Abstract. This study estimates the influence of anthropogenic emission reductions on the concentration of particulate matter with a diameter smaller than 2.5 µm (PM$_{2.5}$) during the 2020 lockdown period in German metropolitan areas. After accounting for meteorological effects, PM$_{2.5}$ concentrations during the spring 2020 lockdown period were 5 % lower compared to the same time period in 2019. However, during the 2020 pre-lockdown period (winter), PM$_{2.5}$ concentrations with meteorology accounted for were 19 % lower than in 2019. Meanwhile, NO$_2$ concentrations with meteorology accounted for dropped by 23 % during the 2020 lockdown period compared to an only 9 % drop for the 2020 pre-lockdown period, both compared to 2019. SO$_2$ and CO concentrations with meteorology accounted for show no significant changes during the 2020 lockdown period compared to 2019. GEOS-Chem (GC) simulations with a COVID-19 emission reduction scenario based on the observations (23 % reduction in anthropogenic NO$_x$ emission with unchanged anthropogenic volatile organic compounds (VOCs) and SO$_2$) are consistent with the small reductions of PM$_{2.5}$ during the lockdown and are used to identify the underlying drivers for this. Due to being in a NO$_x$-saturated ozone production regime, GC OH radical and O$_3$ concentrations increased (15 % and 9 %, respectively) during the lockdown compared to a business-as-usual (BAU, no lockdown) scenario. O$_x$ (equal to NO$_2$ + O$_3$) analysis implies that the increase in ozone at nighttime is solely due to reduced NO titration. The increased O$_3$ results in increased NO$_3$ radical concentrations, primarily during the night, despite the large reductions in NO$_2$. Thus, the oxidative capacity of the atmosphere is increased in all three important oxidants, OH, O$_3$, and NO$_3$. PM nitrate formation from gas-phase nitric acid (HNO$_3$) is decreased during the lockdown as the increased OH concentration cannot compensate for the strong reductions in NO$_2$, resulting in decreased daytime HNO$_3$ formation from the OH + NO$_2$ reaction. However, nighttime formation of PM nitrate from N$_2$O$_5$ hydrolysis is relatively unchanged. This results from the fact that increased nighttime O$_3$ results in significantly increased NO$_3$, which roughly balances the effect of the strong NO$_2$ reductions on N$_2$O$_5$ formation. Ultimately, the only small observed decrease in lockdown PM$_{2.5}$ concentrations can be explained by the large contribution of nighttime PM nitrate formation, generally enhanced sulfate formation, and slightly decreased ammonium. This study also suggests that high PM$_{2.5}$ episodes in early spring are linked to high atmospheric ammonia concentrations combined with favorable meteorological conditions of low temperature and low boundary layer height. Northwest Germany is a hot-spot of NH$_3$ emissions, primarily emitted from livestock farming and intensive agricultural activities (fertilizer application), with high NH$_3$ concentrations in the early spring and summer months. Based on our findings, we suggest that appropriate NO$_x$ and VOC emission controls are required to limit ozone, and that should also help reduce PM$_{2.5}$. Regulation of NH$_3$ emissions, primarily from agricultural sectors, could result in significant reductions in PM$_{2.5}$ pollution.
1 Introduction

To halt the spread of the COVID-19 virus, various strict measures such as social isolation, curfews, and travel restrictions were implemented around the world in early 2020 (Steinmetz et al., 2020). As a result of these restrictions, anthropogenic emissions decreased significantly (Schumann et al., 2021; Le Quéré et al., 2020; Turner et al., 2020). Reduced primary emission activities from road transportation and industrial activities were expected to improve air quality. Numerous studies using satellite and in situ measurements have reported significant reductions in primary air pollutant concentrations during the COVID-19 lockdown period compared to pre-lockdown period in various parts of the world (Bauwens et al., 2020; Biswal et al., 2020; Collivignarelli et al., 2020; Dietrich et al., 2021; Field et al., 2021; He et al., 2021; Pathakoti et al., 2021; Mendez-Espinosa et al., 2020), but they also emphasize the importance of accounting for the effects of different meteorological conditions between the study period and the reference period (Barré et al., 2021; Grange et al., 2021; Kroll et al., 2020; Koutouki et al., 2021; Ordóñez et al., 2020; Solberg et al., 2021). Anomalies in air pollutant concentrations caused by changes in meteorological conditions were also separated from observed changes using modeling work to estimate the actual influence of COVID-19 lockdown restrictions on air pollutant concentration changes (Balamurugan et al., 2021; Goldberg et al., 2020; Kang et al., 2020; Petetin et al., 2020; Qu et al., 2021; Yin et al., 2021). Secondary pollutant concentrations (O$_3$ and PM$_{2.5}$), which are primarily produced by precursor gases through complex atmospheric chemical reactions, remarkably increased or did not reduce commensurate to precursor emission reductions seen in some parts of the world during the COVID-19 lockdown period (Campbell et al., 2021; Deroubaix et al., 2021; He et al., 2021; Huang et al., 2021; Keller et al., 2021; Lee et al., 2020; Putaud et al., 2021; Souri et al., 2021; Wang et al., 2020, 2021). Particulate matter (PM) is the sum of all particles (solid and liquid) suspended in air and can be classified based on aerodynamic behavior, i.e., aerodynamic diameter (AD). Particles with an AD smaller than 10 µm are referred to as PM$_{10}$ while particles smaller than 2.5 µm AD are referred to as PM$_{2.5}$. Understanding of seasonal and inter-annual variability of PM, particularly over urban areas, remains a challenge (Fuzzi et al., 2015). This is mainly due to a lack of understanding in the attribution of PM sources. PM sources include both direct/primary sources (vehicle and industrial emissions, windblown dust, pollen, wildfires, etc.) and secondary formation (gas-to-particle conversion process) via atmospheric chemical reaction of precursor compounds such as NO$_x$ (nitrogen oxides), SO$_2$ (sulfur dioxide), NH$_3$ (ammonia), VOCs (volatile organic compounds), and other organic compounds, including compounds that have partitioned from primary aerosol back to the gas phase, followed by partitioning to the condensed phase (Allen et al., 2015; Ayres et al., 2015; Fisher et al., 2016; Hallquist et al., 2009; Jacob, 1999; Jacobson, 1999; Marais et al., 2016; Seinfeld and Pankow, 2003; Seinfeld, 1998; Zhang et al., 2015). The composition of PM thus varies greatly depending on time and location; for example, in urban areas nitrate and organic aerosol often dominate in wintertime (Cesari et al., 2018; Juda-Rezler et al., 2020; Samek et al., 2020; Salameh et al., 2015; Womack et al., 2019; Zhai et al., 2021).

