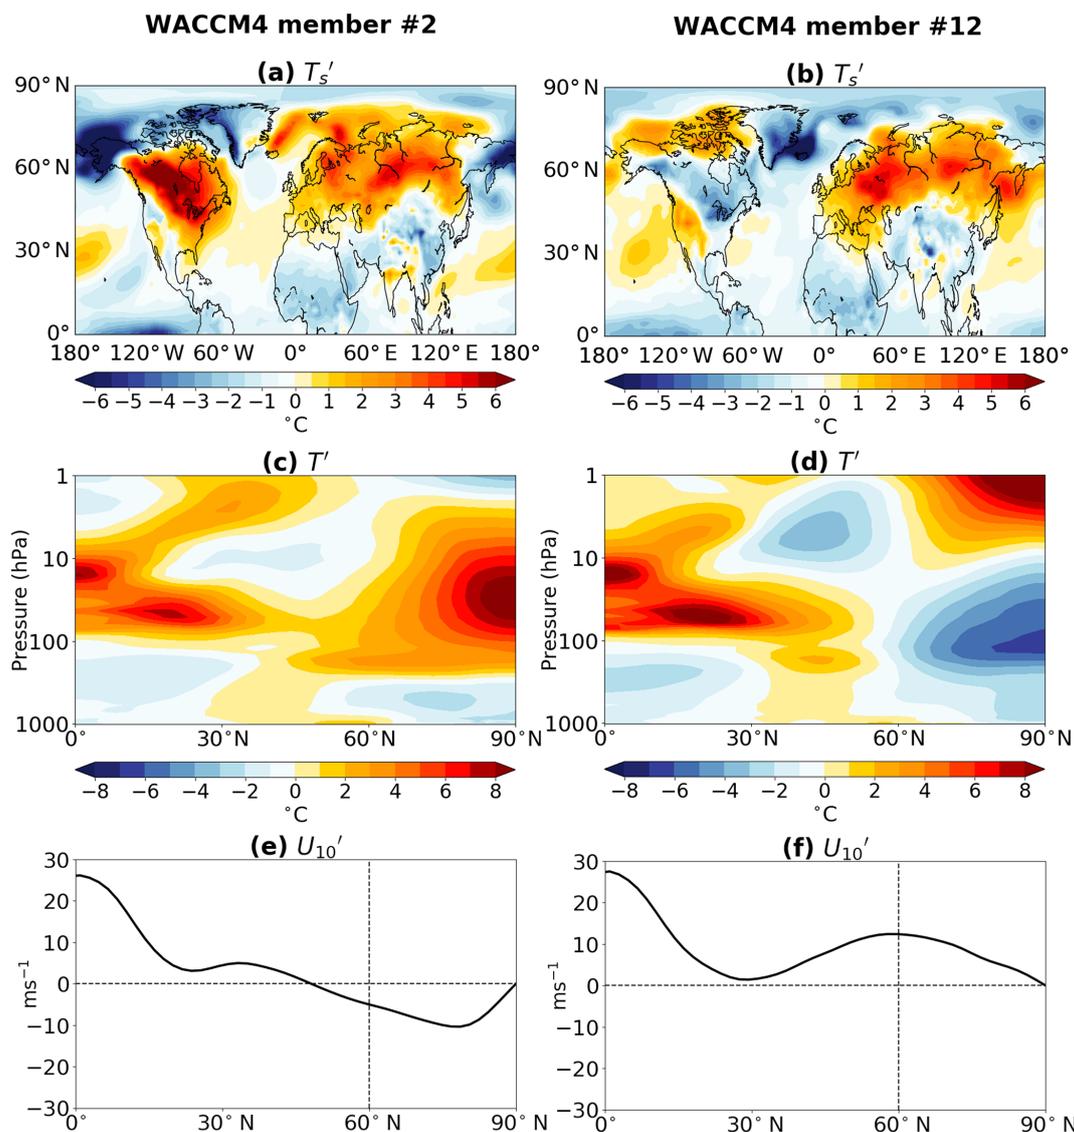

Figure 6. The surface temperature T'_s (a, b), the zonal mean temperature T' (c, d) and 10hPa zonal mean zonal wind U'_{10} anomalies for WACCM4 member no. 2 (a, c, e) and member no. 12 (b, d, f).

fraction of the observed warming anomalies in the NH during the 1991–1992 winter were caused by that volcanic eruption.

