**Abstract.** Snowfall in the northeastern part of South Korea is the result of complex snowfall mechanisms due to a highly contrasting terrain combined with nearby warm waters and three synoptic pressure patterns. All these factors together create unique combinations, whose disentangling can provide new insights into the microphysics of snow on the planet. This study focuses on the impact of wind flow and topography on the microphysics drawing of 20 snowfall events during the ICE-POP 2018 (International Collaborative Experiment for PyeongChang 2018 Olympic and Paralympic winter games) field campaign in the Gangwon region. The vertical structure of precipitation and size distribution characteristics are investigated with collocated MRR (micro rain radar) and PARSIVEL (particle size velocity) disdrometers installed across the mountain range. The results indicate that wind shear and embedded turbulence were the cause of the riming process dominating the mountainous region. As the strength of these processes weakens from the mountainous region to the coastal region, riming became less significant and gave way to aggregation. This study specifically analyzes the microphysical characteristics under three major synoptic patterns: air–sea interaction, cold low, and warm low. Air–sea interaction pattern is characterized by more frequent snowfall and vertically deeper precipitation systems on the wind-

ward side, resulting in significant aggregation in the coastal region, with riming featuring as a primary growth mechanism in both mountainous and coastal regions. The cold-low pattern is characterized by a higher snowfall rate and vertically deep systems in the mountainous region, with the precipitation system becoming shallower in the coastal region and strong turbulence being found in the layer below 2 km in the mountainous upstream region (linked with dominant aggregation). The warm-low pattern features the deepest system: precipitation here is enhanced by the seeder–feeder mechanism with two different precipitation systems divided by the transition zone (easterly below and westerly above). Overall, it is found that strong shear and turbulence in the transition zone is a likely reason for the dominant riming process in the mountainous region, with aggregation being important in both mountainous and coastal regions.

## 1 Introduction

Understanding the developing mechanism of heavy snowfall in the eastern part of the Korean Peninsula (Gangwon region) could have a great impact on improving the accuracy of fore-

casts in winter. The snowfall in this region is known to be characterized by strong orographic effects due to complex terrain in the west (Taebaek Mountains) and by the air-mass transformation in the nearby ocean in the east (East Sea). The orographic enhancement and sea effect induce heavy snowfall in this region (Chung et al., 2004; Cheong et al., 2006; Cho and Kwon, 2012; Jung et al., 2012, 2014). The complexity of the snowfall mechanism arises from the steepness of terrain from the Taebaek Mountains to the ocean (horizontal distance of about 20 km and vertical heights of 1000–2000 m) in combination with air-mass transformation over the warm ocean. Thus, complex airflows of this region affect microphysics, in particular the snow growth process above the melting layer.

The details of the interactions between airflows and microphysical processes have been partially investigated in the past. Indeed, it is well recognized that the dynamics associated with the shear have important implications for two primary snow growth processes (i.e., aggregation and riming). Under strong shear conditions, the turbulent cell and induced updraft are favored, being responsible for the production of a considerable amount of supercooled water that promotes both aggregation and riming as they increase the probability of collision between hydrometeors, in particular, snowflakes and supercooled water droplets (Houze and Medina, 2005; Barnes et al., 2018). Colle et al. (2014) also investigated the relationship between degree of riming and radar measurables (Doppler radial velocity, spectrum width, etc) from vertically pointing radar and determined the degree of riming every 15–30 min for 12 cyclone events. They reported turbulent motions and strong updrafts and downdrafts in heavy riming events. Further insight into the role of the warm conveyor belt and its dynamics on the snow microphysics in the Gangwon region was provided by Gehring et al. (2020), who argued that ascents in the warm conveyor belt contributed to persisting production of supercooled liquid water and that the process enhances the riming process during extreme snowfall events.

The mean airflow governed by the synoptic patterns controls snowfall in the region. Numerous studies have reported that favorable synoptic conditions for heavy snowfall are the eastern expansion of Siberian high pressure and a cyclone passing through the central or southern part of the Korean Peninsula (Lee and Kim, 2008; Park et al., 2009; Jung et al., 2012; Cho and Chang, 2017; J. Kim et al., 2019). The eastern expansion of Siberian high pressure (the so-called “Kaema high pressure”) is responsible for snowstorms by air-mass transformation, which is induced by cold easterly or northeasterly flow over the East Sea. Sea-effect snow (Estoque and Ninomiya, 1976; Nakamura and Asai, 1985; Ikeda et al., 2009; Kindap, 2010; Nam et al., 2014; Bao and Ren, 2018; Steenburgh and Nakai, 2020) is the same kind of mesoscale precipitation caused by the air-mass transformation of cold air over warm ocean. It develops over the East Sea and affects downstream of the wind flow. This mechanism is not greatly

different to the lake-effect snow (Laird et al., 2009; Minder et al., 2015; Kristovich et al., 2017; Wiley and Mercer, 2020) except in that the source of moisture and heat fluxes is here the ocean and not a lake.

It is also known that low-pressure systems passing through the southern part of the Korean Peninsula support the easterly or northeasterly flow over the East Sea in the later part of the low-pressure passage and supply abundant moisture from the Southern Ocean, leading to heavier snowfall (Seo and Jhun, 1991; Park et al., 2009; Gehring et al., 2020). Song et al. (2016) classified the synoptic environments when Siberian highs expand eastward with and without low-pressure systems. They showed that the mean precipitation amount increased by about 45 % in the presence of both Kaema high and low pressure.

The complex and steep orography of the Taebaek Mountain ranges is another important factor for both the dynamics and the precipitation system (amount, distribution, and duration). The orographic effect on airflow and precipitation is difficult to characterize because of the many different mechanisms, as many as 20, following Houze (2012). Yu et al. (2007) also pointed out that multiple precipitation cells produced by different mechanisms can appear simultaneously in complex terrain.

Previous studies on the impact of the Taebaek Mountains in the precipitation systems were carried out mainly by numerical simulation. Lee and Kim (2008) examined the effect of the Taebaek Mountains on the distribution and intensity of snowfall by removing their topography in numerical experiments. They showed that, with the mountains, updraft is strengthened from 0.2 to  $1.2 \text{ m s}^{-1}$ , and the accumulated precipitation amount increases 8.5 times more in mountainous areas than the experiment without mountains. They also found that a topographic blocking by the Taebaek Mountains causes horizontal convergence and stronger updraft along the coastal region, resulting in heavy snowfall. Lee and Lee (2003) also investigated the effect of the Taebaek Mountains by numerical simulation for two heavy snowfall events. They reported that the Froude number, which can represent the blocking degree, is important to determine whether the precipitation amount is more in the coastal region or in the mountainous region. An insufficient Froude number favors an occurrence of convergence between blocked and environmental flow and a shift in maximum precipitation to the coastal area (Ohigashi et al., 2014; Veals et al., 2020). On the other hand, when the Froude number is large enough, the maximum precipitation tends to occur over the mountainous or inland area (Veals et al., 2020).

It is also known that the wind flow plays a critical role in the precipitation patterns of this region. In particular, easterly flow or northeasterly (or sometimes northerly) flow is thought to be necessary for the development of heavy snowfall (Nam et al., 2014; Cho and Chang, 2017; Tsai et al., 2018; J. Kim et al., 2019). The term Korea easterlies (Kor’easterlies hereafter) was proposed by Park and Park

(2020) to emphasize the unique features of the easterly flow in the East Sea, which bring sufficient moisture and interact with topography. In relation to the Taebaek Mountains, the Kor'easterlies can be interpreted as a cross-barrier flow. The higher cross-barrier wind speed tends to have a stronger precipitation rate (Veals et al., 2019). The observation-based study of the evolutions of wind flow and precipitation in this region was carried out by Tsai et al. (2018). They used a three-dimensional high-resolution wind field retrieved from six Doppler radars and found that a small temporary change in direction or speed of cross-barrier flow can considerably affect the distribution and intensity of precipitation. Y.-J. Kim et al. (2019) discussed whether it is possible to determine precipitation over the Gangwon region only by synoptic pressure patterns and found that the synoptic pattern (eastward expansion of Siberian high) itself is not the only factor determining precipitation. They suggested that the wind speed of cross-barrier flow and thermal stability, which determine the Froude number, should be examined together with pressure patterns. Another interesting characteristic in this region led by the Kor'easterlies is cold-air damming in the eastern region of the mountain range (Bailey et al., 2003; Lee and Xue, 2013; Nam et al., 2020). As the Kor'easterlies are blocked and weakened by the mountain barrier, the flow favors their being turned into northwesterly along the barrier resulting from the weakened Coriolis force due to the disrupted balance between the Coriolis and pressure gradient force (Bailey et al., 2003; Lee and Xue, 2013). The air mass in the eastern region of the barrier then becomes cold, stable, and dense as cold air from the north is advected by the northwesterly and accumulated, which is referred to as cold-air damming. This cold-air damming creates a strong convergence zone, resulting in the thermal contrast between the dammed air and East Sea being intensified and the maximum precipitation shifted away from the Taebaek Mountains (Jung et al., 2012; Lee and Xue, 2013). The updraft can also be induced by low-level cold-air damming in coastal areas because its density is relatively higher than that of the air mass coming from the ocean (Tsai et al., 2018). It is also worth noting that when the layer with the Kor'easterlies is generated, we expect that a layer of obvious directional wind shear is located between the westerly flow aloft and the Kor'easterlies below. It implies that shear-generated turbulence may be present and contribute to some microphysical processes. In spite of these precedents, little research has been conducted in the area to examine the impact of the synoptic patterns and topography on the microphysical processes. One of the main reasons for this was the lack of systematic microphysical observations in this region (Nam et al., 2014). It is necessary to explore how the snow microphysical characteristics differ according to both synoptic patterns and terrain to fully understand winter precipitation in the Gangwon region. In spite of great efforts in previous studies, a comprehensive and intensive study had not been conducted

before 2016 due to the limited availability of intensive microphysical observations.

A field campaign named ICE-POP 2018 (International Collaborative Experiment for PyeongChang 2018 Olympic and Paralympic winter games) took place in the Gangwon region to address this issue (Gehring et al., 2020, 2021; Lim et al., 2020; Jeoung et al., 2020). The ICE-POP 2018, contributed to by 29 agencies from 12 countries, was a World Weather Research Programme (WWRP) of the World Meteorological Organization (WMO) and was led by the Korea Meteorological Administration (KMA). One of the main scientific goals of the field campaign was to understand the complex winter precipitation with intensive microphysical observations. For two winter seasons (2016–2017 and 2017–2018 winters), a dense observational network was operated ranging from ground microphysical instruments to remote sensing. The 2017–2018 winter added 19 additional sites operated as supersites. MRR (micro rain radar) and PARSIVEL (particle size velocity) instruments were located in selected locations both along the coastal line and crossing the Taebaek Mountains (parallel to the coastal line). Radiosondes were launched at high temporal resolution at more than eight sites in the Gangwon region during the field campaign. A microphysical study in the Gangwon region with this kind of observational network had not previously been carried out. Such unique comprehensive observations and datasets created during ICE-POP 2018 now enable progress towards a deeper understanding of the complex winter precipitation in the region.

