Abstract. One year of ground-based night-time Raman lidar observations has been analysed under the Optimization of Aerosol Seeding In rain enhancement Strategies (OASIS) project, in order to characterize the aerosol particle properties over a rural site in the United Arab Emirates. In total, 1130 aerosol particle layers were detected during the 1-year measurement campaign which took place between March 2018 and February 2019. Several subsequent aerosol layers could be observed simultaneously in the atmosphere up to 11 km. The observations indicate that the measurement site is a receptor of frequent dust events, but predominantly the dust is mixed with aerosols of anthropogenic and/or marine origin. The mean aerosol optical depth over the measurement site ranged at 0.37 ± 0.12 and 0.21 ± 0.11 for 355 and 532 nm, respectively. Moreover, mean lidar ratios of 43 ± 11 sr at a wavelength of 355 nm and 39 ± 10 sr at 532 nm were found. The average linear particle depolarization ratio measured over the course of the campaign was 15 ± 6 % and 19 ± 7 % at the 355 and 532 nm wavelengths, respectively. Since the region is both a source and a receptor of mineral dust, we have also explored the properties of Arabian mineral dust of the greater area of the United Arab of Emirates and the Arabian Peninsula. The observed Arabian dust particle properties were 45 ± 5 (42 ± 5) sr at 355 (532) nm for the lidar ratio, 25 ± 2 % (31 ± 2 %) for the linear particle depolarization ratio at 355 (532) nm, and 0.3 ± 0.2 (0.2 ± 0.2) for the extinction-related Ångström exponent (backscatter-related Ångström exponent) between 355 and 532 nm. This study is the first to report comprehensive optical properties of the Arabian dust particles based on 1-year long observations, using to their fullest the capabilities of a multi-wavelength Raman lidar instrument. The results suggest that the mineral dust properties over the Middle East and western Asia, including the observation site, are comparable to those of African mineral dust with regard to the particle depolarization ratios, but not for lidar ratios. The smaller lidar ratio values in this study compared to the reference studies are attributed to the difference in the geochemical characteristics of the soil originating in the study region compared to northern Africa.

1 Introduction

The Earth’s energy budget involves the exchange of energy between three levels: its surface, the top of the atmosphere, and the atmosphere in between (Hansen et al., 2005). In this system, aerosol particles are an important, yet underdetermined, component introducing uncertainties in weather and climatic predictions (Boucher et al., 2013; Stevens and Fien-
eral dust, the Arabian Peninsula is also a large emitter of dust to being one of the world’s largest sources of mineral dust, together with northern Africa. Although this region is key to improving the understanding of the climate impact of mineral dust, their spatial distribution in regional and vertical scales varies substantially. Recent studies have shown that fine-mode dust has a cooling effect on the global climate, whereas coarse dust (particle diameter larger than 5 µm) likely has a warming impact (Kok et al., 2017; Miller et al., 2006). Mineral dust particles are characterized as nonspherical with irregular shapes and substantial surface heterogeneity (Wagner et al., 2012; Wiegner et al., 2009). Their optical properties, such as the lidar ratio, are also subject to their chemical composition. Therefore, dust particles originating from different regions exhibit different scattering properties due to their different microphysical and chemical composition (Järvinen et al., 2016; Müller et al., 2007; Nisantzi et al., 2015; Shin et al., 2018). Mineral dust and other aerosol particle types can affect clouds and their microphysical properties and precipitation patterns by acting as cloud condensation nuclei (CCN) and ice nuclei (IN) (DeMott et al., 2003; Karydis et al., 2011). To this end, numerous studies have identified the complex interplay of aerosols and clouds (Morrison et al., 2005; Rosenfeld, 2018). Li et al. (2017) report that dust-mixed ice clouds have warmer cloud top temperatures (CTTs), suggesting their efficiency in acting as IN. Most recent studies, however, stress the complexity of dust in the IN mechanism and its relative effectiveness in different geographic locations (Ansmann et al., 2009; Coopman et al., 2018; Filioglou et al., 2019; Zamora et al., 2017). The complexity of dust particles also becomes evident when comparing observations from remote sensing instruments with modelled dust properties (Binietoglou et al., 2015). Modelling the dust shape and further calculating its optical properties such as dust optical depth rely among others on approximations of the sphericity of the dust particles and assumptions about the contribution of non-dust particles together with vertical dust height information (Dubovik et al., 2002; Hoshuyaripur et al., 2019). Accurate knowledge of the dust optical properties and their spatial distribution in regional and vertical scales is, therefore, a step towards a more realistic understanding of the climatic forcing impact of this component.

