Section S1. Split model configuration

During the observation periods, the diurnal variations of planetary boundary layer (PBL) at the GIG and Heshan sites are shown in Fig.S1 (a, b), which are based on data from the website of NOAA Air Resource Laboratory (https://ready.arl.noaa.gov/READYamet.php). The PBL height decreased significantly at 17:00, which would decouple into nocturnal surface boundary layer (NBL) and residual layer (RL). Besides, O_3 and NO_x at the ground site and 488 m site of Canton Tower agreed well during the day (shown in Fig. 5 (a) ~ (c)), and started to show clear distinction from 17:00 LT, thus we define 17:00 LT as the sunset time. At that time, the box was initialized by the last condition of the daytime model, and was separated into NBL and RL boxes. As the average boundary layer height was 400 m and 1000 m in the nighttime and daytime respectively, the heights of NBL and RL were set to 400 m and 600 m (Fig.S1 (c)). Both nighttime boxes were simulated from 17:00 to the 06:00 LT the following morning, at which time the PBL height began to gradually increase. After 06:00 LT, we assumed RL and NBL layer began to mix as the NBL height linearly increased, instantaneously mixing once per hour until 10:00 LT, the mixing process was completed, and two boxes were combined as a whole box. The mixed layer height was set as 1000 m in the simulation of daytime from 10:00 to 17:00 LT.

In the nighttime at the GIG site, the trace gases of NO_2 and O_3, meteorological parameters RH and T in the RL box, were constrained by the measurements from the 488 m site at Canton Tower. Several arguments justify this approach. Firstly, the trace gases at the surface GIG site were comparable with the Canton ground site in Fig.5, especially during the nighttime; the mean concentration deviations for NO, NO_2 and O_3 between the GIG and Canton ground sites were 1.96%, 6.54% and 0.65%, respectively. In addition, given the short distance between locations, we expect the composition of the aloft RL layer at GIG site to be closely represented by the Canton 488 m site. The O_3 at the Canton 488 m site was higher than at the ground site, and relatively unaffected by surface NO emissions, which would promote the nighttime NO_3 - N_2O_5 chemistry. The temporal evolution of other species in the RL, such as NO and VOCs, were unconstrained, and thus calculated by the box model.

63   However, there was no measurement aloft available for the campaign at Heshan

64   site. Therefore, all species observed at Heshan site at 17:00 LT are set as the initial

65   inputs for the RL box to freely evolve over night. To test this setting, we performed a

66   simulation experiment using observations at GIG and Canton Tower sites. In analog to

67   the settings of Heshan site, the observations at 17:00 LT at the GIG site were used as

68   the initial inputs of RL, and allowed the initial data to freely evolve at night, without

69   the influence from surface emissions. As shown in Fig.S11, the simulated nighttime

70   results of NO_2 and NO_x in the RL compared well with the observation at the 488 m site

71   of Canton Tower, which showed good agreements. Simulated O_3 and Ox were lower

72   than the observations at the 488 m site of Canton Tower, but were within the combined

73   uncertainties. In addition, the simulated nitrate and nitrate production rate from N_2O_5

74   uptake with the observation at the GIG site and 488 m Canton Tower site as initial input

75   were also compared in Fig.S11(e ~ f), showing good agreement. Thus, we adopted this

76   simulation method to perform the simulations at the Heshan site.

77   The physical loss that parameterized as a first order dilution process was the same

78   as the daytime simulation in both the NBL and RL. We did the sensitivity tests

79   combined with the unconstrained OVOCs species (MVK+MACR), O_3, HNO_3 and

80   nitrate at the GIG and Heshan site, as shown in Fig.S2 and Fig.S3. A dilution rate of 24

81   h^{-1} for all species was determined at the GIG site, due to the good consistency between

82   the simulation and observation for the chosen species. Comparing with the diurnal

83   average observation, the simulated diurnal data had relative minor deviation with the

84   observation by dilution constant of 8 h^{-1}. The average variations were -19% for MVK

85   + MACR, -10% for O_3, 25% for HNO_3, and 12% for nitrate with the dilution constant

86   of 8 h^{-1} at the Heshan site. Thus, the dilution constant of 24 h^{-1} and 8 h^{-1} were used at

87   the GIG and Heshan site, respectively.