In this study, we mainly focus on the response of urban surface PM$_{2.5}$ to COVID-19 lockdown restrictions in Germany. Because major anthropogenic emissions are reduced, this unplanned intervention can test the understanding of the contribution of secondary PM$_{2.5}$ sources, as well as the processes important in secondary PM$_{2.5}$ formation. Despite significant reductions in some anthropogenic activities, natural and agricultural air pollutant sources were not affected by the COVID-19 lockdown measures. Ammonia (NH$_3$) emissions (primary sources) are a significant source of PM$_{2.5}$ in Germany in the spring (Fortems-Cheiney et al., 2016), when lockdown restrictions are implemented. Secondary inorganic aerosols such as ammonium sulfate and ammonium nitrate are the largest contributors to PM$_{2.5}$ in Europe (Pay et al., 2012; Petetin et al., 2016). In comparison to sulfate formation, nitrate formation is more dependent on NH$_3$ concentration (Erisman and Schaap, 2004; Sharma et al., 2007; Wu et al., 2008). In the winter and spring (low temperature and high relative humidity), the role of NH$_3$ in PM$_{2.5}$ formation is greater than in the summer (high temperature and low relative humidity) (Schiffler et al., 2016; Squizzato et al., 2013; Viatte et al., 2020). Primary components of PM$_{2.5}$ are directly proportional to primary emission, but secondary components of PM$_{2.5}$ are not directly proportional to secondary precursor emissions or concentrations as they are produced by non-linear complex atmospheric chemical reactions (Shah et al., 2018). Observational and modeling evidence is required to estimate the influence of change in precursor emissions on PM$_{2.5}$ concentrations. To this end, we used ground- and space-based measurements of PM$_{2.5}$, NO$_2$, O$_3$, SO$_2$, CO, and NH$_3$ in conjunction with GEOS-Chem simulations to investigate the influence of lockdown restrictions on PM$_{2.5}$ concentrations.

Modeling studies such as Gaubert et al. (2021), Hammer et al. (2021), Matthias et al. (2021), and Menut et al. (2020) have already reported the PM$_{2.5}$ changes across Europe, including Germany, during the COVID-19 lockdown period. The activity data (e.g., transportation, industrial activities, and energy production) were used in the abovementioned studies to create a COVID-19 emission reduction scenario (Doumbia et al., 2021; Guevara et al., 2021). However, there are large discrepancies between various activity datasets (Gensheimer et al., 2021), necessitating different approaches...
to estimating the actual emission reduction caused by the COVID-19 lockdown restrictions. In this study, GEOS-Chem simulations (using identical anthropogenic emission for 2020 and 2019) were used to estimate the observed pollutant concentrations changes with meteorology accounted for between 2020 and 2019, which were then used as a proxy for emissions reductions caused by COVID-19 lockdown measures to create a COVID-19 emission scenario in the GEOS-Chem model for simulating the lockdown pollutant concentrations (Fig. 1). In addition to looking at the impact of lockdown restrictions on air pollutant concentrations (Sect. 4.1), we focus on process level analysis of the impact of changes in precursor emissions (NOx) on PM2.5 formation (Sect. 4.2), as well as the role of ammonia (NH3) emissions in PM2.5 formation (Sect. 4.3).

2 Data and model

Datasets used in this study are summarized in Table 1. We focused on 10 metropolitan areas in Germany (Bremen, Cologne, Dresden, Düsseldorf, Frankfurt, Hamburg, Hanover, Leipzig, Munich, and Stuttgart) and used surface air pollutant concentration data (PM2.5, NO2, O3) for all of these while SO2 data were only available for five of these areas (Bremen, Dresden, Frankfurt, Hamburg, and Leipzig), and CO data were limited to six metropolitan areas (Bremen, Frankfurt, Hamburg, Hanover, Munich, and Stuttgart). We use data for 2019 and 2020 in this work (data obtained from https://discomap.eea.europa.eu/map/fme/AirQualityExport.htm, last access: 15 January 2022).

TROPOMI tropospheric SO2 (Theys et al., 2017) column products are also used (offline products-obtained from https://s5phub.copernicus.eu, last access: 15 January 2022). The TROPOMI SO2 product provides the total SO2 column between the surface and the top of the troposphere. The TROPOMI overpass occurs around 13:30 local time. At the start of the mission, the TROPOMI product provided data at a resolution of 7 km x 3.5 km, while after 6 August 2019 the resolution improved to 5.5 km x 3.5 km. Stricter quality filtering criteria (quality assurance value (qa) ≥ 0.5) were applied to the dataset. A daily mean of SO2 is calculated by averaging these values within 0.5° radius of the urban center.

The daily atmospheric NH3 variability in Germany was studied using the “near-real time daily IASI/Metop-B ULB-LATMOS ammonia (NH3) L3 product (total column)” dataset. This product contains a monthly averaged NH3 total column with a spatial resolution of 1° x 1° (products obtained from https://iasi.aeris-data.fr/catalog/, last access: 15 January 2022).