The Middle East and the Arabian Peninsula form one of the major source areas of mineral dust particles, together with northern Africa. Although this region is key to improving the understanding of the climate impact of mineral dust, very few measurement campaigns have been conducted and continuous aerosol observations are scarce in the area. In addition to being one of the world’s largest sources of mineral dust, the Arabian Peninsula is also a large emitter of anthropogenic pollution (Rushdi et al., 2017). The United Arab Emirates (UAE) is a crossroad for air masses originating from western and central Asia or from northern Africa (Wehbe et al., 2017). Local emission of mineral dust is also abundant in this area. Regarding anthropogenic pollution, ever-growing energy demand has increased CO₂ emissions and other pollutants of anthropogenic origin over the past decade (Betancourt-Torcat and Almansoori, 2015; Ukho et al., 2018), with adverse health effects (Li et al., 2010). These varying aerosol sources make the UAE an interesting area to study aerosol particles, and, in particular, dust properties.

A few studies indicate that long-range transported dust from the Middle East exhibits different optical properties to that of Saharan origin (Hofer et al., 2017; Mamouri et al., 2013; Müller et al., 2007; Nisantzi et al., 2015). The lidar ratio is a parameter commonly used in lidar-based aerosol typing algorithms to classify the particles within an atmospheric layer (Nicolaes et al., 2018; Papagiannopoulos et al., 2018). This parameter is also critical for elastic lidar retrievals and separation techniques (e.g. Giannakaki et al., 2020, and references therein). Within the European Aerosol Research Lidar Network (EARLINET, Pappalardo et al., 2014), stations are typically affected by dust outbreaks originating from the Saharan region. Amiridis et al. (2013) retrieved Saharan dust lidar ratios at 532 nm of 58 ± 8 sr, while a mean (range) value considering all EARLINET stations is 51 ± 10 sr (30–80 sr), at the same wavelength (Papagiannopoulos et al., 2016). Currently, a mean value of 55 sr is used for dust-related applications (e.g. Tesche et al., 2009). By contrast, the aerosol classification scheme from the satellite-based lidar onboard CALIPSO (Vaughan et al., 2009) uses a lidar ratio for pure dust of 44 ± 9 sr (Kim et al., 2018). Nevertheless, neither approach considers the origins of the dust, which translates into different optical characteristics.

To shed further light on atmospheric aerosol properties in the UAE region, a 1-year long field campaign was conducted from March 2018 to February 2019. The measurement campaign focused on the characterization of the geometrical and optical properties of atmospheric aerosol particles and their interaction with the regional/local meteorology and cloud precipitation patterns under different atmospheric conditions. With less than 100 mm of annual rainfall (Wehbe et al., 2017), precipitation enhancement techniques such as cloud seeding (French et al., 2018; Vonnegut and Chessin, 1971) have been implemented within the UAE’s strategy for tackling water shortages in the region. This approach requires accurate understanding of local/regional meteorology, detailed characterization of the background aerosol particles and their efficiency in acting as CCN/IN, and the complex interplay between aerosol, clouds, and meteorology. Therefore, the Optimization of Aerosol Seeding In rain enhancement Strategies (OASIS) project aimed towards a more robust knowledge of the efficiency of the aerosol particles in acting as CCN/IN in a challenging environment. A multi-instrument approach was used for this purpose, including...
both in situ and remote sensing sensors along with model simulations. In this paper, we will focus on the characterization of the aerosol properties over the measurement site. Observations of a multi-wavelength Raman lidar with water vapour capability were used along with air mass back-trajectories calculated from the Hybrid Single Particle Lagrangian Integrated Trajectory (HySPLIT) model (Stein et al., 2015) in order to identify and classify the aerosol layers during the campaign period. Moreover, the optical properties of the Arabian Peninsula have been characterized.