88   In addition to this dilution loss, the dry deposition rate for HNO_3 and O_3 were

89   treated as first-order loss reactions in the model, set as 2.7 and 0.42 cm s^{-1} in the daytime,

90   0.88 and 0.14 cm s^{-1} in the nighttime NBL, as the deposition rate is known to decrease

91   after sunset (Zhang et al., 2003;Womack et al., 2019).

Section S2 Thermodynamic ISORROPIAII model description

The presence of HNO_3 and NH_3 are conductive to form ammonium nitrate, which influenced by the aerosol pH and partitioning process of nitrate (Guo et al., 2018;Nenes et al., 2020). Thus, the thermodynamic ISORROPIA II model (Fountoukis and Nenes, 2007) was used to evaluate the NH_3 and sulfate impacts on the gas-particle partitioning process of nitrate. The model is run in the "forward" and "metastable" mode, which is used to calculate the gas-particle equilibrium concentrations. The model is based on the available input of total gas and particulate measured matter (HNO_3 + nitrate, NH_3 + ammonium, sulfate, and chloride), T and RH. The low concentration of nonvolatile cations (such as sodium, calcium, potassium, magnesium) in the PRD region is assumed to have minor impact on the thermodynamic equilibrium in PM_1 (Franchin et al., 2018;Guo et al., 2018).

Section S3 Calculation of nitrate production

The different mechanisms that increased nitrate concentrations in the simulations included three contributions: the reaction of OH and NO_2, heterogenous N_2O_5 uptake to the ground in the NBL, and nitrate mixed to the ground from the RL in the morning. The first two contributions were calculated by Eq. S (1) and Eq. S (2), combined with the R1 and R5 listed in the main text, which represented the nitrate production rate in surface boundary layer. The OH, N_2O_5 were based on the model results. $k_{[OH][NO_2]}$ was from the website of MCMv3.3.1 (https://mcm.york.ac.uk/).

$$P_{OH+NO_2} = k_{[OH][NO_2]}[OH][NO_2] * F \qquad\qquad S(1)$$

$$P_{NBL(N_2O_5\ uptake)} = \frac{\omega 1 * \gamma * Sa}{4}[N_2O_5](2 - \varphi) * F \qquad\qquad S(2)$$

The production rate of OH + NO_2 in the model is the total HNO_3 production rate. The nitrate production rate from N_2O_5 uptake in the NBL is based on S (2), here F represents the partition ratio between HNO_3 and nitrate, which is calculated by Cp/ (Cp + Cg), where Cp and Cg are the observed concentration of nitrate and HNO_3, respectively.

With the convective growth of the planetary boundary layer (PBL) following sunrise, the polluted species in RL are vertically entrained into the NBL, which changes

121 surface pollutant concentrations (Curci et al., 2015;Chen et al., 2020). We assume the

122 entrainment mixing process occurred from 6:00 to 10:00 (shown in Fig.S1 (c)), when

123 the height of PBL (H_{PBL}) increased from 400 m to 1000 m, on the contrary, the height

124 of RL (H_{RL}) linearly decreased from 600 m to 0 m, the nitrate produced from NBL and

125 RL would participate in this process. The instantaneous mixed nitrate concentration

126 (C_{mixed}) was the sum of nitrate mixed from RL (C_{RL}) and NBL (C_{NBL}), and the nitrate

127 enhancement from the mixing process (P_{mixed}) was calculated by the difference of mixed

128 nitrate concentration and the NBL nitrate concentration (C_{NBL}), which was described as

129 follows:

130 $$C_{mixed,i} = C_{RL,i} \times \frac{H_{RL,i-1}-H_{RL,i}}{H_{PBL,i}} + C_{NBL,i} \times \frac{H_{PBL,i-1}}{H_{PBL,i}} \qquad \text{S (3)}$$

131 $$P_{mixed,i} = C_{mixed,i} - C_{NBL,i} \qquad \text{S (4)}$$

132 here *i and i-1* represent the current and previous time step, the changing height of

133 different layers represent the weight coefficient of mixed nitrate concentration in RL

134 and NBL. The hourly surface nitrate production was the sum of P_{OH+NO2},

135 $P_{NBL(N_2O_5\ uptake)}$ and P_{mixed}, the total nitrate production in one day included the

136 integral production of P_{OH+NO2} in the daytime (7:00 to 17:00 LT), $P_{NBL(N_2O_5\ uptake)}$

137 in the nighttime (from 17:00 to 6:00 LT the following morning), and P_{mixed} from 6:00

138 to 10:00 LT in the morning.

139 **Section S4** Sensitivity test of isopleth diagrams from F0AM box model simulations.

140   In addition to the discussions about model simulation, several parameters used in

141 the box model might influence the simulation results, which include the concentrations

142 of HONO, the N_2O_5 uptake coefficient (γ) and the $ClNO_2$ yield (φ) (Lammel and Cape,

143 1996). Due to the uncertainty of HONO source and limited measurements, previous

144 studies used the ratio between HONO and NO_x to constrain HONO, such as 0.8% in

145 the high density traffic period in urban areas (Kurtenbach et al., 2001), 2% in the global

146 chemical transport model (Elshorbany et al., 2012;Tan et al., 2019). In this study, we

147 used the observed HONO as the base case, and ran the model in different sensitivity

148 scenarios: with 0.8% of NO_x, with 2% of NO_x and with 2% of NO_2 as HONO

149 concentrations (Fig. S13). Despite the different concentrations of HONO used in the

simulation, they all showed similar variation patterns for ozone and nitrate, indicating little influence of the HONO concentration parameterization on the simulation results. The γ and φ changed widely between laboratory and field studies (Mozurkewich and Calvert, 1988;Riedel et al., 2014;Wang et al., 2017;Yun et al., 2018;McDuffie et al., 2018). The parameterized γ and φ by updated empirical method by Yu et al. (2020) was applied in the base model. Here we chose the median value of γ (0.018) and φ (0.18) as the base input parameters; thus, different values of γ and φ were selected to perform sensitivity simulation (Fig. S14). Compared with the base case, the sensitivity of nitrate did not change with different values of γ and φ although the peak values of nitrate showed little differences with the changing of γ and φ. Overall, varying HONO, the N_2O_5 uptake coefficient, and the $ClNO_2$ yield would not be expected to change the sensitivity region of ozone and nitrate.

164 **Table S1.** Measured chemical species and the analytical methods, time resolution, limit of