Temperature, relative humidity, boundary layer height, and wind information are obtained from the ERA5 product (Hersbach et al., 2020). This product’s native spatial and temporal resolutions are 0.25° and 1 h, respectively. For precipitation information, the GPCP daily gridded product from ERA5 is used, which provides global gridded data at 1° resolution (products obtained from https://cds.climate.copernicus.eu/, last access: 15 January 2022).

We used the GEOS-Chem (GC) chemical transport model (https://doi.org/10.5281/zenodo.3959279) to simulate the pollutant concentration for 2020 and 2019. The GC simulation conducted over Germany (45–57° N, 4–17° E) had a horizontal resolution of 0.5° x 0.625° with dynamic boundary conditions generated from a global simulation with 4° x 5° resolution. We ran the GC simulation for two cases. In the first case, anthropogenic emissions from the 2014 CEDS inventory (Hoesly et al., 2018), the most recent version of which is 2014, are used in the GC simulations for both 2019 and 2020, but with the corresponding meteorology from MERRA-2 global reanalysis product for 2019 and 2020. Natural emissions from soil and lightning are calculated for the corresponding year using mechanisms described in Hudman et al. (2012) and Murray (2016). The corresponding year’s open fire emissions from GFED4 (Werf et al., 2017) are used for 2019 and 2020. In the second case, the 2014 CEDS anthropogenic emission inventory was scaled down by the estimated emissions reduction caused by the lockdown restrictions for the 2020 lockdown period. The remaining (natural and fire) emissions are calculated in the same way as in the first case. Even though the 2014 CEDS anthropogenic emission inventory is used in GC simulations, the effects of anthropogenic emission changes between 2014 and 2019 or 2020 will be canceled out because we use the difference between two years (e.g., 2020–2019) or two cases (e.g., 2020lockdown − 2020no lockdown) in our study.

3 Method

The following is our methodology for estimating observed pollutant concentration changes with meteorology accounted for between 2020 and 2019, similar to Balamurugan et al. (2021) and Qu et al. (2021). We estimate the difference in pollutant concentrations between 2020 and 2019 caused by changes in meteorology using GC-simulated concentrations (first case). Since GC uses identical anthropogenic emission for 2020 and 2019, with the corresponding year’s meteorology, the difference between 2020 and 2019 GC pollutant (e.g., PM2.5) concentrations only results from meteorology.
Figure 1. Schematic diagram of our methodology for calculating the observed pollutant concentration changes with meteorology accounted for between 2020 and 2019 and GC pollutant concentration changes with emissions accounted for between 2020 lockdown and 2020 BAU scenarios.

</table>
changes between 2020 and 2019. We use $\Delta$ to signify absolute concentration change and $f$ to signify fractional (percentage) change.

$$\Delta PM_{2.5}(GC) = PM_{2.5}(GC, 2020) - PM_{2.5}(GC, 2019)$$  \hspace{1cm} (1)

The observed (ground-truth measurements) pollutant concentration changes between 2020 and 2019, which include the effects of lockdown restrictions and meteorology, are

$$\Delta PM_{2.5}(obs) = PM_{2.5}(obs, 2020) - PM_{2.5}(obs, 2019).$$  \hspace{1cm} (2)

To disentangle the meteorology contribution from the observed pollutant concentration changes, we subtract the GC pollutant concentration changes caused by meteorology from observed pollutant concentration changes between 2020 and 2019.

$$\Delta PM_{2.5}(obs, emi) = \Delta PM_{2.5}(obs) - \Delta PM_{2.5}(GC).$$  \hspace{1cm} (3)

The fractional change in pollutant concentration with meteorology accounted for between 2020 and 2019; i.e., fractional change (%) in pollutant concentration between 2020 and 2019 due to emission changes only, is calculated as

$$fPM_{2.5}(obs, emi) = \frac{\Delta PM_{2.5}(obs, emi)}{PM_{2.5}(obs, 2019)} \cdot 100,$$  \hspace{1cm} (4)

where “obs”, “GC”, and “obs,emi” refer to ground-truth measurements (observations data), GEOS-Chem simulations, and ground-truth measurements with meteorology accounted for, respectively.

We estimate the fractional change with meteorology accounted for in other pollutant concentrations analogously. Our previous study (Balamurugan et al., 2021), using the same methodology, reported the NO$_2$ and O$_3$ concentration changes with meteorology accounted for for eight German metropolitan areas. Here, we reproduce the results for NO$_2$ and O$_3$ concentrations, but for 10 metropolitan areas. We use $fNO_2(obs, emi)$ and $fCO(obs, emi)$ to capture fractional changes in anthropogenic NO$_x$ and VOC emission ($fNO_x(emission)$ and $fVOC(emission)$) due to lockdown restrictions, respectively. Because of the scarcity of VOC measurements, CO data were used as a proxy for anthropogenic VOCs (Fujita et al., 2003; Jiménez et al., 2005; Stephens et al., 2008; Yarwood et al., 2003), and NO$_2$ was used as proxy for NO$_x$. This assumption is supported by studies such as Baker et al. (2008) and Von Schneidemesser et al. (2010), which show anthropogenic VOCs are well correlated with CO, and Blanchard and Tanenbaum (2003), which shows comparable changes in VOCs and CO between weekdays and the weekend. Changes in biogenic VOCs are not directly affected by lockdown measures.

$$fNO_x(emission) \approx fNO_2(obs, emi)$$  \hspace{1cm} (5)

$$fVOC(emission) \approx fCO(obs, emi)$$  \hspace{1cm} (6)