2 Methodology

2.1 The measurement site

Between March 2018 and February 2019 the OASIS campaign was established at a palm plantation located 10 km south-west of Al Dhaid, in the emirate of Sharjah in the UAE (25°14′7.8″ N, 55°58′39.97″ E; 165 m a.s.l.). This rural site is located in a desert area about 70 km north-east from Dubai and the Arabian Gulf, where oil extraction and shipping activities are situated. To the east, the site faces a mountainous area whose altitude ranges from 1 to 2.1 km and the sea (Gulf of Oman and Arabian Sea, respectively) (Fig. 1a). In principle, the measurement site receives dust from three different sources. To the north, including Iraq and the surrounding countries, is a region with several sources of dust, and the sediment surface may contain sand deposits with particle sizes which are easily lofted by winds. In fact, it is the largest source of aeolian dust in the Arabian Gulf. Northeast in Iran and Pakistan are regions responsible for dust and sandstorms in Asia. Lastly, Saudi Arabia and the Arabian Peninsula provide the third major dust source with multiple terrain types. Towards the western side from the measurement location, mountains up to 2.5 km form a natural barrier between this region and the Red Sea. The region itself can be considered a fourth dust source where dust can be emitted locally due to thermal lows, unstable conditions, or human activities. Anthropogenic pollution is also present in the greater area, where oil and gas extraction activities add up to the man-made aerosol particulate burden from the cities. The aerosol optical depth (AOD) at 500 nm in the region varies between 0.4 and 0.5 (Eck et al., 2008), where the contribution of mineral dust particles can be 60 %–70 % even in urban areas (Roshan et al., 2019). Figure 1b shows the air mass backward trajectory cluster analysis, computed with HySPLIT (Stein et al., 2015; see Sect. 2.3), and their frequency over the course of the campaign period. The aforementioned aerosol sources can be viewed at the location of the backward trajectory paths.

2.2 The multi-wavelength Raman lidar FMI–Polly\textsuperscript{XT}

The FMI–Polly\textsuperscript{XT} lidar is a fully automated instrument capable of 24/7 operation (Engelmann et al., 2016). It is equipped with three elastic backscatter channels at 355, 532, and 1064 nm, two rotational–vibrational Raman channels at 387 and 607 nm, two linear depolarization channels at 355 and 532 nm, and one water vapour detection channel at 407 nm. In addition to the far-field capabilities, the system includes two near-field elastic backscatter channels at 355 and 532 nm and two near-field rotational–vibrational Raman channels at 387 and 607 nm. Due to the near-field capability, full overlap is attained at around 120 m. Data are acquired with a vertical resolution of 7.5 m in temporal steps of 30 s.

The lidar has been employed under various campaigns and locations over the course of years. Among others, two long-term aerosol experimental campaigns at Gual Pahari, India (Komppula et al., 2012), and Elandsfontein, South Africa (Giannakaki et al., 2015, 2016; Korhonen et al., 2014), and at the permanent measurement site in Vehmäsmäki, Finland (Bohlmann et al., 2019; Filioglou et al., 2017), have been conducted. The system is also part of the Finnish lidar network (Hirsikko et al., 2014), EARLINET (Bösenberg et al., 2003; Pappalardo et al., 2014), and PollyNET (Baars et al., 2016), which is an independent Raman and polarization lidar network where measurements from all member stations are visualized through “quick looks”, publicly available on the web page of PollyNET (http://polly.tropos.de, last access: 22 July 2020).

2.3 Processing of lidar observations

For the analysis presented, two aerosol profiles were retrieved per day using the Raman method (Ansmann et al., 1990, 1992; Whiteman, 2003) at 01:00 and 20:00 UTC in order to derive all possible optical properties minimizing the assumptions in the retrievals. The 2 h average profiles were further processed by detecting intensive aerosol layers and isolating them from air segments containing very low aerosol particle burden. We should note here that, at this point, cloud-contaminated height bins were already excluded from the signal. For the automatic detection of the aerosol particle layers we used the second derivative of the backscatter profiles at 1064 nm. Detected aerosol layers with geometrical depths less than 50 m were discarded. In total 1130 high-quality aerosol particle layers were detected during the campaign period. We considered high-quality aerosol layers to be the ones which (a) were not affected by clouds, (b) exhibited lidar ratios between 5 and 150 sr, (c) had a linear particle depolarization ratio between 0 % and 40 %, and (d) had Ångström exponents between −1.1 and 3. The geometrical boundaries of the aerosol particle layers were retrieved from a less vertically smoothed lidar profile (less than 400 m), as opposed to the optical properties, which were retrieved by applying higher smoothing (case-dependent). By applying less smoothing to the signals, we were able to appoint correct geometrical depths and boundaries of these layers, while the higher smoothing assigned meaningful optical properties. Mean values of all the available optical properties, i.e. backscatter ($\beta$)