The purpose of this paper is to elucidate the microphysical characteristics of snow in the Gangwon region in both different heights and surface by using MRR and PARSIVEL datasets obtained in the two winter seasons during the ICE-POP 2018 project. We analyze all the events that were jointly observed by both remote and in situ instrumentation. Such a combination makes the research unique in terms of the datasets and allows us to provide new results about the microphysics in the region. The article is organized as follows. Section 2 describes how observations were performed during ICE-POP 2018, the sites and instruments used for analysis, and how data were processed and analyzed. In Sect. 3, the three main synoptic conditions which were responsible for the heavy snowfall during ICE-POP 2018 are presented. In Sect. 4, the general microphysical characteristics of snow and the characteristics for each synoptic pattern are presented. The conclusions of this study (Sect. 5) transcend the cases presented and provide insights into the microphysics of snow.

## 2 Data and methodology

### 2.1 Experimental design

The ICE-POP 2018 field campaign employed 19 supersites, which include ground and remote sensing microphysical in-

struments, six fixed 3-hourly radiosounding sites (In et al., 2018), four mobile sounding sites including dropsonde from research aircraft (Jung et al., 2020) and radiosounding from mobile cars and the research ship *Gisang 1* (Choi et al., 2020), and two wind profilers in both coastal and mountainous areas (see Fig. 1). The supersites are designed to be aligned both along the coastal line (from the Sokcho regional weather office, SCW, to the Donghae regional weather office, DHW, site) and across (from the Gangneung–Wonju National University, GWU, to the PyeongChang observatory, PCO, site) the Taebaek Mountains. The PARSIVEL disdrometers had been deployed at all 19 supersites, as indicated as an open circle in Fig. 1b. The MRRs were collocated with the PARSIVEL disdrometers at 10 supersites (filled circle). We take advantage of the site design to investigate the vertical structure and size distribution of snow according to the topography (crossing the Taebaek Mountains), which is characterized by steep orography that rises abruptly from the coast to an altitude of 800 m (see Fig. 1b).

We selected five sites for the study with the criteria (1) being aligned in transect (dashed line in Fig. 1a) from a mountainous area to coastal area so that they capture the precipitation evolution and modification with the cross-barrier flow, (2) stable collection of data during the campaign, and (3) having a good environment for the observation (i.e., no taller trees or buildings near the MRR antenna and PARSIVEL). Based on the criteria, we selected YPO (Yongpyong Observatory; 37.6433° N, 128.6705° E; 772 m a.m.s.l.), MHS (Mayhills supersite; 37.6652° N, 128.6996° E; 789 m a.m.s.l.), CPO (Cloud Physics Observatory; 37.6870° N, 128.7188° E; 855 m a.m.s.l.), BKC (Bokwang-ri community center; 37.7382° N, 128.7586° E; 175 m a.m.s.l.), and GWU (37.7717° N, 128.8703° E; 36 m a.m.s.l.) from west to east. Three sites (YPO, MHS, and CPO) are located in mountainous regions (Yeongseo, PyeongChang county), and the others (BKC and GWU) are in coastal regions (Yeongdong, Gangneung city).

During the field campaign, 20 events were observed by collocated MRR and PARSIVEL at five sites (Table 1). The MRR and PARSIVEL measurements of a total of 374 h (15.6 d) were used to analyze the vertical structure and size distribution in the Gangwon region.

## 2.2 Instruments

This study analyzes measurements from MRR, which is the K-band (24.23 GHz) frequency-modulated continuous-wave (FM-CW) vertically pointing radar. MRRs were deployed at 10 sites in total during the field campaign (Petersen et al., 2018; Gatlin and Wingo, 2019). The MRR can provide vertical profiles of the equivalent reflectivity factor ( $Z_e$ ), mean Doppler velocity ( $V_D$ ), and the Doppler spectral width (SW). These variables are used to gather detailed information on the vertical structure of precipitation according to the observational sites.

The range (vertical) resolution of MRR is adjustable with 31 range steps. During the field experiment, an identical observational strategy was assigned to MRRs for each site. The time resolution was 10 s, and the range resolutions were 200 and 150 m for 2016–2017 and 2017–2018 winters, respectively.

Because this instrument was originally developed to observe liquid precipitation, it has been used for rain observation (Löffler-Mang et al., 1999; Yuter and Houze, 2003; Peters et al., 2005; Tokay et al., 2009; Adirosi et al., 2016). However, after Kneifel et al. (2011) and Maahn and Kollias (2012) showed that MRR can be utilized for snow observation, MRR started to be actively used in snow studies (Kristovich et al., 2017; Souverijns et al., 2017; Durán-Alarcón et al., 2019; Vignon et al., 2019). We applied the post-processing algorithm proposed by Maahn and Kollias (2012), which is suited to snow (or weak rain) measurement. This algorithm improves the sensitivity of MRR by enhancing noise level estimation and de-alias Doppler velocity. Unless this algorithm is applied to the MRR measurement, upward-moving particles will appear as very high Doppler velocity.

In addition to MRR, five laser-based optical disdrometers were utilized to see characteristics of size distribution on the ground. The PARSIVEL, manufactured by OTT Hydromet, provides the size and fall velocity of each hydrometeor at the ground (Löffler-Mang and Joss, 2000; Tapiador et al., 2010; Tokay et al., 2014). The measuring area of the instrument is 54 cm<sup>2</sup> (180 mm × 30 mm), and minimum observable size and fall velocity are 0.2 mm and 0.2 m s<sup>−1</sup>, respectively (Tapiador et al., 2010). The PARSIVELs used in the study were collocated with MRRs (Petersen et al., 2018; Petersen and Tokay, 2019) so that the size distribution of snow was obtained at each MRR site.

The PARSIVEL has been widely used in microphysical studies for solid particles (Yuter et al., 2006; Aikins et al., 2016; Pokharel et al., 2017) as well as for rain (Friedrich et al., 2016; Park et al., 2017). As documented in Friedrich et al. (2016), however, PARSIVEL can suffer from splashing of particles (observed as a small diameter with large fall velocity when particles fall on the head of the sensor) and margin fallers (observed as a faster velocity than true fall velocity when particles fall through the edge of the sampling area). Some limitations in measuring snow particles due to particle shape assumption are well described in Battaglia et al. (2010). To address these issues, we applied a quality control procedure that discards particles with a diameter of < 1 mm to avoid splashing and border effects (Yuter et al., 2006; Aikins et al., 2016). Further, particles with a fall velocity of above 1.4 times the empirical fall velocity of rain (Atlas et al., 1973) were removed. To eliminate rain data, we classified the major precipitation type every minute based on the precipitation type classification mask of Yuter et al. (2006). If the number of raindrops was greater than 40 % of the total

## 2.3 Methodology

between two winter seasons (200 and 150 m). We can thus compare the values of CFADs at each height between sites, which is a similar approach to that of Minder et al. (2015) except for the height interpolation. The lowest two range gates are discarded in order to avoid a near-field effect (Maahn and Kollias, 2012; Minder et al., 2015). The CFADs are constructed from 1.5 km a.m.s.l. height by considering the site height (maximum of 855 m) and the near-field effect.

The microphysical characteristics of snow at the ground level are analyzed by particle size distribution (PSD;  $N(D)$ ).

**Table 1.** Summary of events used in this study. The time is in UTC.

No.	Year	Synoptic pattern	Date and time [UTC]

from PARSIVEL, which is calculated as

$$N(D_i) = \sum_j \frac{N_{i,j}}{A v_{i,j} \Delta t \Delta D_i}, \tag{1}$$

where  $i$  and  $j$  are the index of the diameter and velocity channel, respectively;  $D_i$  is the diameter of  $i$ th diameter channel;  $N_{i,j}$  is the number of observed particles of the  $j$ th velocity bin in  $i$ th diameter bin;  $A$  is the horizontal measurement area ( $54\text{ cm}^2$ );  $v_{i,j}$  is the fall velocity of the  $j$ th velocity bin in  $i$ th diameter bin;  $\Delta t$  is the sampling time interval; and  $\Delta D_i$  is the width of  $i$ th diameter channel.

Generalized characteristic number concentration ( $N'_0$ ) and diameter ( $D'_m$ ) are calculated with third and fourth moments as follows (Testud et al., 2001; Lee et al., 2004; Bang et al., 2020):

$$N'_0 = \frac{M_3^5}{M_4^4}, \tag{2}$$

$$D'_m = \frac{M_4}{M_3}, \text{ and} \tag{3}$$

$$M_n = \sum_i N(D_i) D_i^n \Delta D_i, \tag{4}$$

where  $M_n$  is  $n$ th moment of particle size distribution in units of  $\text{m}^{-3}\text{ mm}^n$ . The  $N'_0$  and  $D'_m$  can represent the shape of particle size distribution. The parameter  $N'_0$  is proportional to the intercept parameter of an exponential PSD, and  $D'_m$  is the volume-weighted mean diameter (Lee et al., 2004). We

calculate generalized characteristic parameters every minute after the quality control process.

Snowfall rate (SR) is calculated from particle size distribution:

$$\text{SR} = \frac{\pi}{6\rho_w} \sum_i \frac{\rho(D_i) \sum_j N_{i,j} D_i^3}{A \Delta t}. \tag{5}$$

Here, the assumed density–size relationship was proposed by Brandes et al. (2007):

$$\rho(D) = 0.178 D^{-0.92}, \tag{6}$$

where  $\rho$  is the density of snow, and  $\rho_w$  is the density of liquid water.

### 3 Classification by synoptic patterns

The synoptic patterns are classified into three categories in our study: “air–sea interaction”, “warm low”, and “cold low” (Jeoung et al., 2020). The following sections describe each synoptic pattern in detail and explain how observed events are classified into three defined synoptic patterns.

#### 3.1 Air–sea interaction

The “air–sea interaction” pattern is related to the air-mass transformation by cold air and relatively warm ocean. This is known to be related to the synoptic condition of the Siberian

high pressure expanding eastward to the Kaema Plateau (i.e., Kaema high pressure), located in the northeastern part of the Korean Peninsula. The snowfall mechanism is air-mass transformation by warm ocean surface and cold-air outbreak. The precipitation system is initiated and developed by air-mass transformation over the East Sea, then propagates to inland areas due to Kor'easterlies and is intensified as it is lifted by steep topography. The precipitation pattern is known to be linked with the cross-barrier flow (Cheong et al., 2006). The precipitation intensifies as the cross-barrier flow is strengthened and dissipates as the cross-barrier flow is weakened when the pressure gradient is reduced, or the wind direction changes. Because the precipitation cannot go further west beyond where the Kor'easterlies can reach it, the precipitation area is restricted in the eastern area of the Korean Peninsula. The Gangwon region can frequently have precipitation of this type. According to Choi and Kim (2010), the occurrence of the snowfall events in Korea associated with expansion of Siberian high is 43.8 % for 36 years.