The base anthropogenic emission inventory was then scaled down by $fNO_x(emission)$ and $fVOC(emission)$ for NO$_x$ and VOC emission, respectively, in the GC model for the 2020 lockdown period (second case), which simulates all pollutant concentrations for the lockdown emission scenario. The fractional change in GC pollutant levels with emissions accounted for, i.e., using scaled emission inventories, during the 2020 lockdown period compared to the 2020 business-as-usual (BAU), i.e., no lockdown, level is calculated as

$$fPM_{2.5}(GC, emi) = \frac{PM_{2.5}(GC, lock) - PM_{2.5}(GC, 2020)}{PM_{2.5}(GC, 2020)} \cdot 100,$$  \hspace{1cm} (7)

where “GC,emi” refers to GC simulations accounting for scaled emissions, and $PM_{2.5}(GC, 2020)$ is the $PM_{2.5}$ concentrations during the lockdown period determined via the 2020 GC simulations with down-scaled emissions. We estimate the concentration changes of other pollutants with emissions accounted for in the same way. Figure 1 illustrates our methodology for calculating the observed pollutant concentration changes with meteorology accounted for between 2020 and 2019, as well as GC pollutant concentration changes with emissions accounted for between 2020 lockdown and 2020 BAU scenarios.

4 Results and discussion

4.1 Influence of lockdown restrictions on the concentrations of air pollutants

To assess the impact of lockdown restrictions on the concentration of air pollutants, we compared the 2020 lockdown period pollutant concentrations to the same period in 2019. These comparison results, however, need to take the effects of both meteorological and lockdown restrictions into account. As mentioned in Sect. 3, we used GEOS-Chem simulations to disentangle the effects of meteorology on observed pollutant concentration changes between 2020 and 2019. Studies such as Balamurugan et al. (2021) and Tai et al. (2012) have shown that GEOS-Chem can reproduce the temporal variability of observed pollutant concentrations including $PM_{2.5}$, emphasizing that GC can be used for process level analysis of $PM_{2.5}$ variability. We also compared the 2019 GC and 2019 observed in situ $PM_{2.5}$ concentrations and found that the GC and observed in situ $PM_{2.5}$ concentrations were in good agreement ($R > 0.5$ for all metropolitan areas, except Leipzig, which has a $R$ value of 0.39). Table A1 shows the statistical evaluation ($R$, RMSE, and mean bias) of the GC model performance for each metropolitan area. The GC simulations underestimate the $PM_{2.5}$ when compared to observed in situ $PM_{2.5}$ concentrations (mean bias ($GC – in situ$) in situ) ranges from $-12.7\%$ to $-37.4\%$, except for the Cologne metropolitan area ($+11.7\%$). However, since we use the GC’s relative difference between 2020 and 2019,
this bias should cancel out. We also compared the 2019 GC simulated nitrate and ammonium concentration for the urban measurement station in Germany (51.75° N, 14.33° E). The statistical evaluation \((R, \text{RMSE}, \text{and mean bias})\) of the GC model performance for these species is given in Table B1.

Figure 2 shows mean \(\text{PM}_{2.5}, \text{NO}_2,\) and \(\text{O}_3\) concentration changes with meteorology accounted for between 2020 and 2019 for 10 German metropolitan areas from 1 January through 31 May. Mean \(\text{PM}_{2.5}, \text{NO}_2,\) and \(\text{O}_3\) concentration changes with meteorology both accounted for and unaccounted for between 2020 and 2019 for 10 German metropolitan areas are shown in Appendix Fig. A1. The German government imposed COVID-19 lockdown restrictions on 21 March 2020 in Germany. In figures and for specific cases, the pre-lockdown period (1 January to 20 March) is divided into two sections, and the lockdown period (21 March to 31 May) is also divided into two sections (unless otherwise specified): (a) 1 to 31 January 2020 – no lockdown restrictions; (b) 1 February to 20 March 2020 – no lockdown restrictions in the event of unusual weather conditions (occurrence of storms); (c) 21 March to 30 April 2020 (spring) – strict lockdown measures; and (d) 1 to 31 May 2020 (late spring) – loose lockdown measures. Germany experienced high wind conditions due to storms in February 2020 (Matthias et al., 2021), which was used to determine the extent of meteorology’s role in pollutant concentration changes. Mean \(\text{NO}_2\) and \(\text{PM}_{2.5}\) concentrations with meteorology accounted for for the 1 February to 20 March 2020 period (before the implementation of lockdown) are lower than the corresponding ones in 2019 by 30% and 42% \((f_{\text{NO}_2(\text{obs})} \text{ and } f_{\text{PM}_{2.5}(\text{obs})})\), respectively, due to the dilution and/or dispersion from the high wind conditions. However, after accounting for meteorology, the difference in mean \(\text{NO}_2\) and \(\text{PM}_{2.5}\) concentrations between 2020 and 2019 for the period from February 1 to March 20 \((f_{\text{NO}_2(\text{obs,ens})} \text{ and } f_{\text{PM}_{2.5}(\text{obs,ens})})\) is 8% and 18%, respectively. This finding is consistent with mean \(\text{NO}_2\) and \(\text{PM}_{2.5}\) changes with meteorology accounted for between 2020 and 2019 for the period from 1 January to 31 January (Fig. 2a, b). This highlights the importance of accounting for meteorological impacts.