https://doi.org/10.5194/acp-20-8909-2020 Atmos. Chem. Phys., 20, 8909–8922, 2020
and extinction ($\alpha$) coefficients, lidar ratios (LRs), Ångström exponents (AE for the extinction-related and BAE for the backscatter-related Ångströms), colour ratios (CRs), linear particle depolarization ratios ($\delta_p$), and AODs, were then calculated for each of the layers, along with their geometrical properties (depth and centre mass). For the mean optical properties, only regions where the extensive aerosol properties (backscatter and extinction coefficients) were nearly constant were considered. This means that within the defined layer, the variability of the optical properties should be less than the statistical uncertainty of the individual data points. On top of that, aerosol layers were further eliminated if minimum backscatter thresholds were not met (0.25, 0.10, and 0.05 Mm$^{-1}$ sr$^{-1}$ for 355, 532, and 1064 nm, respectively) A 5 d backward trajectory analysis at the centre mass of each of the aerosol layers was also computed using HySPLIT in order to assess the origin of the detected aerosol particle layers. The timestamp used for the trajectories was the centred 2 h lidar retrieval.

2.4 Microanalysis of the collected dust particles

To aid the findings in Sect. 3.3 where we retrieve the optical properties of the Arabian dust particles, we have collected two soil samples from the surrounding region. The samples were dry collected, accounting for both microphysical (colour of the soil) and regional discrepancies; one sample was close to the observation site and the other one a few tens of kilometres away. Two particle distributions were studied to reveal physicochemical properties of gathered particles, i.e. size, morphology, and composition. In order to analyse the chemical composition of the particles, energy dispersive X-ray spectroscopy (EDX, Thermo Pathfinder 1.4, Thermo Fisher Scientific, Madison, WI, USA) was used in synergy with a scanning electron microscope (SEM, Zeiss SigmaHD/VP, Carl Zeiss NTS, Cambridge, UK) which was used to observe the morphology of the dust particles. For this, dust samples were attached on a standard 12 mm aluminium stub for SEM specimens using a piece of double-sided carbon adhesive tape. The SEM imaging was executed without any sputter coating in a low-vacuum (Zeiss Variable Pressure mode) nitrogen atmosphere at 30 Pa pressure using 15 kV acceleration voltage, a variable pressure secondary electron (VPSE) detector, and a working distance of 15 mm. The elemental composition for individual particles was obtained using EDX mapping. The chemical analysis and two SEM images can be found in Appendix A.

3 Results

3.1 Geometrical properties and aerosol optical depths of aerosol particle layers

Altogether 1130 night-time aerosol particle layers were analysed throughout the campaign period in order to characterize the background aerosol properties over the measurement site. The time series of the geometrical extent of the retrieved aerosol particle layers showed up to seven simultaneous lay-
ers (Fig. 2). Indeed, as observed in the dataset, frequent multiple aerosol particle layer structures were present most of the time, with single layers mostly occurring during December and January. In fact, only 10% of the cases had a single aerosol layer present, with two (30%), three (29%), or even more simultaneous layers (31%). The multiple aerosol particle layers result from gravitational waves generated by the sea breeze passing over the mountains, stratifying the atmosphere over the measurement site. The gaps in the dataset during May to August and between September and November were due to instrumental malfunction, mainly failure of the cooling unit of the system while performing under such demanding conditions where maximum ambient temperatures up to 51 °C were measured.