Previous studies have emphasized the importance of both synoptic and regional factors in the snowfall in this region (Nam et al., 2014; J. Kim et al., 2019). It has been shown that the correlation between the precipitation in this region and sea level pressure over the Kaema Plateau and Bering sea has intensified recently (after 1999) (Cho and Chang, 2017). Kwon et al. (2015) investigated low-level stratiform cloud associated with heavy snowfall and showed that it is mostly related to the expansion of Siberian high pressure with an air–sea temperature difference of 7–12 °C. Nam et al. (2014) reported a correlation of  $R = 0.67$  between the snowfall amount in coastal areas and temperature difference between 850 hPa and sea surface temperature (SST) over the East Sea. Kim and Jin (2016) emphasized the importance of SST as a source of the energy for the formation of air–sea interaction snowfall. Their results suggest that the warm SST anomalies in the East Sea result in heavy snowfall as the lower part of the air mass becomes warmer, which increases thermal instability and moisture. The role of low-level instability by cold-air outbreak and warm ocean in heavy snowfall was also highlighted by Lee et al. (2012). The strong surface heat fluxes produced by the East Sea are also known to be an important contributor to heavy snowfall in this region (Lee et al., 2018). Air–sea interaction pattern depends greatly on these factors.

Various terms have been used to refer to this synoptic pattern. It was referred to as air-mass transformation type (AT) in Cheong et al. (2006). It is also called east coast terrain effect type (TE) (Cheong et al., 2006) since a snowstorm of this type is likely to interact with the complex topography. On the other hand, Song et al. (2016) called it “cP high expansion” type or “cP high expansion type + trough” type, emphasizing the cold and dry air mass. It is also referred to as stagnation type (Ko et al., 2016) as is often related to an atmospheric blocking pattern (Rex, 1950).

One of the examples of weather chart and sounding of this pattern is shown in Fig. 2. The radiosonde is launched in a coastal area. The northeasterly wind is induced in the East Sea and eastern coastal region along with the eastward expansion of the Siberian high to the East Sea (Fig. 2a). A saturated layer is observed from the surface to 790 hPa, along with the northeasterly or easterly winds. This layer is responsible for the snowstorm by air–sea interaction. The layer is bounded to the altitude where the Kor'easterlies exist. A strong thermal-inversion layer is located from the height slightly higher than the upper boundary of the saturated layer to 650 hPa with dry and weak wind speed of less than  $5 \text{ m s}^{-1}$ . The easterly winds in the lower level then turn to northwesterly and westerly above the inversion layer, with a dry layer up to 500 hPa. Note that the saturated layer above 500 hPa is not a typical situation in this pattern and was not related to the snowfall in this event.

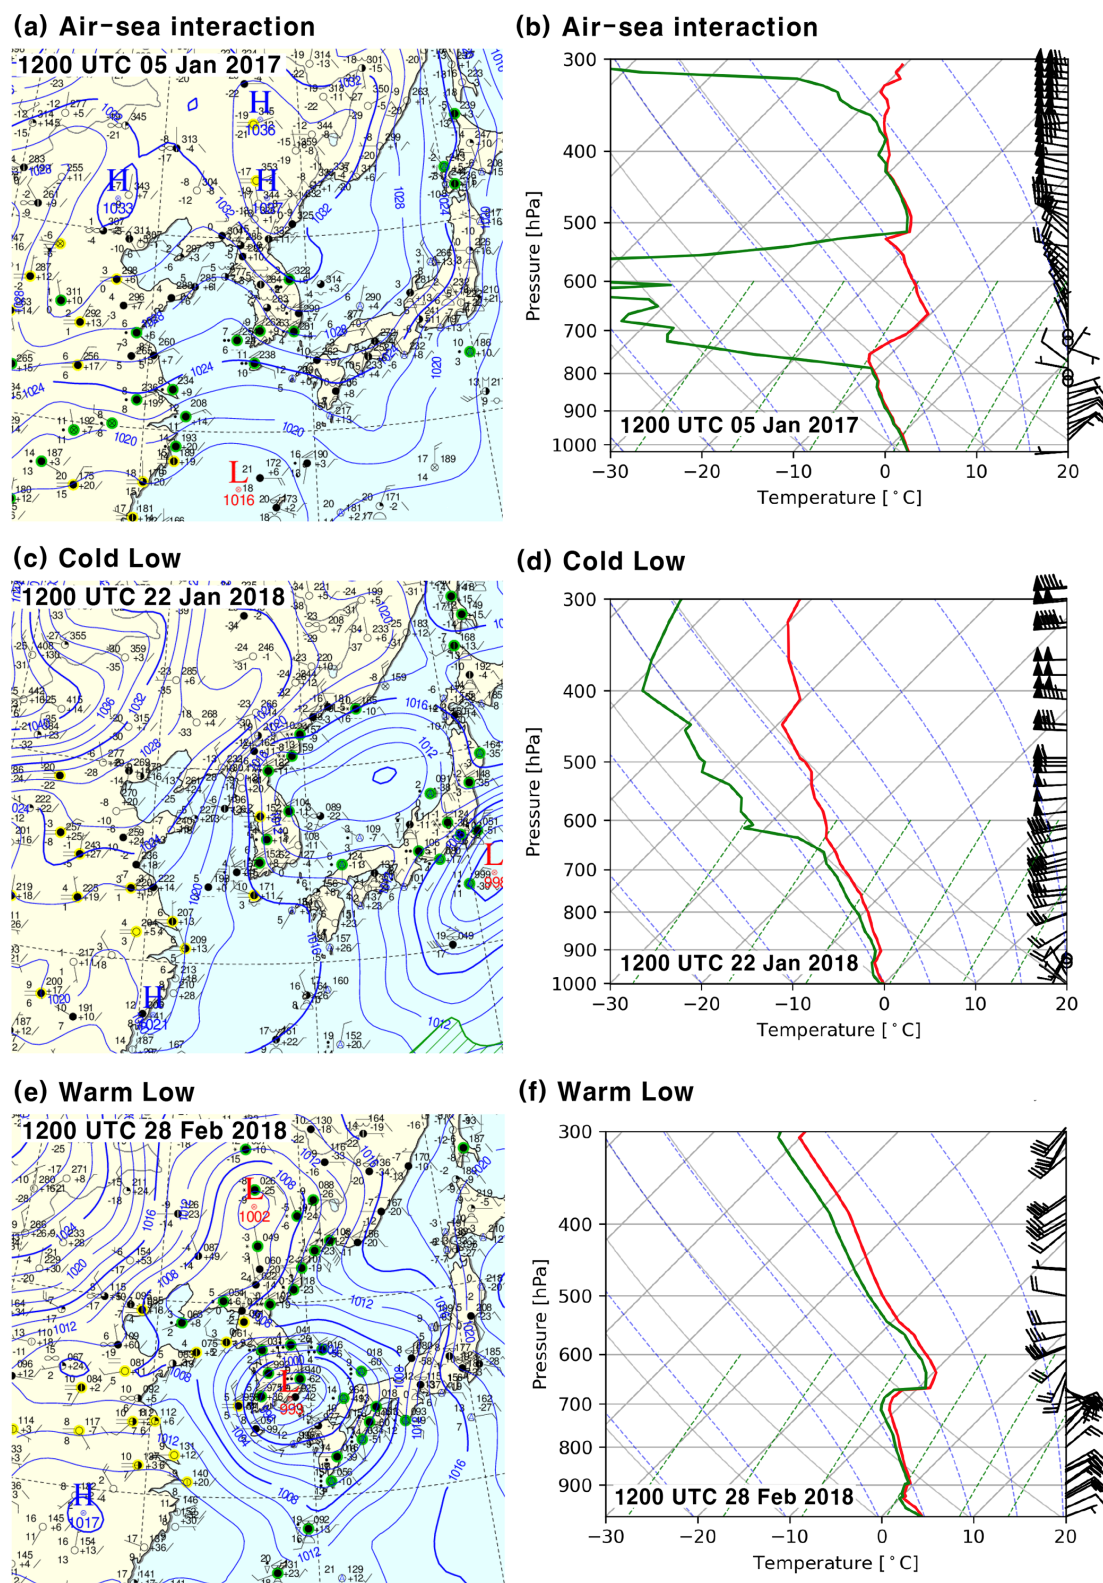

### 3.2 Cold low

In the “cold low” pattern, the low pressure is located in the north of the polar jet stream and crosses the middle of the Korean Peninsula. In this synoptic condition, the precipitation is associated only with a low-pressure system (not with induced airflow) and moves towards the east. The western area (mostly in the middle area) of the Korean Peninsula as well as the eastern area is expected to have precipitation as the low crosses the Korean Peninsula.

The Gangwon region is not always expected to have heavy precipitation in this pattern. The moisture is consumed by precipitation in the western part of the mountains when the low system approaches the Gangwon region. The eastern coast (leeward) usually has less precipitation than the mountainous area (windward) in the Gangwon region due to sublimation of snow by diabatic warming and drier conditions when crossing the mountains.

Precipitation can occur not only when there is a well-developed low-pressure system but also in the middle part of the Korean Peninsula, even when a weak surface trough extends out over the Yellow Sea. In this case, the heated air parcel over the Yellow Sea, which forms warm advection under 850 hPa, is lifted by a cold pool inland, which is usually intensified in the early morning. However, this system tends to precipitate mostly in the western part of the Korean Peninsula and is not likely to produce heavy snow in the Gangwon region. This type is considered to be a cold low in this study.

Since the low-pressure system is responsible for the precipitation, the snowfall rate depends on the location and intensity of the low-pressure system in contrast to air–sea interaction type. The cold low is the same type as the extratropical cyclone type (EC; Cheong et al., 2006) in which the precipitation is mainly produced by cold and warm fronts of the extratropical cyclone that crosses the middle part of the Korean Peninsula. This pattern is called the low crossing type in the synoptic classification by Ko et al. (2016). Song et al.

**Figure 2.** (a, c, e) Surface weather chart from the KMA for (a) air-sea interaction, (c) cold-low, and (e) warm-low types. (b, d, f) The radiosonde data plotted on a skew  $T$ -log  $p$  chart in a coastal area (Gangwon regional weather administration, GWW, near GWU) for (b) air-sea interaction, (d) cold-low, and (f) warm-low types. The skew  $T$ -log  $p$  chart was created using the MetPy package (May et al., 2008–2021) in Python. The red (green) solid line represents the temperature (dew point temperature).