Second, we have examined in detail the potential role of an often invoked stratospheric pathway mechanism, which would allegedly mediate the signal from a low-latitude eruption to the higher-latitude continents by accelerating the polar vortex, and subsequently causing a positive phase of North Atlantic Oscillation (or the annular mode). Analyzing the WACCM4 model, which is a stratosphere-resolving model with interactive stratospheric ozone chemistry, we find the polar vortex acceleration accompanying the increased lower stratospheric temperature gradient after the Mt. Pinatubo eruption to be no larger than a few meters per second at best. And, we wish to emphasize, the WACCM4 model (like most others) produces an unrealistically large warming of the trop-

ical lower stratosphere (see Figs. 2d and 7a, b), which implies an unrealistically strong acceleration of the polar vortex. Even so, that acceleration is actually *not* statistically significant in our 13-member WACCM4 ensemble. This is in total agreement with the recent study of Bittner et al. (2016), who reported that 15–20 members are needed to detect a significant acceleration of the polar vortex of 3–4 m s^{-1} in the winter following a large-magnitude low-latitude eruption. This, in and of itself, is clear evidence that the forced polar vortex response is very small compared to the internal stratospheric variability in wintertime, where wind perturbations of many tens of meters per second are not unusual. And ultimately, in terms of affecting the tropospheric circulation and surface temperature, such small polar vortex anomalies are completely dwarfed by the internal tropospheric vari-

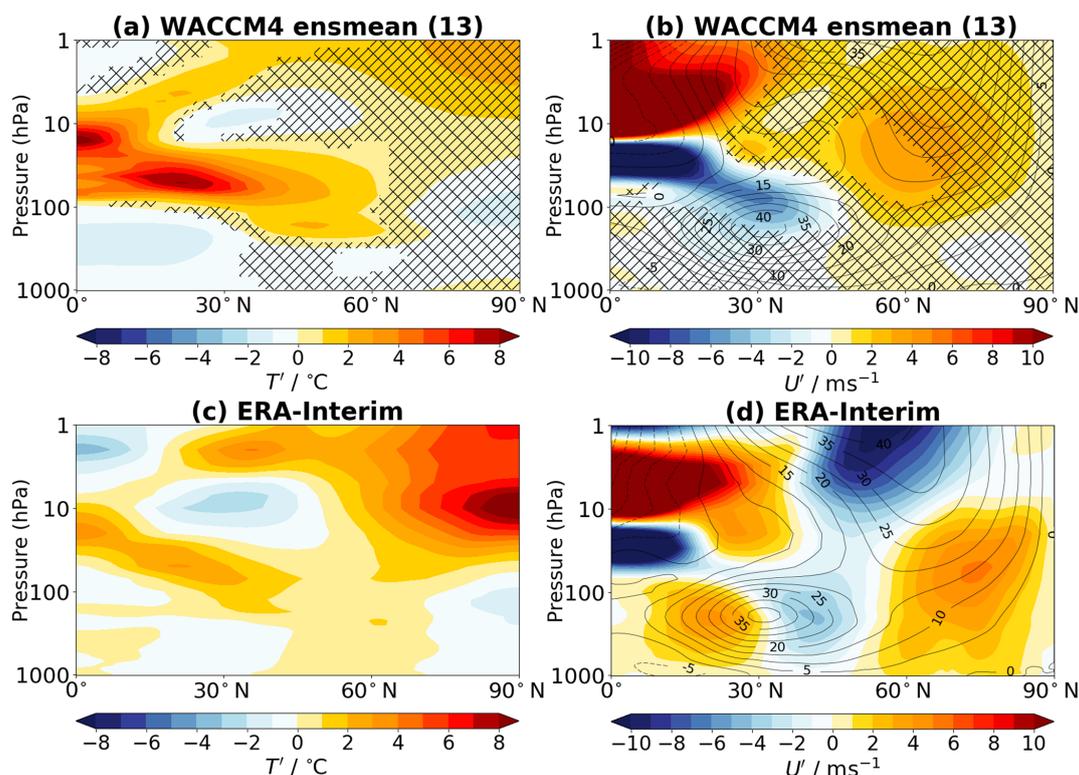

Figure 7. Latitude–pressure anomalies for the winter following the 1991 Mt. Pinatubo eruption. **(a, c)** Zonal mean temperature (T'). **(b, d)** Zonal mean zonal wind U' , with the climatology in black contours. **(a, b)** The ensemble mean of the WACCM4 simulations, with hatching for values that are not significant at the 95 % confidence level. **(c, d)** Corresponding anomalies in the ERA-Interim reanalysis.