Geometrical features of the aerosol particle layers are further characterized by frequency distributions (Fig. 3). Up to 61% of the layers identified were located below 2.5 km in altitude, with a few layers reaching as high as 11 km. The geometrical depths of the layers varied from a few hundred metres to several kilometres throughout the period. Most commonly (58% of the cases) the geometrical depth varied between 0.4 and 0.8 m.

In order to define the geometrical boundaries of the aerosol particle layers in the free troposphere (FT) and the planetary boundary layer (BL), we determined the top height of the BL using the methodology described in Baars et al. (2008). The night-time BL over the measurement site ranged between 0.35 and 1.2 km, while the mean top of the mixed layer height during daytime was at 2.0 ± 0.3 km (not shown here). It should be noted that the observed night-time lidar BL height is expected to depict, apart from any mechanically driven layer during the stable and transition periods, the top of the residual layer from the previous day. The rather low in altitude, daytime BL is suppressed by several limiting factors: (1) the frequent high-pressure system in the region, (2) gravitational waves, (3) low wind speeds, and (4) very dry air, which altogether limit convection. The gravitational waves define the horizontal transport of air and limit the growth of the BL to higher altitudes. In total, 844 FT aerosol particle layers were observed, and 286 BL layers. To have a better insight into the time variation of the aerosol particle layers, Fig. 4 presents the monthly geometrical and aerosol optical depth characteristics of aerosol layers located at the BL and FT. Figure 4a corresponds to the centre of mass of the detected aerosol layers at the BL (red) and FT (green). While there is a very persistent night-time BL with a top height at 1 km or so throughout the measurement year, the aerosol layers located at the FT show seasonality. The FT aerosol particle layers extend to higher altitudes during the warmer months (April–August) and have a minimum height during November–December. Regarding their average geometrical depth (Fig. 4b), both BL and FT aerosol layers exhibit similar characteristics. The geometrical depth is calculated from the aerosol layer boundaries (top/bottom) in which the subtraction of these boundaries results in the actual geometrical thickness of the corresponding aerosol layers.

The optical depths of BL and FT aerosol layers at 355 nm wavelength and their contribution to the total layer AOD are shown in Fig. 4c–d. Similar conclusions are valid for AOD at the 532 nm wavelength, which is not shown here but is discussed in the paper. The optical depths were determined by integrating the layer aerosol extinction coefficient at 355 and 532 nm. For the first layer, where the overlap is incomplete, we assumed that the extinction coefficient value at the lowest trustworthy bin is representative for the values down to the surface to account for the incomplete overlap region. The highest-layer AODs were measured during the summer months and the lowest values during November and
Note that the marking of the month in the table indicates the average aerosol properties along with 1 standard deviation. Figure 5 shows the time series of intensive (lidar ratios, linear particle depolarization ratio) and extensive (backscatter-related Ångström exponents) aerosol properties of the retrieved aerosol layers over the site, frequently a mixture of mineral dust (dominant over the site, occasionally strong dust storms) with anthropogenic and/or marine aerosol presence. The dust events take place mainly between March and August when enhanced shamal conditions cause an increase in the probability of dust suspension and dust storms. Average Ångström exponents of 2.5 ± 1.9, 2.1 ± 1.9, and 1.6 ± 1.6 Mm−1 sr−1 for 355, 532, and 1064 nm were observed, respectively. During strong dust events, Ångström exponents values up to 19.7 (18.5, 16.4) Mm−1 sr−1 at 355 (532, 1064) nm and Å values of 800 (774) Mm−1 sr−1 at 355 (532) nm were measured (not shown in the figure). In general, the intensive optical properties exhibit similar characteristics with little variation throughout the year apart from the period from mid-November to January. During the winter season increased LR values related to bigger Ångström exponents and lower linear particle depolarization values indicate a greater share of anthropogenic pollution in the aerosol particle mixture compared to other seasons.