(2016) interprets this pattern as a low passing type, but it is close to a low crossing type based on their description of this type where a low-pressure system crosses the middle part of the Korean Peninsula.

Figure 2c shows an example of the surface chart of a cold-low pattern. The low-pressure system was originated from Shandong Peninsula and propagated to the East Sea, leading to precipitation in the middle of the Korean Peninsula. It can be seen from the vertical wind profile in Fig. 2d that the westerly is dominant except for near the surface. Wind speed at higher levels than 800 hPa is stronger than  $15 \text{ m s}^{-1}$ . Saturated air is found up to 650 hPa, which is relatively higher than that of an example of air–sea interaction pattern (Fig. 2b).

### 3.3 Warm low

The “warm low” type indicates the synoptic situation where the low is located south of the polar jet stream and leads to precipitation over the Korean Peninsula. The low is usually formed over east-central China and moves through the south and southeast of the Korean Peninsula (see Fig. 2e). This synoptic type is the most complicated and has several interesting features that can only be found in the Gangwon region.

Tsai et al. (2018) showed that the system can be separated into two stages with different precipitation mechanisms during the passage of a low-pressure system through the southern Korean Peninsula. As the low-pressure system approaches the Korean Peninsula (early stage), precipitation that is directly related to low pressure affects the southern and central parts of the Korean Peninsula. A large amount of moisture from the warm ocean along the southwesterly flow is continuously supplied to the system, resulting in a vertically developed deep precipitation system. Tsai et al. (2018) demonstrated that the precipitation is associated with a warm front and warm advection, which means the intensities of low pressure and snowfall rate are correlated. Additionally, the Kor’easterlies are induced on the eastern coast of Korean Peninsula by the low in the south, leading to air-mass transformation in the East Sea. The Kor’easterlies and resulting air-mass transformation can be more intense if the Kaema high-pressure system is present, being the synoptic condition of the air–sea interaction.

Thus, the system in the early stage is divided into two layers vertically. The precipitation (embedded in the low-pressure system) above the shear layer develops up to a high altitude of almost 10 km along with the westerly, and there is precipitation generated by Kor’easterlies below the shear layer (see Fig. 2f). In the layer where the westerly and Kor’easterlies meet, named the transition zone, there is a thermal-inversion layer (see 670 hPa in Fig. 2f). The thermal inversion in the shear layer can also be found in Tsai et al. (2018) (see dash-dotted line and wind barbs in their Fig. 7) and Kim et al. (2018) (see their Fig. 6a) when the synoptic condition is similar to this stage. Kim et al. (2018)

interpreted this vertical structure as a two-layer cloud and reported that the altitudes of both inversion and shear layers are at 3 km a.m.s.l. In contrast to the air–sea interaction pattern that is dry in the upper inversion layer, this pattern is mostly saturated, even in the upper layer.

In the later stage, when the low moves to the southeast of the peninsula, Kor’easterly-associated precipitation remains as the low pressure in the south can still induce an easterly flow in the East Sea. The Kor’easterlies tend to change from southeasterly to northeasterly because of eastward movement of low pressure (Tsai et al., 2018). The depth of precipitation is shallow, and precipitation features are similar to those of air–sea interaction type.

The warm-low type is thought to be a favorable condition for heavy snowfall. The north–south-oriented high-to-low pressure pattern is generally known to promote Kor’easterlies and heavy snowfall (Bae and Min, 2016; Lee et al., 2018), which is the case when Kaema high pressure is supported. When atmospheric blocking (Rex, 1950) restrains this system from propagating to the east, extreme snowfall events (snow depth of 192.6 cm within 9 d) in the Gangwon region could occur (Bae and Min, 2016). All the synoptic patterns of three extreme heavy snow events over 12 years (2001–2012) analyzed by Kwon et al. (2014) were similar to the warm-low type. Nam et al. (2014) analyzed snowfall amount and frequency for 100 years (1912–2012) and found that the Gangwon region has more frequent and more intense precipitation in late winter (i.e., February and March). This is consistent with the period when the polar jet moves north as the cold continental air mass is weakening, leading to a greater possibility of a warm low rather than a cold low.

The possible causes for the heavy snowfall could be as follows. (1) The substantial heat and moisture from the ocean both south and east of the Korean Peninsula can contribute to the precipitation system; (2) precipitation enhancement by a seeder–feeder mechanism (Bergeron, 1965; Rutledge and Hobbs, 1983; Minder et al., 2015) is led by the microphysical interaction between falling seeding precipitation particles aloft generated by the low-pressure system and the feeder orographic cloud below (note that the feeder cloud in this region is originally produced in the East Sea and is expected to be further developed by steep orography); (3) thermodynamic instability at a low level over the East Sea causes the snow by air-mass transformation, resulting from cold and dry air brought by a cold-air outbreak over the warm ocean (Lee et al., 2012; Lee and Xue, 2013; Nam et al., 2014); (4) up-draft occurs in the steep orographic ascent region (or coastal area due to orographic blocking or damming) by an orographic effect in unblocked condition, leading to production of supercooled liquid water and growth by riming (Medina and Houze Jr., 2003; Rotunno and Houze, 2007); and (5) both aggregation and riming processes are facilitated by a turbulent cell in a directional shear layer (Houze and Medina, 2005).

The distribution of accumulated precipitation is concentrated both in the southern region (directly influenced by precipitation embedded in the low-pressure system) and on the east coast (indirectly produced by Kor'easterlies induced by the low-pressure system) since this type has two stages and two layers. Thus, the precipitation area is sometimes used to determine this kind of synoptic pattern. Ko et al. (2016) referred to this type as low passing, and they determined it by searching for precipitation events only in the southern Korean Peninsula and eastern coastal area. Here the term “low passing” may imply that the low passes through the southern part of the Korean Peninsula.

There have been several terminologies of this synoptic condition in previous studies. Song et al. (2016) called it the south trough type in their synoptic classification. Cheong et al. (2006) refer to the extratropical cyclone type in the south of the Korean Peninsula (ECS). They mentioned that the snowstorm is indirectly affected by extratropical cyclones and is supported by abundant moisture and orographic effect. They also reported that the relative importance of factors controlling the precipitation development could vary depending on the location of low pressure. In addition, when the expansion of Siberian high pressure and the low pressure passing through the southern sea occurs simultaneously, they used the term combined type (COM). Arguably, there will be more different terms depending on the perspective of looking at the pattern in the same synoptic condition, but most of these are consistent with the synoptic condition and precipitation features of our classification.

Figure 2e shows well-developed low pressure located in the southern part of the Korean Peninsula with a minimum mean sea level pressure of 993 hPa. Precipitation in the Gangwon region is in the early stage of a warm-low pattern at this time. The easterly and northeasterly are shown on the eastern coast and in the East Sea since they are located north of low pressure. A strong directional wind shear and collocated thermal inversion are identified in the skew  $T$ -log  $p$  chart (Fig. 2f). An obvious veering of wind just below and above the transition zone is found, indicating the warm advection. It is also revealed that the air is nearly saturated from the ground to the altitude over 300 hPa, indicating a vertically deep precipitation system. It is expected that temperature, moisture, and wind profile will change to be similar to the air–sea interaction type (Fig. 2b) in the later stage when the low-pressure system is located in the East Sea.

As discussed above, a seeder–feeder process is expected due to “seeding” precipitation from the frontal precipitation system and air–sea effect (and orographic) “feeder” cloud. A dual-layered cloud structure, which is necessary for the seeder–feeder process, can be confirmed by looking at an example of typical vertical structure of a warm-low event from upper-air sounding (Fig. 3). A distinct lower cloud pre-existed below 800 hPa with the Kor'easterlies at 09:00 UTC (Fig. 3a), and an upper layer (associated with westerly) became saturated from high altitude (300 hPa at 09:00 UTC)

**Figure 3.** Skew  $T$ -log  $p$  diagrams for (a) 09:00 UTC, (b) 12:00 UTC, and (c) 18:00 UTC of a warm-low event (4 March 2018) at the Daegwallyeong weather office (DGW; mountainous area). The skew  $T$ -log  $p$  chart was created using the MetPy package (May et al., 2008–2021) in Python. The red (green) solid line represents the temperature (dew point temperature).

to the middle layer (540 hPa at 12:00 UTC) (Fig. 3a and b). Then all the altitudes were covered by the clouds with an apparent thermal-inversion layer collocated with the transition zone between the easterly below and westerly aloft (Fig. 3c). These three plots indicate that the upper cloud and lower cloud were separated initially, then combined later as the low-pressure center moved closer to the south of the studied area. Note that this kind of vertical structure was evident in warm-low events.

### 3.4 Classification of observed events

We have determined a synoptic pattern for each event based on our knowledge of each pattern. Basically, the weather map, composite radar image, and ground-accumulated precipitation distribution provided by the KMA were utilized. Precipitation distribution is obtained from a heated tipping rain gauge at automatic weather stations (AWSs) of the KMA. If Siberian high pressure expands to the east, and precipitation is concentrated on the east coast, it was determined as an air–sea interaction pattern. If precipitation is concentrated in the west-central region of the Korean Peninsula, and the location of precipitation on the radar image is directly related to the location of low pressure, it is classified as a cold-low type. When the surface trough of low pressure extends to the Yellow Sea, snowfall due to warm advection in 850 or 925 hPa was also classified as a cold-low type. It was determined as a warm-low pattern when low pressure passed through the south of the Korean Peninsula, and precipitation was concentrated on the south and east coasts of the Korean Peninsula, and precipitation developed in the East Sea due to the indirect effect of low pressure as well as the Kor’easterlies.

It is necessary to confirm our classification using other available observation data. Radiosondes launched at GWW (Gangwon regional weather administration, 37.8046° N, 128.8554° E; 79 m a.m.s.l.) near GWU on the east coast were utilized to check the vertical wind profile and depth of the precipitation system. We also checked soundings in the mountainous region if necessary. Surface wind from AWSs at GWW and DGW (Daegwallyeong weather office; 37.6773° N, 128.7188° E; 773 m a.m.s.l.) near MHS in the mountainous region was also utilized to check the prevailing wind. In addition, we also checked wind profiles from ultra-high-frequency (UHF) wind profilers at GWW and DGW. Satellite images of infrared and visible channels from the Communication, Ocean, and Meteorological Satellite (COMS) were also utilized in order to check the location of clouds.