In the 2020 pre-lockdown period (1 January to 20 March), both \(\text{NO}_2\) and \(\text{PM}_{2.5}\) levels with meteorology accounted for are lower by 9% and 19%, respectively, compared to the same period in 2019. During the 2020 lockdown period (21 March to 31 May), mean \(\text{NO}_2\) concentrations with meteorology accounted for dropped significantly (23%) compared to the same period in 2019, which is greater than the drop in the 2020 pre-lockdown period compared to 2019 (9%). Comparatively, mean 2020 lockdown \(\text{PM}_{2.5}\) concentrations with meteorology accounted for show a smaller reduction (5%) compared to the same period in 2019, while an important precursor, \(\text{NO}_2\), decreased by 23% during the same period. Furthermore, the \(\text{PM}_{2.5}\) reduction with meteorology accounted for during the 2020 lockdown period (5%) is less than the \(\text{PM}_{2.5}\) reduction with meteorology accounted for observed during the 2020 pre-lockdown period (19%) compared to the corresponding 2019 periods (Fig. 2). Especially in Munich and Stuttgart, \(\text{PM}_{2.5}\) concentrations with meteorology accounted for during the 2020 lockdown period are higher than in 2019. The mean \(\text{O}_3\) concentrations with meteorology accounted for in the 2020 lockdown period are increased by 6% compared to the same period in 2019. The increase in \(\text{O}_3\) concentration during the 2020 lockdown period is mainly due to being in a \(\text{NO}_x\)-saturated regime (Gaubert et al., 2021), in which reducing \(\text{NO}_x\) emission results in an increase in \(\text{O}_3\) concentrations (Sillman, 1999; Sillman et al., 1990). It is also possible that the increase in ozone is due to less ozone destruction via lower \(\text{NO}_x\) titration, in addition to an increase in ozone formation efficiency through \(\text{NO}_x\)-saturated regime chemistry. The mean \(\text{O}_3\) \((=\text{NO}_2+\text{O}_3)\) concentrations with meteorology accounted for in the 2020 lockdown period are 2% higher than in 2019 (Fig. 21a), implying that the reduced NO titration effect partly contributed to the increased ozone. \(\text{O}_3\) analysis also implies that the decrease in \(\text{NO}_2\) was offset by an increase in \(\text{O}_3\), and ozone production is overwhelmingly \(\text{NO}_x\) saturated in Germany.

The effects of lockdown restrictions on \(\text{SO}_2\) concentrations are insignificant. In comparison to 2019, TROPOMI \(\text{SO}_2\) levels with meteorology accounted for are decreased by 1% during the 2020 lockdown period compared to 2019 (Fig. A1). When accounting for meteorological impacts on TROPOMI satellite column concentrations, GEOS-Chem diagnostics (47 vertical layers) were converted to a column, applying TROPOMI’s averaging kernel. Because of the large influence of background concentration on satellite column measurements, we also investigated in situ \(\text{SO}_2\) concentrations, but only for five metropolitan areas. Similarly, we found that the impact of lockdown restrictions on in situ \(\text{SO}_2\) concentrations is marginal (Fig. B1). The road transportation sector contributes less than 1% of total sulfur dioxide emissions, while coal-related fuel burning (industrial and energy production) accounts for nearly 80% of total sulfur dioxide emissions \((\text{SO}_2, 2021)\). Because the lockdown restrictions primarily reduced traffic-related emissions, we see far less effects of the lockdown on \(\text{SO}_2\) concentration (slight increase or no significant decrease in other European metropolitan areas; Collivignarelli et al., 2020; Filonchyk et al., 2021; Higham et al., 2021). We found similar effects on in situ CO concentration changes in six metropolitan areas. The mean CO concentrations with meteorology accounted for are lower by 3% during the 2020 lockdown period compared to 2019 (Fig. B1). Stuttgart CO concentrations with meteorology accounted for in 2020 were higher than in 2019 at all times. Other metropolitan areas experienced minor reductions (Clark et al., 2021; Hörmann et al., 2021).
4.2 Model evidence of changes in air pollutant concentration resulting from lockdown restrictions

As mentioned in Sect. 3, we use the NO\textsubscript{2} and CO changes with meteorology accounted for to adjust the anthropogenic NO\textsubscript{x} and VOC emissions in inventories due to lockdown restriction impacts. GC model simulations are then obtained with this scaled anthropogenic emission scenario (23 % reduction in anthropogenic NO\textsubscript{x} emission and unchanged anthropogenic VOC emissions) for the 2020 lockdown period. The NO\textsubscript{x} emission reduction is within the range of estimated anthropogenic NO\textsubscript{x} emission reductions using activity data for Europe by previous authors (Doumbia et al., 2021; Guevara et al., 2021) (25 % and 33 %, respectively). For those studies there are large differences in estimated anthropogenic VOC emission changes for Europe; Doumbia et al. (2021) estimated 34 % while Guevara et al. (2021) estimated 8 % reduction in anthropogenic VOC emissions, compared to the BAU scenario. However, the real-time measurements at a UK station show no significant changes in many VOC concentrations during the lockdown period (Grange et al., 2021). For the NO\textsubscript{x}-saturated ozone production regime, VOC emission reductions can decrease ozone levels, while NO\textsubscript{x} emission reductions increase them. Gaubert et al. (2021) conducted a sensitivity study of modeling work on ozone levels in response to NO\textsubscript{x} or VOC or both emission reductions for the 2020 lockdown period. The reduction in both emissions (NO\textsubscript{x} and VOC), suggested by Doumbia et al. (2021), results in a slight increase in lockdown ozone levels (<2.5 %) over only northwestern Germany and a slight decrease in lockdown ozone levels over other regions of Germany, compared to BAU levels. However, only reduction in NO\textsubscript{x} emission results in increased lockdown ozone levels (0 %–10 %) over all of Germany compared to BAU levels, which is also consistent with our results of an increase in ozone levels with meteorology accounted for over different metropolitan areas across Germany during the 2020 lockdown period compared to 2019 levels. This implies that anthropogenic VOC emissions were either not reduced at all or by a much smaller percentage than anthropogenic NO\textsubscript{x} emissions, compared to the BAU scenario. According to the European Environment Agency (EEA) (https://www.eea.europa.eu/data-and-maps/indicators/eea-32-nitrogen-oxides-nox-emissions-1/assessment, last access: 15 January 2022), the road transport sector accounts for 40.5 % of total NO\textsubscript{x} emissions (https://www.eea.europa.eu/data-and-maps/indicators/eea-32-non-methane-volatile-1/assessment, last access: 15 January 2022). According to Guevara et al. (2021), the transportation sector accounts for nearly 90 % of the reduction in total anthropogenic NO\textsubscript{x} and VOC emissions during lockdown. As we noted that NO\textsubscript{x} emission decreased by 23 %, and
the lockdown restrictions primarily reduced traffic-related emissions, we can directly extrapolate this to a reduction in road-transportation-related emissions: approximately 43\% (23–40.5)/40.50\%). This finding also corresponds to a 40\% decrease in traffic vehicle count (Gensheimer et al., 2021). Therefore, the decrease in VOC emission from the transport sector should be 6\% (14.6 × 0.43). However, due to a significant decline in the transport sector’s VOC emissions in recent years, this reduction in VOC emissions from the transport sector, calculated based on the EEA’s 2015 data, should be even less than 6\%. There is also no evidence that lockdown measures affect the major source of VOC emissions, which is use of volatile chemical products such as cleaning agents and personal care products, as well as biogenic emissions.