Histograms of the aforementioned optical properties are presented in Fig. 6. In the same figure, the statistical distribution is also presented with box and whisker plots. For 40 (35) % of the cases, the LR at 355 (532) nm ranged between 35 and 45 sr, while the second most frequent LR range was 45–55 (25–35) sr for 355 (532) nm, representing 27 (25) % of the cases. Furthermore, less than 12 % of the cases exhibited δp ≥ 27 %, indicating the complexity of the aerosol type over the site, frequently a mixture of mineral dust (dominant aerosol) with anthropogenic and/or marine aerosol presence. This is also consistent with the backscatter-related Ångström.
Figure 7. Height-dependent aerosol properties for 0–1, 1–2, 2–3, 3–4, and > 5 km altitude. (a) Backscatter coefficient at 355 nm (blue), 532 nm (green), and 1064 nm (red). (b) Extinction coefficient at 355 nm and 532 nm. (c) Lidar ratio at 355 nm and 532 nm. (d) Linear particle depolarization ratio at 355 nm and 532 nm. (e) Extinction-related Ångström exponent (AE) at 355/532, backscatter-related Ångström exponent (BAE1) at 355/532, and backscatter-related Ångström exponent (BAE2) at 532/1064.

In order to reveal height-dependent aerosol particle properties, we have further divided the atmosphere into five altitude ranges (0–1, 1–2, 2–3, 3–4, and > 5 km) and grouped the aerosol properties contained in each altitude segment (Fig. 7). As expected, the β and α coefficients decreased with increasing altitude. In contrast, LRs showed rather constant behaviour up to 5 km, suggesting similar aerosol mixtures throughout these altitude ranges. Interestingly, δp at 532 nm wavelength increased or remained constant with altitude except for aerosol layers above 5 km. This behaviour was seen at 355 nm wavelength up to 2 km, but δp then decreased with altitude above 2 km. The most plausible explanation is that up to 2 km or so the night-time residual layers contain mixtures of mineral dust and anthropogenic pollution or/marine aerosols resulting in lower linear particle depolarization values. The mean relative humidity of these aerosol layers is much less than 60 % for 82 % of the cases; hence, hygroscopicity effects can be excluded. Ångström exponents increasing with altitude show the height-dependent nature of the aerosol size distribution (the higher the altitude, the smaller the particles).

3.3 Optical properties of Arabian dust

To characterize the properties of mineral dust over the region, we have selected the top decile of linear particle depolarization values in the dataset. We discarded cases when the path of a backward air mass trajectory passed over regions other than the Arabian Peninsula and the minimum height of the air mass over these regions was less than 3 km in altitude. The backward trajectories of the selected 46 cases are shown in Fig. 8a and the characteristic optical properties and the aerosol type-dependent optical properties in Fig. 8b–d for both 355 and 532 nm wavelengths, including 95 % confidence ellipsoids. Figure 8b–d also present the rest of the available aerosol layer optical properties apart from the ones defined as Arabian dust. We assume that cases with the highest linear depolarization ratios represent the pure Arabian dust optical properties since no volcanic aerosols are present over the measurement site at the given period. It is also evident from the scatter plots that the aerosol sources and types are varying; thus, no detailed conclusions can be made for the full dataset except the ones mentioned in previous sections. The mean values of the Arabian dust optical properties are further reported in Table 1 along with literature values. The mean altitude of these layers was 1.8 ± 0.9 km; in 73 % of the cases the centre mass of the layer was located above 1 km, excluding the one well-mixed with anthropogenic or/marine pollution night-time BL. The retrieved dust aerosol properties over the region concerning the
lidar ratios fluctuated between 35(34) and 55(54) sr with a mean value of 45 ± 5 (42 ± 5) sr at 355 (532) nm. The values ranged between 22 (29) and 32 (35) % with an average value of 25 ± 2 (31 ± 2) % for the linear particle depolarization ratio at 355 (532) nm and 0.3 ± 0.2 (0.2 ± 0.2, 0.3 ± 0.1) for the extinction-related Ångström exponent (backscatter-related Ångström exponent at 355/532 and 532/1064). The ratio of LR532 fluctuated between 1.0 and 1.2. Moreover, we report on the ratio of backscatter coefficients known as the colour ratio (CR) between the 355/523, 355/1064, and 532/1064 wavelengths. This ratio is usually below 1 for aerosols and can be used in a simple aerosol/cloud detection scheme, but dust particles show ratios above 1, which complicates this rather simple and straightforward relationship. Note that in the literature the CR is retrieved interchangeably from bigger to smaller wavelength or the opposite. In this paper we calculated the CR as smaller to bigger wavelength selections.