We chose 20 events when both MRR and PARSIVEL observed well for all sites (see Table 1). We identified 5 air–sea interactions as well as 5 cold-low and 10 warm-low patterns among the events. Cheong et al. (2006) reported that the frequency of each synoptic pattern within 21 years (1981–2001) is 65, 14, and 30 for the air–sea interaction (AT

and TE), cold-low (EC), and warm-low (ECS and COM) types, respectively. The frequency ratio between the cold-low and warm-low type is similar to the dataset of Cheong et al. (2006) (the warm-low type is almost double the cold low). However, air–sea interaction pattern in our studied events is relatively less frequent. The air–sea interaction type is mostly found in 2016–2017, while the cold-low type occurred only in 2017–2018. Note that the warm-low events in 2017–2018 are mostly related to the heavy snowfall events during the ICE-POP 2018.

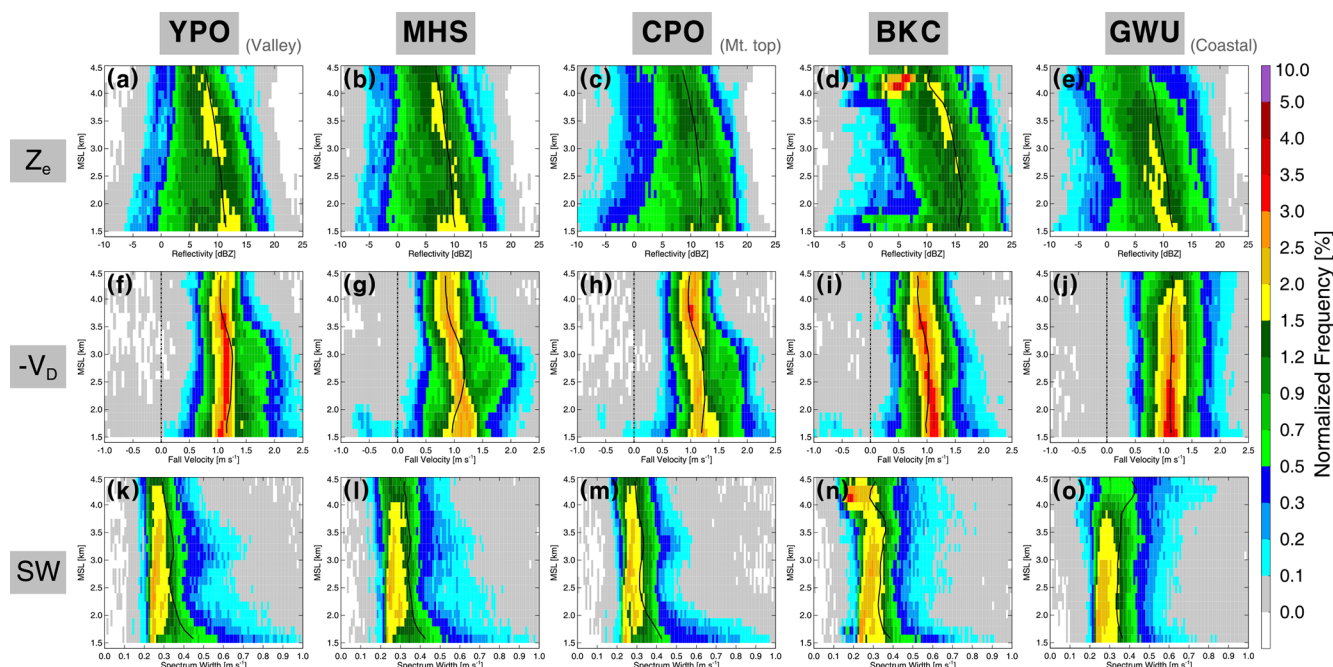

## 4 Results

### 4.1 General snow characteristics during ICE-POP 2018

In this section, the characteristics of vertical structure and snow size distribution from the ICE-POP 2018 period (i.e., 2017–2018 winter, 12 events) are analyzed according to the topography to explore general characteristics of snow in the Gangwon region. During ICE-POP 2018, five sites (YPO, MHS, CPO, BKC, and GWU from the west to the east) were equipped with PARSIVEL and MRR. To examine the vertical structure of precipitation, CFADs of reflectivity, Doppler velocity, and spectral width are plotted for the five selected sites (Fig. 4).

The reflectivity is generally increased with decreasing heights at all sites, resulting from the growth of snow particles. However, the increase can be characterized by different slopes of roughly 2.0 (0.5) dBZ km<sup>−1</sup> above (below) 3.0 km height, particularly at the CPO, BKC, and GWU sites. The steady growth below 3 km heights is shown at the mountain sites, YPO and MHS. This may imply that some different microphysical processes occur based on the altitude of 3 km when comparing between coastal and mountainous regions. A distinctly different characteristic can also be seen in the CFAD of Doppler velocity. The values of frequency peak of Doppler velocity are 1–1.5 ms<sup>−1</sup> at all sites, with a slight increase as height decreases, consistent with typical terminal velocity of snow particles. However, an increase in Doppler velocity at 3.0–3.5 km clearly appears at mountainous (YPO, MHS, and CPO) sites and weakly at the BKC site. These increased Doppler velocities maintain their speed as height decreases. Since the Doppler velocity of the vertically pointing radar is the combination of reflectivity-weighted terminal velocity of particles and vertical wind, increases in Doppler velocity could be explained by faster-falling particles or downdraft. We hypothesize that the increased Doppler velocity is mostly contributed to by faster-falling particles. This is because it is unlikely that there was a sustained downdraft or updraft for most of the precipitation events in such a huge volume with a height of almost 2 km (1.5–3.5 km altitude).

It is also found that spectral width is noticeably increased at the level where the Doppler velocity is increasing

**Figure 4.** CFADs of radar reflectivity (dBZ; **a–e**), negative of Doppler radial velocity ( $\text{m s}^{-1}$ ; **f–j**), and spectral width ( $\text{m s}^{-1}$ ; **k–o**) from MRR for 2017–2018 winter at (**a, f, k**) YPO at the valley, (**b, g, l**) MHS, (**c, h, m**) CPO at the mountain top, (**d, i, n**) BKC, and (**e, j, o**) GWU sites at the coastal region. The solid line indicates the average value for each diagram. Dash-dotted lines represent  $0.0 \text{ m s}^{-1}$  in Doppler velocity. The mean liquid-equivalent precipitation rate from the  $Z_e$ –SR relationship at 24.23 GHz (Souverijns et al., 2017) at 1.5 km height is  $0.79, 0.61, 0.86, 1.91$ , and  $0.84 \text{ mm h}^{-1}$  for YPO, MHS, CPO, BKC, and GWU, respectively.

(i.e., 3.0–3.5 km) at mountainous sites. The enhanced spectral width can be contributed to by either turbulence or diversity of fall speed of particles due to coexistence of non-rimed and rimed particles. The most likely causes for enhanced spectral width at 3.0–3.5 km is the turbulence rather than the diversity of fall speed. If this is caused by diversity of fall speed, we should still see a similarly high value at the altitude below the layer, but we can see the spectral width is decreased as the height decreases. Note that the enhanced spectral width is stronger at mountainous sites and further intensified at western sites. The higher spectral width at 1.5–2.0 km height is also shown at mountainous sites, indicating the turbulence at this level because only the diversity of fall speed may not be attributable to such a high spectral width such as  $1.0 \text{ m s}^{-1}$ . At the coastal sites (BKC and GWU), depositional growth or aggregation process is dominant, and the degree of turbulence is lower because neither significant increased Doppler velocity nor spectral width is found.

Size distribution of snow on the ground is represented in  $N'_0$  and  $D'_m$  (Fig. 5). Normalized frequency of  $N'_0$  and  $D'_m$  for the YPO and GWU sites shows that the mountainous site (YPO) has a greater number concentration (mean value of  $97.72 \text{ m}^{-3} \text{ mm}^{-1}$ ) and a larger diameter (mean value of  $2.38 \text{ mm}$ ) compared with the coastal site (GWU), which has a mean number concentration of  $38.02 \text{ m}^{-3} \text{ mm}^{-1}$  and a mean diameter of  $2.04 \text{ mm}$ , leading to higher snowfall rate

at YPO. This is consistent with relatively higher normalized frequency of reflectivity in moderate intensity (0–15 dBZ) at YPO, although the reflectivity pattern is similar, with a mean value of approximately 12 dBZ at 1.5 km height for two sites.

To support the fact that YPO has heavier snow due to broader particle size distribution, the difference in normalized frequency of  $N'_0$ – $D'_m$  between the two sites is shown in Fig. 6. The difference in normalized frequency of  $N'_0$ – $D'_m$  is consistent with that found in Fig. 4. Higher number concentration is more frequent for a given diameter, and a larger diameter for a given number concentration is found at the YPO site, resulting in broader snow size distribution. This implies that a higher snowfall rate is frequent at YPO, with larger snowflakes due to more active aggregation as well as stronger riming.

#### 4.2 Snow characteristics in air–sea interaction pattern

We divide the 20 observed events into 3 synoptic patterns, as described in Sect. 3. In this section, the snow characteristics during the air–sea interaction pattern are explored. Compared with the previous section, MHS and BKC sites are excluded because they were deployed during the 2017–2018 winter season only.

The echo top height is higher in the coastal region (GWU) compared with the mountainous region (YPO and CPO), indicating that the vertical depth of precipitation is decreased

**Figure 5.** Normalized frequency of (a)  $\log N'_0$  and (b)  $D'_m$  for YPO (in red) and GWU (in blue) sites. Dashed lines denote the mean value of each site.

**Figure 6.** Difference in normalized frequency of  $N'_0 - D'_m$  between YPO and GWU sites. A warm (cold) color indicates that YPO (GWU) has more frequency.

when the system crosses the mountains (Fig. 7). The reflectivity is rapidly increased until 3.0 km with increasing Doppler velocity as height decreases at all sites, suggesting depositional growth. Below 2.5–3.0 km, primary peaks of reflectivity (larger reflectivity) show nearly constant values with a steady increase in Doppler velocity. This implies that the riming is the main snow growth process in this layer regardless of site location. When riming occurs, Doppler velocity is increased because the mass of snow increases due to collection of supercooled liquid water, while the size of the snow does not greatly enlarge (Heymsfield, 1982), resulting in a nearly constant or smaller increase in reflectivity.