The GC lockdown NO\textsubscript{2} concentrations with emissions accounted for decreased by 21\% (f\textsubscript{NO\textsubscript{2}(GC, envi)}) while GC lockdown O\textsubscript{3} concentrations with emissions accounted for increased by 9\% compared to 2020 BAU (Fig. 3). This is consistent with previous studies (such as Balamurugan et al., 2021; Gaubert et al., 2021), which show that German metropolitan areas are in a NO\textsubscript{3}\textsuperscript{-} saturated production regime in spring. However, the diurnal cycle of GC O\textsubscript{3} changes between 2020 lockdown and BAU suggests that nighttime ozone increases are solely due to a decrease in NO titration effects (Fig. C1b). The GC lockdown PM concentrations with emissions accounted for show small decreases compared to 2020 BAU (Fig. 3). These results are consistent with previous studies (Gaubert et al., 2021; Hammer et al., 2021; Matthias et al., 2021; Menut et al., 2020), which used activity data to develop an emission reduction scenario and estimated small to no reduction in PM\textsubscript{2.5}, a significant drop in NO\textsubscript{2}, and a marginal increase in O\textsubscript{3} levels during the 2020 lockdown period, compared to BAU levels, over northern Europe including Germany.

We investigated the GC PM\textsubscript{2.5} composition for the studied period to determine the role of reduced NO\textsubscript{4} emission in total PM\textsubscript{2.5}. Major secondary PM\textsubscript{2.5} components are nitrate, sulfate, ammonium, and organic aerosol, which, on average, correspond to 24\%, 23\%, 15\%, and 30\% of total PM\textsubscript{2.5}, respectively, from 21 March to 31 May 2019 (Fig. D1). Mean relative contribution of PM\textsubscript{2.5} species for 2020 (BAU) and 2020 (lockdown) is shown in Figs. E1 and F1, respectively. The GC PM nitrate levels with emissions accounted for during the 2020 initial lockdown period (21 March to 30 April) are 9.5\% lower than the 2020 BAU levels (f\textsubscript{NIT(GC, envi)}) (Fig. 3a); however, we see NO\textsubscript{2} decreased by 21\% during the same period. The decrease in GC PM nitrate with emissions accounted for is also less than the decrease in NO\textsubscript{2} during the second half of the lockdown (1 May to 31 May). The GC lockdown PM sulfate level with emissions accounted for shows a marginal increase (3.5\%), while GC lockdown PM ammonium with emissions accounted for shows a marginal decrease (5.8\%), compared to the 2020 BAU level. The slight increase (and decrease) in sulfate (and ammonium) was also found in the studies of Hammer et al. (2021) and Matthias et al. (2021), who used activity data to adjust the COVID-19 emission scenario.

It is notable that the reduction in NO\textsubscript{3}, a precursor to PM nitrate, does not directly translate into a decrease in PM nitrate formation. There are several pathways for the formation of nitric acid (HNO\textsubscript{3}), which partitions to PM nitrate (Allen et al., 2015; Bauer et al., 2007). The reaction of OH and NO\textsubscript{2} (homogeneous pathway) and the hydrolysis of N\textsubscript{2}O\textsubscript{5} on aerosol particles (heterogeneous pathway) are the two major pathways (Chang et al., 2011, 2016; Mollner et al., 2010).

The reaction for HNO\textsubscript{3} formation via gas-phase oxidation of NO\textsubscript{2} by OH is:

\[
\text{NO}_2 + \text{OH} \rightarrow \text{HNO}_3. \tag{R1}
\]

The reactions resulting in HNO\textsubscript{3} formation via hydrolysis of N\textsubscript{2}O\textsubscript{5} on aerosol surfaces are:

\[
\text{NO}_2 + \text{O}_3 \rightarrow \text{NO}_3 + \text{O}_2, \tag{R2}
\]
\[
\text{NO}_3 + \text{NO}_2 \leftrightarrow \text{N}_2\text{O}_5, \tag{R3}
\]
\[
\text{N}_2\text{O}_5 + \text{H}_2\text{O}(l) \rightarrow 2\text{HNO}_3. \tag{R4}
\]

The formation of HNO\textsubscript{3} from the reaction of OH and NO\textsubscript{2} dominates during the day, while hydrolysis of N\textsubscript{2}O\textsubscript{5} on aerosol particles dominates at night as OH nighttime concentrations are low and N\textsubscript{2}O\textsubscript{5} photolyzes easily (Russell et al., 1986). At night, the NO\textsubscript{3} radical can be an important precursor for PM nitrate via reactions (Reactions R3, R4) (Kang et al., 2021; Shah et al., 2020; Wang et al., 2013). The concentrations of OH and NO\textsubscript{3} with emissions accounted for, which drive day and nighttime formation of PM nitrate, increased substantially (15\% and 12\%, respectively) during the lockdown period compared to BAU (Fig. 3). The increase in OH radicals results from German metropolitan areas being in a NO\textsubscript{3}\textsuperscript{-} saturated regime (Shah et al., 2020). The increase in GC lockdown NO\textsubscript{3} levels is predominantly at night due to a significant increase in nighttime O\textsubscript{3} (Fig. 4b, e); the reaction of NO\textsubscript{2} with O\textsubscript{3} is the most important source of NO\textsubscript{3} radicals (Reaction R2) (Geyer et al., 2001).