To the authors’ knowledge, four earlier studies have attempted to characterize the properties of dust originating from the Arabian Peninsula using the lidar technique; however, the full properties of dust were not characterized, and particularly multi-wavelength optical properties and/or linear particle depolarization values have not been simultaneously defined. Müller et al. (2007), using lidar observations during INDOEX (Indian Ocean Experiment, Ramanathan et al., 2001), were the first to stress the lower LR values of free-tropospheric dust when originating from the Arabian Peninsula compared to that from the northern Sahara. However, the long-range transported Arabian dust (aged) in their study suggests smaller LR values and greater Ångström exponents than the ones reported here (Table 1). Similar conclusions were found by Mamouri et al. (2013) and Nisantzi et al. (2015), whose studies show a lower LR for the Arabian dust over a Mediterranean site in Cyprus than dust originating from the Saharan area, based on study cases (Table 1). A recent study by Hofer et al. (2017) using lidar observations in Tajikistan, central Asia, also reports on Middle East dust optical properties and comparisons of those to Asian dust. In the same direction, the study cases used over Dushanbe in Tajikistan show similar Arabian dust characteristics to those in the present study (see Table 1).

A few limited studies are also available for the characterization of the Arabian dust properties using sunphotometric observations. Sunphotometric observations are column-integrated values which often include the contribution of BL aerosols and the contribution of non-dust aerosols (smoke, marine and anthropogenic aerosols). Nevertheless, Schuster et al. (2012) report a mean LR of 43 sr at 532 nm with a 39 to 43 sr range. By contrast, Shin et al. (2018) result in higher LR values such as 54 ± 7 sr at 440 nm and 37 ± 4 sr at 670 nm. The reported linear particle depolarization ratios are 0.21 ± 0.03 % at 440 nm and 0.25 ± 0.03 % at 670 nm, whereas the Ångström exponent is 0.18 ± 0.10 at 440/870 nm.

Examining the reasons behind the different LR values in Arabian compared to African dust, previous studies related the optical characteristics to the chemical composition of the dust particles themselves. Numerous studies have analysed

samples from various regions exploring the mineralological composition of dust (Di Biagio et al., 2017; Egan and Hilgeman, 1979; Query, 1987; Sokolik and Toon, 1999). Schuster et al. (2012) linked the LR behaviour of dust to the percentage of illite in the soil. Clay minerals and specifically the content of illite (a K-rich argillaceous component of sedimentary rocks) in the dust define the real refractive index which strongly influences LR. Since the real refractive index, which is determined by the mineralogical composition of dust, defines the lidar ratio, an aerosol-type parameter, it is expected that different dust types would exhibit different optical characteristics. Lower content of illite signifies lower LR compared to, for example, higher content of illite in Saharan soils, which results in the somewhat higher real refractive index. The real refractive index of dust from the Arabian Peninsula is 1.50 and for Saharan dust the corresponding value is 1.54 (Di Biagio et al., 2017; Kim et al., 2011; Schuster et al., 2012). Moreover, the study of Di Biagio et al. (2019) reports that the imaginary part of the refractive index in dust samples originating from Saudi Arabia scores less than that of African dust, presenting a lower absorbing efficiency compared to African dust. The difference is attributed to the content of iron oxides in the dust. In this direction, we have collected two different dust samples from the area around the measurement site and further retrieved SEM images and performed elemental analysis (see Appendix A). Comparable to previous studies mentioned above, the fraction of a K-rich argillaceous component of sedimentary rocks was well below 5.5% in the collected dust samples. Regarding the absorption properties of dust, it has been found that dust optical properties are more correlated with the fraction of iron oxides than the iron content itself. Nevertheless, the iron content in the collected dust samples was lower than that recorded in African dust (Di Biagio et al., 2019).