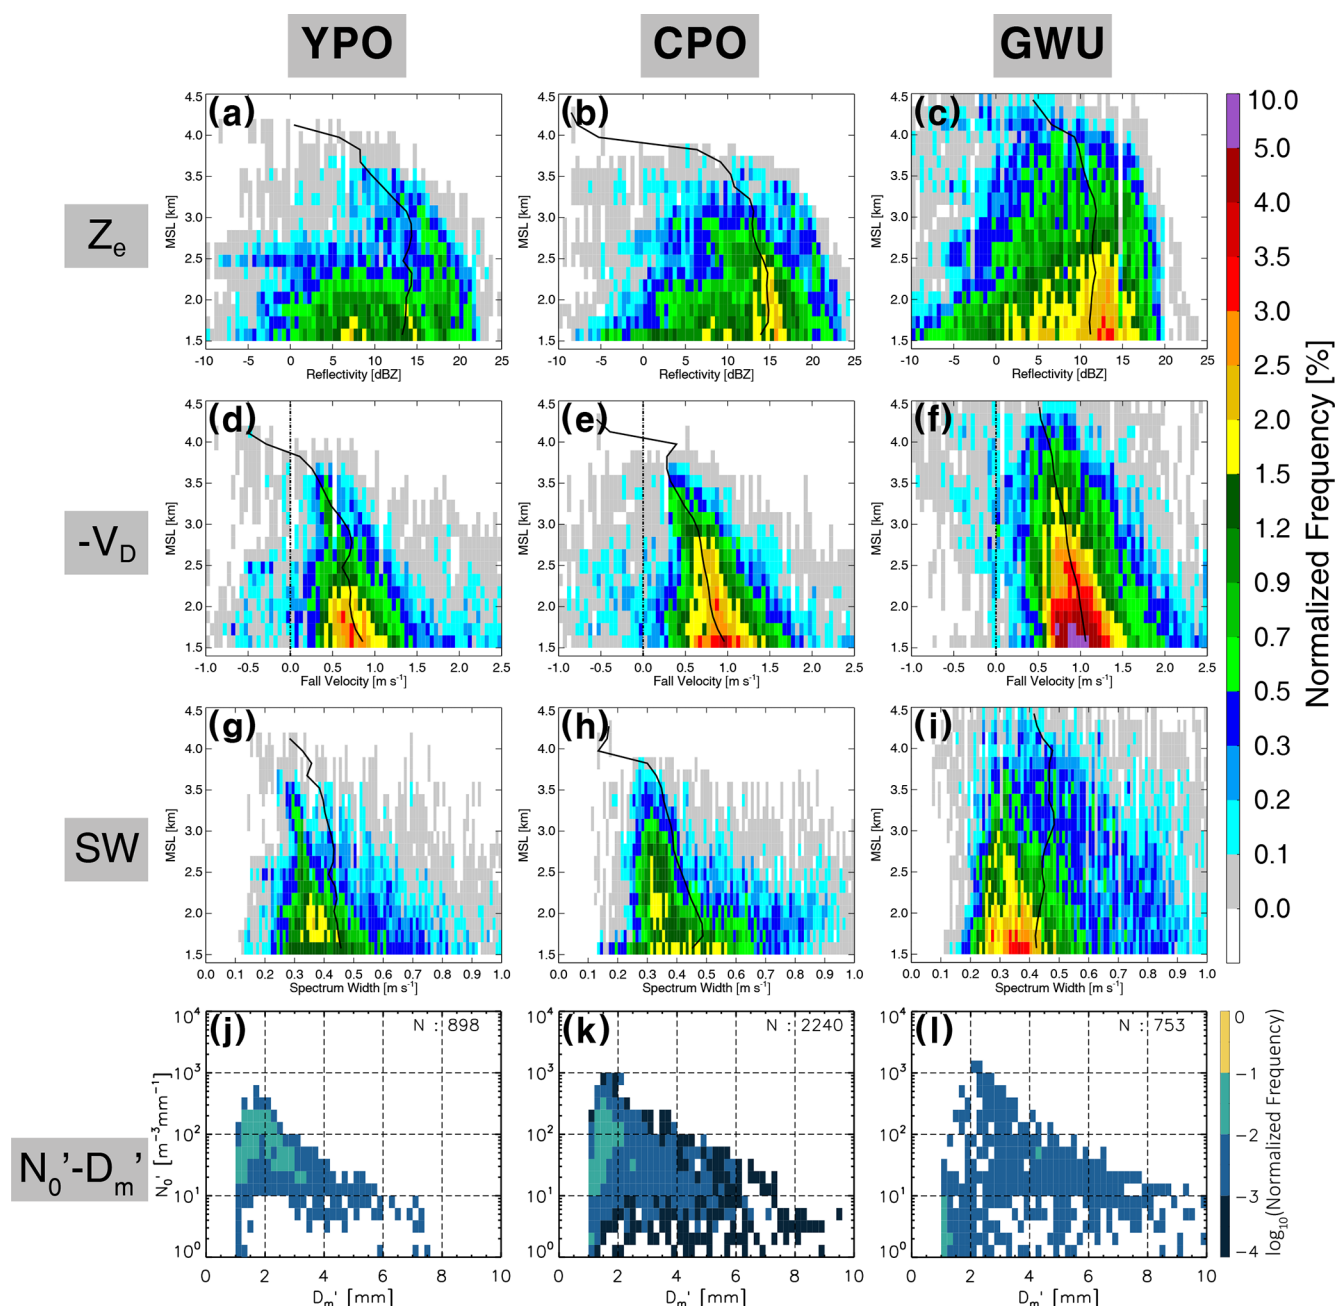

The Doppler velocities less than  $0 \text{ m s}^{-1}$  below 3 km are revealed at YPO and CPO, indicating that updraft exists at mountainous sites. These updrafts may be induced by uplift of airflow by topography. Updraft is also found at the GWU site with less frequency at higher levels. In the layer where

the updraft is present, there is a secondary peak of reflectivity (at lower reflectivity less than 12 dBZ) and enhanced spectral width at mountainous sites up to a height of 3 km. This may suggest that new ice crystals are generated at a low level due to adiabatic cooling resulting from the updraft in mountainous regions. Increased spectral width may be contributed to by turbulence due to interaction between airflow and complex topography.

Although reflectivity is higher at CPO compared with GWU, the particles on the ground show higher frequency of big snowflakes at GWU, not CPO. The lower frequency of small snowflakes and higher frequency of big snowflakes at GWU indicate that the aggregation process is active in the coastal area. The aggregation signature can also be found in the histograms of characteristic diameter shown in Fig. 8. The mean values of characteristic diameter increase from west (YPO, 2.28 mm) to east (GWU, 3.88 mm). The snowflakes with a diameter larger than 12 mm are shown only at GWU, and a broader distribution is found at GWU, which indicates that strong aggregation is favorable in coastal regions. This result agrees with the findings of Bang et al. (2019), who conducted a similar analysis using two air–sea interaction events and showed that the GWU site has a greater number concentration and a larger diameter than the YPO site.

### 4.3 Snow characteristics in cold-low pattern

In the cold-low pattern, the moisture is likely consumed in the western part of the Korean Peninsula, resulting in less strong precipitation in the eastern part. As expected, the reflectivity generally showed a low mean value of less than 10 dBZ, and the lowest mean value of 5 dBZ is shown at GWU at the bottom layer (Fig. 9). This can also be supported by the smaller values of both  $N'_0$  and  $D'_m$  at the GWU site, suggesting strong evidence of depletion or sublimation

**Figure 7.** CFADs of radar reflectivity (dBZ; **a–c**), negative of Doppler radial velocity ( $\text{m s}^{-1}$ ; **d–f**), and spectral width ( $\text{m s}^{-1}$ ; **g–i**) from MRR (**a–i**) and normalized frequency of  $N'_0 - D'_m$  (**j–l**) at YPO, CPO, and GWU sites for the air–sea interaction events during two winter seasons. The number of snow-observed minutes at the ground by PARSIVEL is shown in the upper right corner of the diagram in the fourth row. The mean liquid-equivalent precipitation rate from the  $Z_e$ –SR relationship at 24.23 GHz (Souverijns et al., 2017) at 1.5 km height is 1.16, 1.33, and 0.75  $\text{mm h}^{-1}$  for YPO, CPO, and GWU, respectively.

of snow. The CFAD value at the GWU site shows lower frequency, which means it snowed over less time, and echo top height is also decreased at the GWU site. A possible explanation for depletion of snow in the coastal region may be dry air mass in the coastal area and diabatic heating as the airflow descends through the steep mountain slope.

All sites are characterized by strong turbulence below 2 km a.m.s.l. height, leading to high spectral width and high variability in Doppler velocity. The strong turbulence at this layer corresponds to that shown in the general characteristics (Fig. 4). The possible reason for the low-level turbulence may be the interaction between the complicated orography in the Taebaek Mountains and the strong westerly. Note that

**Figure 8.** Normalized frequency of  $D_m'$  at (a) YPO, (b) CPO, and (c) GWU sites for air–sea interaction events during two winter seasons. The dashed red line indicates the average value for each diagram.

the median wind speed of all cold-low events was  $6.70 \text{ m s}^{-1}$  at DGW, located between YPO and CPO, while it was  $2.60$  and  $2.30 \text{ m s}^{-1}$  for air–sea interaction and warm-low events, respectively.

Interestingly, there were distinct differences between the two mountainous sites (YPO and CPO). Comparing two sites, the Doppler velocity spectrum at CPO has a similar median to that at YPO, but the spectrum is much wider, suggesting an increased frequency of both slowly falling aggregates and faster-falling rimed particles (Fig. 9). Figure 10 illustrates the normalized frequency of characteristic diameter and number concentration at the ground as a function of snowfall rate. It is apparent from this figure that even though those two sites have the same snowfall rate, CPO is characterized by a lower number concentration with larger snowflake size for a given snowfall rate. This means that the aggregation process plays an important role in the region between the YPO and CPO sites even though the distance is 6.46 km only.