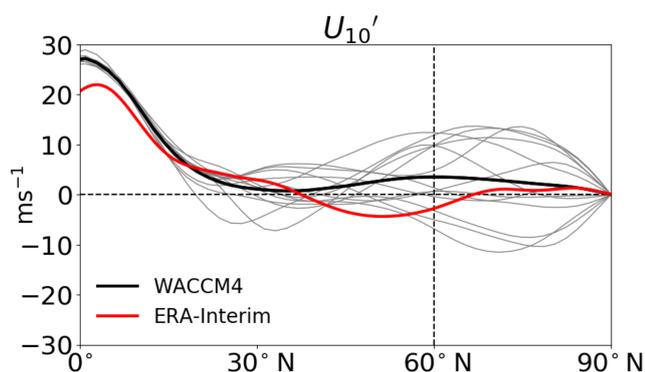

Figure 8. Zonal mean zonal wind anomalies at 10 hPa (U'_{10}) vs. latitude, for the individual WACCM4 simulations (gray), for the ensemble mean (black) and for the ERA-Interim reanalysis (red).

ability; this is why no statistically significant anomalies are found when averaging over many model simulations.

One might now ask how such evidence can be reconciled with several influential early modeling studies, which have argued for the key role of the stratospheric pathway in causing the NH continental surface warming in the winter following the Mt. Pinatubo eruption. We suggest the following: most of those early models simply lacked a good representa-

tion of the stratosphere and, more crucially, of its variability, and this resulted in an overestimate of the forced response to the volcanic eruption. For instance, the model employed in Graf et al. (1993) had a mere 19 vertical levels in the vertical direction, with the model top at only 10 hPa. The same applies to the study of Kirchner et al. (1999), who improved the horizontal resolution but retained the same deficient vertical structure of their model. A severe lack of vertical resolution is also evident in the AMIP models analyzed in Mao and Robock (1998), all of which (with only one exception) have between 10 and 20 vertical levels (see Table 2 of Gates, 1992). The same goes for the study of Collins (2003): 19 vertical levels. As for Shindell et al. (2004), the two models used in that study have only 20 and 23 vertical levels, and the latter has a very coarse horizontal resolution as well (8° latitude \times 10° longitude): that model was, in fact, evaluated for its ability to simulate stratospheric sudden warmings, and was found to greatly underestimate their frequency (see Fig. 3c of Charlton et al., 2007, under the item GISS23). The reader may want to contrast that model with the WACCM4 model used here, with 66 vertical levels, a model top at ~ 140 km and an excellent simulation of the frequency of stratospheric sudden warmings (see Fig. 3a of Marsh et al., 2013).

A note is also in order regarding the recent study of Zambri and Robock (2016). They reanalyzed a larger set of CMIP5

models than those in Driscoll et al. (2012), and considered only the anomalies in the first winter after the eruptions. From the multi-model average anomalies following the two largest eruptions since the preindustrial era they concluded that “the observed surface temperature anomalies are related to changes in the winter circulation *caused* by the volcanic eruptions” (emphasis added), a claim obviously at odds with much of the previous literature, and with the results presented here. However, as their conclusion was drawn by averaging anomalies from the 1883 Krakatau eruption with those from the 1991 Mt. Pinatubo eruption, it is not immediately obvious how to disentangle the forced response to Mt. Pinatubo alone, which is the primary goal of the present study. We plan to carefully examine other volcanic eruptions in future studies.