4 Summary and conclusions

One year of ground-based night-time lidar observations was analysed in synergy with backward air mass trajectories in order to characterize the seasonal variability of the background aerosol particle properties in a – heavy dust and anthropogenically polluted – region in the United Arab Emirates (UAE). Our analysis suggests that aerosol particle populations over the UAE are sensitive to transport from Saudi Arabia, Iran, and Iraq but also from local sources. Two seasons exist in this area, summer and winter, where the main difference is the higher wind speeds between March and August compared to the rest of the year. The AOD was positively correlated with the season, with maximum values being observed in the warmest months, June to August, resulting from the increased probability of dust suspension and dust storms. Multiple aerosol layers were present in the majority of identified cases, except during November–December; for 58% of the cases the geometrical depth ranged between 0.4 and 0.8 km. The geometrical properties are determined by large-scale pressure systems over the region as well as gravitational waves introduced by local and regional topography. Regarding the optical properties, Ångström exponent values increased with altitude, indicating the incapacity of bigger aerosols to reach higher up in the atmosphere. Lidar ratios were almost constant up to 5 km, with mean values of 43 ± 11 sr at 355 nm and 39 ± 10 sr at 532 nm. The linear particle depolarization, $\delta_p$, at 532 nm (355 nm), however, increased with altitude up to 3 km (2 km). The most probable explanation is that up to 2 km or so, night-time residual layers contain mixtures of mineral dust and urban-marine aerosols resulting in lower linear particle depolarization values. Higher up the linear particle depolarization decreases; the aerosol particles at higher altitudes are usually long-range transported, and while aging in the atmosphere they become more spherical.

The Arabian Peninsula is a major contributor of airborne dust, yet very few studies have been made in order to characterize the pure dust optical properties of the region. To our knowledge this study is the first long-term one reporting the complete lidar-based optical characteristics of the Arabian dust. The FMI–PollyXT Raman lidar enabled the provision of lidar ratios and linear particle depolarization ratios at two wavelengths (355, 532 nm), giving us the possibility of an answer to wavelength-dependent dust properties. The observed dust particle properties over the region regarding the lidar ratio amounted to 45 ± 5 sr at 355 nm and 42 ± 5 sr at 532 nm wavelength. Linear particle depolarization ratios of 25 ± 2% (31 ± 2%) were observed at 355 (532) nm, and 0.3 ± 0.2 (0.2 ± 0.2) values were retrieved for the extinction-related Ångström exponent (backscatter-related Ångström exponent) at 355/532. The findings of this study suggest that the pure dust properties over the Middle East and western Asia, including the observation site, are comparable to those of African mineral dust regarding the linear particle depolarization ratios, but not for the lidar ratios. The lower lidar ratio values are attributed to the different geochemical characteristics of soil, with Arabian dust having lower K-rich values in the dust mixture, a component which determines the real refractive index of the dust and lower absorbing efficiency than that of Saharan dust which is attributed to the iron content. These findings propose that the use of a lidar ratio value for dust aerosol particles should consider the origin of the dust itself, otherwise biased results can be anticipated, for example in satellite or ground-based extinction and aerosol typing retrievals as well as separation methods of a lidar signal into its aerosol components. This becomes evident in stations where they are receptors of both Arabian and Saharan dust and the selection of adequate dust optical parameters is important for further analysis. In turn, all the aforementioned products are usually the basic input for advanced methodologies such as the retrieval of CCN/IN concentrations from lidar observations.

Data availability. The data used in this work are available upon request.

Author contributions. MF, MK and EG conceptualized and finalized the methodology. MF and MK were responsible for the lidar data and collection of the dust samples; RE and XS helped with the upkeep of the data and troubleshooting of the instrument. JL analyzed the dust samples. MF performed the data analysis and wrote the paper. All the co-authors were involved in the paper editing, interpretation of the results, and discussion of the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This work was supported by the National Center of Meteorology, Abu Dhabi, UAE, under the UAE Research Program for Rain Enhancement Science. The authors are grateful to the NOAA Air Resources Laboratory (ARL) for the provision of the HySPLIT transport and dispersion model used in this publication. The EM facility of SIB Labs at the University of Eastern Finland is thanked for providing their SEM and EDX equipment to the study. We would also like to thank Timo Anttila and Siddharth Tampi for providing on-site technical support.

Financial support. This research has been supported by the H2020 European Research Council (ECLAIR, grant no. 646857) and the Academy of Finland, Biotieteiden ja Ympäristön Tutkimuksen Toimikunta (grant no. 270108).

Review statement. This paper was edited by Stelios Kazadzis and reviewed by three anonymous referees.