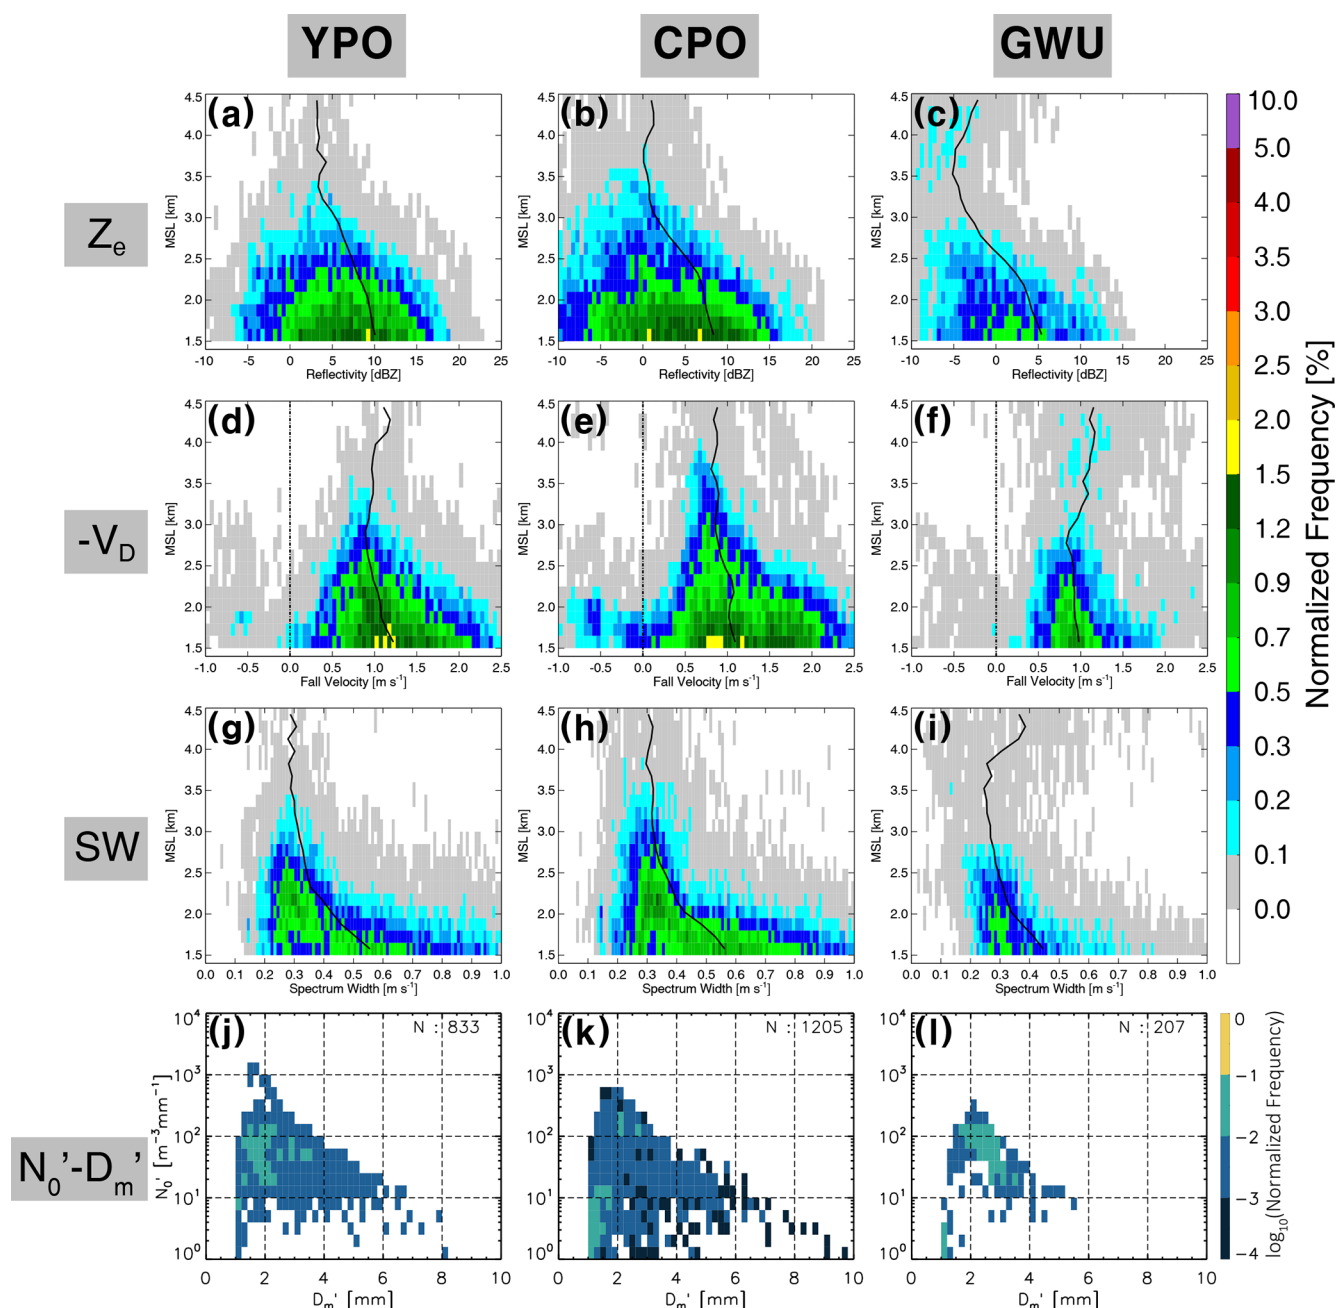

#### 4.4 Snow characteristics in warm-low pattern

As explained in Sect. 3, a warm-low pattern is likely to have unique characteristics as a result of its unique precipitation mechanism and complex geographical features in the Gangwon region. The vertical depth of precipitation is at least higher than 4.5 km (Fig. 11), which is consistent with saturated air over 300 hPa shown in Fig. 2f. In contrast to the differential growth rate of reflectivity below and above 3 km found in general characteristics (Fig. 4), almost constant increases in reflectivity with decreasing height are identified at all sites.

A strong riming signature at mountainous sites is identified around 3 km height, which is also found in the general characteristics (Fig. 4). It can be seen that Doppler veloc-

ity obviously increases in the enhanced-spectral-width layer at 3.0–3.5 km. As a higher spectral width is found at YPO, the Doppler velocity is also found at higher values compared with CPO (see the Doppler velocities close to  $2.5 \text{ m s}^{-1}$  in Fig. 11d). Both the frequency of Doppler velocity above  $1.5 \text{ m s}^{-1}$  and primary frequency peak of Doppler velocity of approximately  $1.0 \text{ m s}^{-1}$  rise in that layer (3.0–3.5 km) and maintain their velocity as they fall. A possible reason for this is that a strong riming process occurs in the enhanced-spectral-width layer, leading to production of fast-falling particles.

The enhanced spectral width may be explained by directional shear. There is a strong directional wind shear layer between the easterly or northeasterly in the lower and westerly in the upper layer in the early stage of a warm-low pattern, resulting in a turbulent layer. The transition zone where strong wind shear exists is generally with thermal inversion. Lee (1999) reported that the inversion layer is usually located at 700 hPa in the synoptic situation when the snowstorm is affected by the strength of a low-pressure system in the south-east of the Korean Peninsula. This altitude is consistent with an enhanced-spectral-width layer in Fig. 11. Thus, the layer of enhanced spectral width at 3.0–3.5 km suggests that it is caused by wind shear. It is also found that the general altitude of the wind shear in this region is located between 3.0–3.5 km a.m.s.l. (see Fig. 2f). The shear-generated turbulence could produce the updraft cell which is responsible for generation of supercooled liquid droplets and favors both aggregation and riming processes (Houze and Medina, 2005; Kumjian et al., 2014; Grazioli et al., 2015). This is a probable explanation of why the riming signature is identified. It is also found that the farther west, the higher the spectral width found below 2 km, which is also found in the general characteristics in Sect. 4.1. This may be caused by mechanical

**Figure 9.** Same as in Fig. 7 except for the cold-low events. The mean liquid-equivalent precipitation rate from the  $Z_e$ –SR relationship at 24.23 GHz (Souverein et al., 2017) at 1.5 km height is 0.59, 0.42, and 0.22 mm h<sup>-1</sup> for YPO, CPO, and GWU, respectively.

turbulence as Koroasterlies flow over the complex orography.

As discussed above, snow in the upper and lower layers was initiated and developed from different systems, respectively. The upper snow is generated by a low-pressure system at synoptic scale, while the lower snow is produced by interaction between cold air and warm ocean at the mesoscale and orographic lifting. Snow crystals generated by large-scale forcing (acting as a seeder cloud) collect supercooled

liquid water or collide with snowflakes below and become rimed or aggregated snowflakes as they fall through feeder clouds produced by mesoscale forcing. Possible evidence of snowfall enhancement by the seeder–feeder mechanism (Bergeron, 1965) may be found in the continuous increase in reflectivity of the primary peak (see normalized frequency > 2.5 %).

Comparing mountainous regions (YPO and CPO) and coastal regions (GWU), we can see that the increase in re-

**Figure 10.** Normalized frequency of  $D'_m$ -SR (a, b) and  $N'_0$ -SR (c, d) at the YPO and CPO sites for the cold-low events.