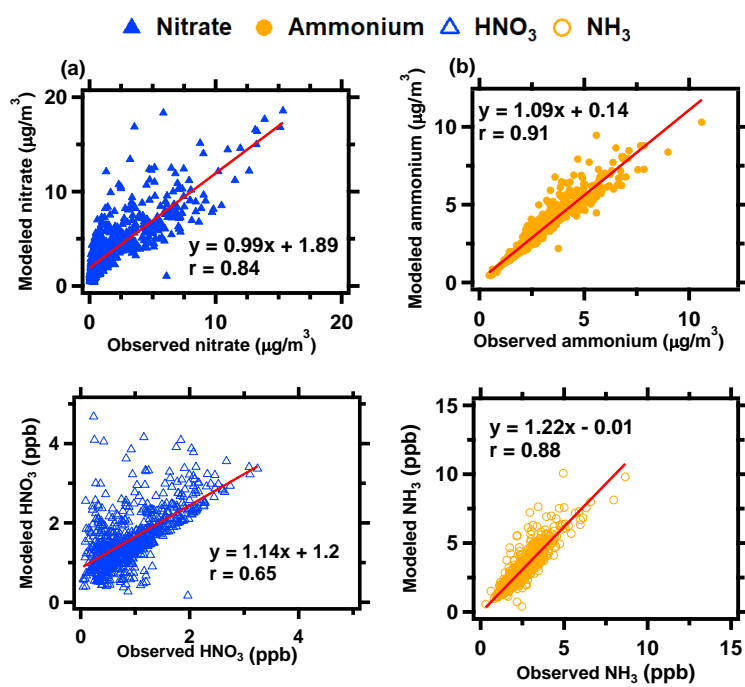

Figure S9. Scatter plot of observations vs ISORROPIAII modeled results of nitrate, ammonium, HNO_3 and NH_3 at the Heshan site during the study period.

Figure S10. Comparison of daily-averaged box model simulated and observed nitrate at the GIG and Heshan site.

Figure S11. Time series of the simulated trace gases ((a) NO_2, (b) NO_x, (c) O_3 and (d) O_x) in the RL, when the observations at 17:00 LT at GIG were setting as the initial inputs of the RL simulation and all chemical species were freely evolved in the box model. (e) the simulated nitrate and (f) nitrate production rate from N_2O_5 uptake with the observation data at the GIG (black line) and 488m Canton Tower (blue line) as the initial inputs in the RL. The observations at GIG and 488m site of Canton Tower are also shown for comparison. The error bars represent the standard deviation of the observations.

**Figure S12.** Comparison of the daily-averaged simulated nitrate concentration and production rate from N_2O_5 uptake in the NBL and RL at the (a, b) GIG site and (c, d) Heshan site**.** The error bars represent the standard deviation of the average data.
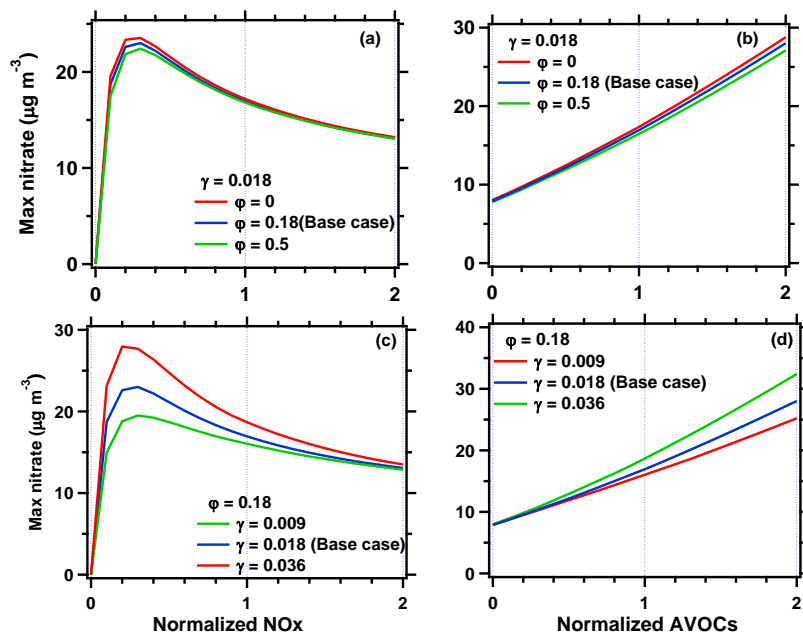

Figure S13. Sensitivity tests of HONO parameterization on the production of (a, b) ozone and (c, d) nitrate as a function of the normalized NOx and AVOCs relative to the base concentration at the GIG site.

287

288

Figure S14. Sensitivity tests of the production yield of ClNO$_2$ (φ value) and the uptake

parameter of N$_2$O$_5$ (γ value) on maximum nitrate concentrations as a function of the

normalized NOx and AVOCs relative to the base concentration at the GIG site.