Liu et al. (2020) have demonstrated that analyzing the diurnal cycle of total inorganic nitrate helps to identify the dominant pathway for the particulate nitrate production. The GC lockdown PM nitrate levels with emissions accounted for decreased significantly during the day, while nighttime lockdown PM nitrate levels decreased slightly compared to BAU levels (Fig. 4h). Even though GC lockdown OH levels increased, HNO\textsubscript{3} production from the OH + NO\textsubscript{2} reaction during the lockdown period is reduced due to significantly lower daytime NO\textsubscript{2} levels compared to BAU (Fig. 4d); as a result, GC daytime lockdown PM nitrate levels are significantly lower compared to BAU levels. However, higher nighttime NO\textsubscript{3} levels result in relatively unchanged nighttime HNO\textsubscript{3} production from N\textsubscript{2}O\textsubscript{5} hydrolysis, resulting in slightly lower nighttime lockdown PM nitrate compared to...
BAU (Fig. 4b, e, f, g). This implies that the increase in NO$_3^-$ radicals due to increased ozone partially offsets the effect of reduced NO$_x$ on nitrate formation. Previous studies have also shown that N$_2$O$_5$ hydrolysis plays a more important role in nitrate formation than the gas-phase daytime pathway (NO$_2$ + OH) (Allen et al., 2015; Chan et al., 2021; Kim et al., 2014; Liu et al., 2020; Yan et al., 2019). Figure 5 illustrates the conceptual model of generalized daytime and nighttime lockdown NO$_x$ chemistry compared to the BAU scenario. The oxidation of SO$_2$ is a major source of sulfate, and the reaction with the OH radical dominates the gas-phase oxidation of SO$_2$ (Zhang et al., 2015). Therefore, the enhanced sulfate formation during the 2020 lockdown period could be due to the increased oxidizing capacity of atmosphere (OH) since we observe no significant change in GC SO$_2$ concentration with emissions accounted for, compared to BAU concentration (Fig. 3). Organic aerosol (OA) formation could be affected by the changes in oxidizing capacity of the atmosphere (Carlton et al., 2009), but no changes in GC lockdown OA with emissions accounted for were observed compared to the 2020 BAU scenario. Therefore, the fact that no significant change in PM$_{2.5}$ due to lockdown restrictions is observed can be explained by a significant offset of the decreased daytime PM nitrate formation by enhanced formation of PM sulfate, while PM ammonium shows a marginal decrease.

4.3 Link between spring PM$_{2.5}$ pollution episodes and high NH$_3$ concentrations

It is worth noting that a significant fraction of PM$_{2.5}$ is PM nitrate. Ammonia (NH$_3$) is an important precursor for particulate nitrate formation (Ansari and Pandis, 1998; Banzhaf et al., 2013; Behera and Sharma, 2010; Wu et al., 2016). This explains the importance of monitoring and potentially regulating ammonia emissions. Therefore, the inter- and intra-annual changes in ammonia (NH$_3$) concentrations over Germany, as well as their relationship to PM$_{2.5}$ variability, are reviewed and analyzed further below. In Germany, atmospheric NH$_3$ levels follow a monthly pattern, with NH$_3$ levels peaking in April (Fig. 6). NH$_3$ levels are also elevated during summer months. In Europe, major agricultural practices (fertilizer and manure applications) take place in the early spring (Petetin et al., 2016; Ramanantenasoa et al., 2018; Viatte et al., 2020). The higher atmospheric ammonia levels in April are attributable to agricultural practices such as fertilizer application. The high NH$_3$ values in summer are most likely due to the warm climate (Kuttippurath et al., 2020). Monthly average NH$_3$ maps clearly show the high NH$_3$ values over northwest Germany from April to August, with particularly high values in April. This indicates that northwest Germany is a hot-spot of ammonia emissions compared to the rest of the country. Northwest Germany is known for its high livestock density (livestock farming; EUROSAT, 2013; Scarlat et al., 2018), and it is dominated by cropland and grassland (ESA, 2017). Livestock farming and fertilizer application account for 75% of NH$_3$ emissions in Europe (Webb et al., 2005). NH$_3$ concentrations in Germany vary greatly from year to year (inter-annual variabilities). We consider the period between 21 March and 30 April when a stricter lockdown was in place to illustrate the inter-annual variability of atmospheric NH$_3$ between 2018 and 2020 (Fig. 7). NH$_3$ levels are lower in 2019 than in 2018, which can be attributed to the lower temperature in 2019 compared to 2018. Meanwhile, even though a strict lockdown was in place, NH$_3$ levels in 2020 are higher than in 2019 and 2018, possibly due to low precipitation. High temperatures promote NH$_3$ volatilization (increases the NH$_3$ level in the atmosphere) (Ernst and Massey, 1960), whereas high rainfall favors wet deposition (removal of atmospheric NH$_3$). Schiferl et al. (2016) and Viatte et al. (2020) have also shown that mete-
Figure 4. Diurnal cycle of GC NO\textsubscript{2}, O\textsubscript{3}, OH radical, HNO\textsubscript{3} production from oxidation of NO\textsubscript{2} by the OH pathway, NO\textsubscript{3} radical, N\textsubscript{2}O\textsubscript{5}, HNO\textsubscript{3} production from the N\textsubscript{2}O\textsubscript{5} hydrolysis pathway, PM nitrate, sulfate, and ammonium concentration changes with emissions accounted for between 2020 lockdown and 2020 BAU (no lockdown) scenarios ($\mathcal{f}X_{(GC,emi)}$). Error bars represent the standard error of the respective hour in 10 metropolitan areas.
orological parameters such as temperature and precipitation play a greater role in NH₃ inter-annual variability.