Nonetheless, we have briefly analyzed other recent⁷ eruptions simulated by the three models described in Sect. 2.1. Of particular interest is the 1982 eruption of El Chichón (Robock, 1983), which was also followed by anomalous wintertime warming over the Northern Hemisphere continent (as shown in Fig. S7). As for the 1991 Mt. Pinatubo eruption, all three models produce (1) a statistically insignificant forced response and (2) both warm and cold anomalies with identical volcanic forcing (see Fig. S8), indicating that the observed continental winter warming following the 1982 El Chichón eruption was also, very likely, a simple manifestation of internal variability. Of course, the validity of our interpretation is dependent on the models’ ability to accurately simulate the internal variability of the climate system.

Still, leaving models – and their possible biases – aside, one could nonetheless argue that several studies have “demonstrated”, on the basis of various temperature reconstructions, that many low-latitude volcanic eruptions have been followed by NH continental warming in wintertime. Whether those demonstrations are truly convincing depends, crucially, on the quality of the surface temperature reconstructions and on the soundness of the methodology employed. The early claim of Robock and Mao (1992) was based on the analysis of a single temperature dataset for 12 eruptions, half of which occurred at latitudes outside 30° S–30° N, averaging together larger and smaller events, and commingling anomalies from the first or second winters (depending on the eruption). Similar commingling is found in the study of Shindell et al. (2004), who analyzed 18 eruptions, of which only a dozen were at low latitudes. Ignoring the possible errors introduced by commingling of first and second winters, and of high-latitude and low-latitude eruptions, our work shows that a dozen eruptions may be far from sufficient to demonstrate the existence of a significant vol-

canic signal at the surface. And our findings simply corroborate those of Bittner (2015, see his Fig. 6.4, specifically), who showed that even 100 identically forced, large, low-latitude eruptions are insufficient to yield a statistically significant surface winter warming at high northern latitudes.

It is not impossible, we concede, that an extraordinarily large eruption (e.g., Tambora) may be capable of causing significant winter warming over the NH continents. But a question then arises: how many such eruptions are actually available in the record for which reliable observations of winter surface temperatures at high latitude also exist? As of this writing, the most compelling observational evidence for a volcanically forced surface winter warming at high latitudes is found in the study of Fischer et al. (2007). They averaged 15 large, low-latitude eruptions extending back to the middle of the last millennium, and carefully separated the first and second winter anomalies in temperature (and precipitation) over Europe. Notably, they found that the warmer (and wetter) winter anomalies are found in the *second* winter following the eruption, not the first winter. This result was obtained from a single proxy reconstruction, and warrants independent validation with one or more different reconstructions. In addition, if the largest European surface anomalies are indeed found in the second winter, the stratospheric-pathway mechanism proposed by Robock and Mao (1992), Graf et al. (1993), Kodera (1994), and others appears implausible. Little volcanic aerosol is left in the stratosphere 12–15 months after an eruption, and we can think of no physical mechanism in the stratosphere that would allow an anomaly to survive into a second year. Nonetheless, in climate models, volcanic signals have been shown to propagate through the ocean on decadal timescales (Gleckler et al., 2006). This suggests the possibility, at least in theory, of an oceanic pathway. It remains to be demonstrated, however, whether oceanic anomalies are indeed capable of affecting the Northern Annular Mode and, ultimately, Eurasian surface temperatures.

In any case, coming back to the most recent large eruption of Mt. Pinatubo, the fact remains that from December 1991 to February 1992, the observed surface temperatures were anomalously warm over North America and Eurasia, and that fact may deserve an explanation. Our analysis indicates that the continental warming that occurred in the first winter following the 1991 eruption was most likely a simple manifestation of internal atmospheric variability, and was completely unrelated to the eruption itself. So, the next question is simply, what might be the source of variability that resulted in the NH continental warming? An obvious candidate would be the El Niño–Southern Oscillation (ENSO) phenomenon, since it is well known that the eruption of Mt. Pinatubo corresponded with an El Niño event (see, e.g., Lehner et al., 2016), which is believed to influence the North Atlantic and Eurasia in winter (Brönnimann, 2007; Rodríguez-Fonseca et al., 2016). Unfortunately, El Niño conditions are typically associated with a contraction of the tropical belt (Lu et al., 2008) and a negative phase of the North Atlantic Oscillation (Li and

⁷After the 1963 eruption of Mt. Agung, the volcanic aerosol cloud spread primarily into the Southern Hemisphere (Viebrock and Flowers, 1968): that eruption is thus not the best candidate for exploring the causal link between low-latitude eruptions and anomalies over the Northern Hemisphere continents.