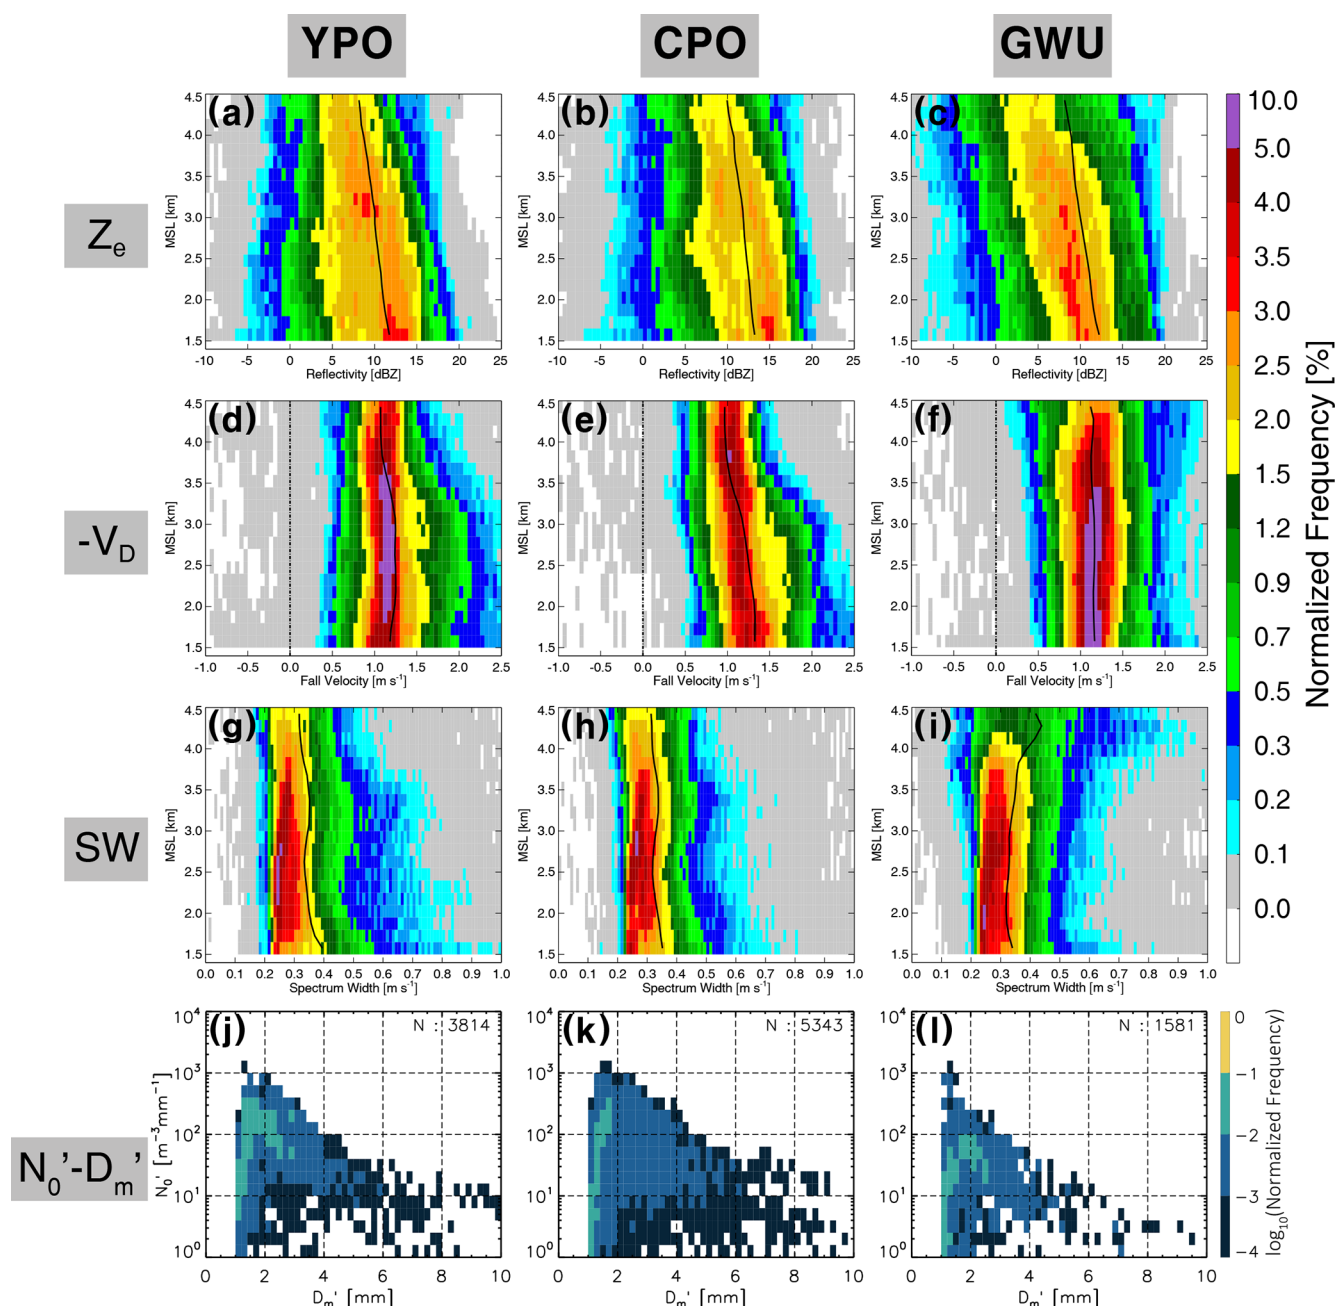

flectivity at the GWU site below 3 km is more rapid (approximately  $2.0 \text{ dBZ km}^{-1}$  for normalized frequency  $> 2.5 \%$ ) than at mountainous sites (approximately  $1.3 \text{ dBZ km}^{-1}$  for normalized frequency  $> 2.5 \%$ ). There are two probable explanations for this result. First, a snowstorm at the low level in coastal areas which is produced by an air–sea interaction type is likely to have more sufficient moisture than mountainous areas since it is closer to the ocean. Second, aggregation is the primary growth mechanism in the feeder zone at the GWU site because the Doppler velocity does not show a significant increase (almost constant at  $1.2 \text{ m s}^{-1}$ ). A large snowflake grown by the aggregation process can promote an increase in reflectivity that is approximately proportional to the fourth moment of particle size distribution in the Rayleigh scattering regime (Bukovčić et al., 2018, 2020; Matrosov, 2020). The low frequency of high number concentration above  $500 \text{ m}^{-3} \text{ mm}^{-1}$  for a small diameter ( $< 3 \text{ mm}$ ) in Fig. 11l confirms that small snowflakes are mostly consumed dominantly by aggregation dominantly, except for the case of weak precipitation with small  $N'_0$  and small  $D'_m$ . At YPO and CPO, on the other hand, Doppler velocity apparently increases in the layer below 3.5 km, and reflectivity shows less enhancement, suggesting that snow is likely to

predominantly grow by riming processes in the feeder zone with a modest contribution of aggregation. Large-diameter ( $> 5 \text{ mm}$ ) snowflakes found at the YPO and CPO sites (Fig. 11) imply that the aggregation process is also an important growth mechanism in mountainous regions.

It is also worth noting that the reflectivity at the low level is the highest at CPO. It is possible to hypothesize that the seeder–feeder effect would have been strongest at CPO because both seeder and feeder precipitation could be strong since the CPO is still not only close to the East Sea but also located at the mountainous site; thus it can be considerably influenced by embedded precipitation in the low-pressure system. The higher frequency of large-diameter ( $> 5 \text{ mm}$ ) snowflakes at CPO compared to that of YPO (Fig. 11) may be explained by a stronger seeder–feeder effect at CPO.

Figure 12 depicts the frequency comparison of number concentration and diameter between the YPO and GWU sites to compare between mountainous and coastal regions. The mean values of number concentration and diameter of YPO (GWU) are  $104.71 (34.67) \text{ m}^{-3} \text{ mm}^{-1}$  and  $2.30 (1.97) \text{ mm}$ , respectively, indicating that the mountainous region is characterized by heavier snowfall with more and larger snowflakes. The size distributions are not much dif-

**Figure 11.** Same as in Fig. 7 except for the warm-low events. The mean liquid-equivalent precipitation rate from the  $Z_e$ –SR relationship at 24.23 GHz (Souverein et al., 2017) at 1.5 km height is 0.84, 1.15, and 0.93 mm h<sup>−1</sup> for YPO, CPO, and GWU, respectively.

ferent to those of the general characteristics (Fig. 5) because warm-low events account for half of all events.

## 5 Conclusions

The main purpose of the study was to demonstrate the impact of wind pattern and topography on microphysical characteristics in the Gangwon region. A total of 20 snowfall events during the ICE-POP 2018 field campaign for 2 years were

examined with collocated MRR and PARSIVEL data at the five sites aligned in crossing mountains. This study analyzed CFADs of equivalent reflectivity, Doppler velocity, and spectral width from MRR and distribution of generalized characteristic diameter ( $D'_m$ ) and number concentration ( $N'_0$ ) of snow size distribution from PARSIVEL.

The 20-event composite analysis suggests that snow at mountainous sites at YPO, MHS, and CPO tends to grow by riming with moderate aggregation, whereas snow growth

**Figure 12.** Same as in Fig. 5 except for the warm-low events.

at coastal sites at BKC and GWU is dominant by aggregation or vapor deposition. Signatures of riming are found as a notable higher frequency of enhanced Doppler velocity below 3.0–3.5 km altitude. We hypothesize that the reason for this is that the turbulent layer at 3.0–3.5 km altitude, which can be seen by higher spectral width, produces a large amount of supercooled liquid water and subsequently fosters riming, as suggested by Houze and Medina (2005). It is also revealed that the snowfall rate is more intense at mountainous sites, resulting from broader size distribution.

Since the wind pattern is governed by the synoptic condition, this study divided the events according to the synoptic pattern in order to further discover possible linkages between airflow, topography, and characteristics. Synoptic patterns are classified into three categories (air–sea interaction, cold low, and warm low). MRR observations for air–sea interaction suggest that riming exists at all sites. This may be explained by low-level updraft induced by orographic lifting and convective instability over the ocean due to the Kor’easterlies. This can be supported by the observational evidence presented by Kusunoki et al. (2005) that terrain-induced updraft favors the production of supercooled liquid water, which leads to snow growth by riming, even over the small-scale (horizontal scale of approximately 3 km) terrain. Updraft is more frequent at mountainous sites, leading to a stronger signature of riming. Size distribution characteristics from PARSIVEL indicate that larger snowflakes by aggregation are more frequent in coastal regions. This is probably due to the deeper depth of precipitation and the moisture-rich condition because of the shorter distance from the ocean.

This study shows that, in a cold-low pattern, precipitation in coastal regions can be characterized by relatively shallower, less intensive, and less turbulent snow with a smaller size and number concentration, indicating strong sublimation of snow on the downwind side of the mountain ranges. The possible explanations for this are the diabatic heating due to descent of airflow and the relatively drier condition be-

cause moisture is mostly consumed in the west. The CFADs of spectral width suggest that strong turbulence is located at a low level at the mountainous sites, probably resulting from the interaction between complex terrain and high wind speed. It is speculated that turbulence plays a vital role in promoting aggregation in mountainous regions. This hypothesis is supported by the fact that the CPO site is characterized by greater aggregation for a given snowfall rate in contrast to YPO.

The evidence that the wind pattern and topography affect microphysical processes can be clearly seen in the warm-low pattern. It is found that a layer with enhanced spectral width at 3.0–3.5 km a.m.s.l. is responsible for strong and obvious riming signatures beneath the layer. Directional wind shear generally located at 3.0–3.5 km generates shear-induced turbulence, leading to intense riming, particularly in mountainous regions, by producing supercooled liquid water and increasing collision probability. MRR measurements suggest that the effect of the seeder–feeder mechanism on microphysics is probably different in mountainous and coastal regions. The mountainous region is more likely to present intensive riming with moderate aggregation, whereas the coastal region is likely to be affected by greater aggregation in the feeder zone. Reflectivity from MRR and size distribution from PARSIVEL suggest that seeder–feeder enhancement is thought to be the strongest at CPO. In addition, the size distribution of YPO and GWU indicates that a mountainous region has a heavier snowfall rate, as seen in the larger size and larger number concentration. Given the physical mechanisms invoked to explain the observations, these results are not necessarily particular of the region but likely applicable to other regions of the planet.

The present study provides evidence of the role of airflow and topography in microphysics in the Gangwon region by means of a comprehensive network of MRR and PARSIVEL instruments. While this study is more focused on multi-storm characteristics, detailed analysis for each pat-

tern or for a specific event will need to be undertaken to support the hypotheses and to answer questions remaining, such as the reasons for the stronger turbulence in the transition zone in the west in a warm-low pattern. In future research, the use of observation-based three-dimensional wind or dual-polarization radar variables in the direction of cross-barrier flow is suggested as well as high-resolution simulation from numerical models.

**Data availability.** Data are available upon request (Kwonil Kim via [kwonil.kim.0@gmail.com](mailto:kwonil.kim.0@gmail.com)).

**Author contributions.** KK designed and performed the research under the supervision of GL. WB processed the PARSIVEL data. GL, ECC, FJT, CLT, and EJ contributed to the scientific discussions and gave constructive advice. KK and WB carried out the MRR and PARSIVEL measurements. KK wrote the manuscript with substantial contributions from all co-authors. GL, FJT, and EC revised the manuscript.