Lau, 2012), which is typically accompanied by cold anomalies over Eurasia. It is, therefore, difficult to argue that the observed post-Pinatubo continental warming was caused by El Niño. In fact, there is some good modeling evidence confirming this. First, Thomas et al. (2009) reported a “very strong” response to El Niño in their model that “can mask the effects due to volcanic warming”. Second, analyzing so-called pacemaker⁸ simulations with the CAM5-LE model, McGraw et al. (2016) show a large forced signal in the tropospheric circulation from El Niño in the Northern Hemisphere, which greatly resembles a negative annular mode (see their Fig. 11f); they do not show surface temperatures, but one would easily expect cold anomalies over the NH continents in those simulations. If, then, El Niño needs to be ruled out, we may just have to admit that the intrinsic variability of the high-latitude tropospheric circulation, which is known to be very large (Shepherd, 2014), might have to suffice as an explanation.

Data availability. Observational data. The datasets used in this study can be downloaded from their respective web servers, provided by the GISTEMP team at the NASA Goddard Institute for Space Studies for GISTEMP (<https://data.giss.nasa.gov/gistemp/>, last access: 9 May 2019), the Climate Research Unit (CRU) for HadCRUT4 (<https://crudata.uea.ac.uk/cru/data/temperature/>, last access: 9 May 2019), NOAA ESRL PSD FOR NCEP/NCAR (<https://www.esrl.noaa.gov/psd/data/gridded/data.ncep.reanalysis.pressure.html>, last access: 9 May 2019), and the European Centre for Medium-Range Weather Forecasts (ECMWF) for ERA-I (<https://apps.ecmwf.int/datasets/data/interim-full-daily/levtype=sfc/>, last access: 9 May 2019).

Modeling data. The CAM5-LE large ensemble data are publicly available via the Earth System Grid: <http://www.cesm.ucar.edu/projects/community-projects/LENS/data-sets.html> (last access: 9 May 2019). The CanESM2 data are available at <http://climate-modelling.canada.ca/climatemodeldata/cgcm4/CanESM2/index.shtml> (last access: 9 May 2019). The WACCM4 data are stored on the High Performance Storage System at the National Center for Atmospheric Research, in Boulder, Colorado, and are available upon request.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/acp-19-6351-2019-supplement>.

Author contributions. LMP originally conceived of the study and designed it together with AB, in consultation with AS. AB performed the analysis of the model output and drafted the figures. LMP wrote the paper, with input from AB and AS. All authors contributed to the interpretation of the results.

⁸In these simulations a fully coupled atmosphere–ocean is employed, but sea surface temperature anomalies in the eastern tropical Pacific are nudged to observations, so as to faithfully simulate El Niño events.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Lorenzo M. Polvani and Antara Banerjee are grateful for the support of the US National Science Foundation (USNSF), and wish to express their gratitude to Ryan Neely for performing and making available some of the WACCM4 model integrations. Computing resources for WACCM4 and CAM5-LE were provided by the Computational and Information Systems Laboratory (CISL) at the National Center for Atmospheric Research (NCAR). We also acknowledge the National Oceanic and Atmospheric Administration (NOAA) Research and Development High Performance Computing Program, for providing computing and storage resources for some of the WACCM4 runs, and wish to thank Henry LeRoy Miller for his assistance with NOAA’s high-performance computing facilities. The CESM Large Ensemble Project and supercomputing resources were provided by the USNSF and NCAR/CISL. We also acknowledge Environment and Climate Change Canada’s Canadian Centre for Climate Modelling and Analysis for executing and making available the CanESM2 large ensemble simulations used in this study, and the Canadian Sea Ice and Snow Evolution Network for proposing the simulations.

Financial support. This research has been supported by the US National Science Foundation (grant nos. AGS 14-02931 and AGS13-22449).

Review statement. This paper was edited by Rolf Müller and reviewed by Georgiy Stenchikov and three anonymous referees.