High-PM-pollution episodes are likely to occur frequently during the winter due to high residential heating demand and favorable meteorological conditions (e.g., low temperature and inversion condition). However, high concentrations of PM₂.₅ are apparent in German metropolitan areas in the early spring (from the second half of March to the end of April, e.g., Fig. 8a for Munich metropolitan area). On 21 March 2020, the German government imposed COVID-19 lockdown restrictions. However, in situ PM₂.₅ concentrations during the initial lockdown period are higher than during the pre-lockdown period in 2020. High PM₂.₅ levels from the second half of March to the end of April are also consistent with previous years without lockdown restrictions. The high PM₂.₅ events that occur in the spring have also been observed in other European cities, and they typically contain ammonium nitrate and ammonium sulfate (Fortems-Chiney et al., 2016; Renner and Wolke, 2010; Schaap et al., 2004; Viatte et al., 2020, 2021). Above, we show the high NH₃ levels in early spring (April) and summer months. High PM₂.₅ concentrations are evident in spring; however, we did not observe high-PM₂.₅ episodes in summer (Fig. 8a). It is also worth noting that even in the spring and winter PM₂.₅ is not consistently high on days with high NH₃. This reflects the complexity of the process of gas-to-particle conversion. Despite high NH₃ concentrations, ammonia (NH₃)-to-ammonium (NH₄⁺) conversion is mainly driven by various meteorological factors such as temperature (and relative humidity). Studies (Viatte et al., 2020; Wang et al., 2015; Watson et al., 1994) have shown that conditions such as temperature of less than 10 °C and a high relative humidity of more than 70% are optimal for atmospheric gas-phase NH₃ to transform into ammonium salts, mainly due to reversible ammonium nitrate formation, which depends on temperature and relative humidity; warm and dry conditions partition ammonia back to the gas phase (Mozurkewich, 1993). In comparison to summer, the impact of NH₃ on PM₂.₅ formation is considerable for winter and spring over Europe (Viatte et al., 2020, 2021) and the US (Schiferl et al., 2016). Summer weather is typically warmer (and has lower relative humidity) than winter and spring, which could explain why high NH₃ concentrations are not associated with high PM₂.₅ in summer or late spring. Furthermore, it is important to note that PM₂.₅ anthropogenic precursor emissions (NOₓ, SO₂, VOCs) have a seasonal cycle, with higher emissions in winter than summer; however, biogenic VOC emissions dominate in the summer. To further demonstrate the relationship between PM₂.₅ and NH₃ for German metropolitan areas, we consider two cases ("Simultaneous" and "Independent") for 2018 and 2019 (e.g., Fig. 8b for Munich metropolitan area). Simultaneous is the simultaneous increase in NH₃ (IASI) and PM₂.₅ (in situ) concentrations on the same day. Independent is the increase in NH₃ (IASI) concentration not corresponding to an increase in PM₂.₅ (in situ) concentration on the same day. As an example, for the Munich metropolitan area, the temperature and boundary layer height for the Simultaneous case (14.8 ± 8.3 °C and 557.9 ± 193.4 m, respectively) are lower than for the Independent case (15.5 ± 5.4 °C and 599.8 ± 196.3 m, respectively). In addition to low temperature, low boundary layer height results in higher pollutant concentrations and can thus result in more intense atmospheric chemical reactions. We found similar results for other metropolitan areas, but with different absolute values (Ta-
The regional differences are unsurprising, because other factors also influence the formation of PM$_{2.5}$ from NH$_3$ (e.g., other precursor concentrations such as NO$_x$ and SO$_x$). However, these findings support previous studies and imply that low temperature and low boundary layer height are most favorable for the formation of PM$_{2.5}$ during the periods of high NH$_3$.

5 Conclusions

Our study estimates the influence of anthropogenic emission reductions on PM$_{2.5}$ concentration changes during the 2020 lockdown period in German metropolitan areas. Mean PM$_{2.5}$ concentrations with meteorology accounted for decreased by 5% during the 2020 lockdown period (spring) compared to the corresponding period in 2019. However, during the 2020 pre-lockdown period (winter), PM$_{2.5}$ concentrations with meteorology accounted for are 19% lower than in 2019. Meanwhile, NO$_2$ levels with meteorology accounted for de-
increased 23% during the 2020 lockdown period, which is a larger decrease than in the 2020 pre-lockdown period compared to 2019 (9%). No significant change in SO2 and CO concentrations with meteorology accounted for was observed during the 2020 lockdown period, compared to 2019.

The GC model with the COVID-19 emission reduction scenario based on observations (23% reduction in anthropogenic NOx emissions with unchanged anthropogenic VOCs and SO2) supports our findings of only a marginal decrease in PM2.5 and a significant decrease in NO2 levels. Due to being in a NOx-saturated ozone production regime, the GC lockdown OH and O3 concentrations increased by 15% and 9%, respectively, compared to BAU levels. However, O3 analysis suggests that the only increase in ozone during the daytime is due to increased ozone production efficiency via NOx-saturated regime chemistry, whereas the increase at nighttime is due to decreased NO titration. Despite an increase in OH radicals, the GC lockdown PM nitrate formation decreased significantly during the day, due to a significant decrease in NO2, compared to the BAU scenario. Increased nighttime ozone, however, results in increased nighttime NO3, despite decreased NO2, in turn, resulting in slightly increased nighttime N2O5 concentration and only a small change in nighttime PM nitrate. Overall this results in a small decrease in daily PM nitrate. In addition, the increased OH concentration results in a marginal increase in sulfate formation. Nitrate, sulfate, ammonium, and organic aerosol are the major secondary components of PM2.5. The decreased daytime PM nitrate is partially offset by the enhanced PM sulfate, and there is no significant impact from slightly decreased PM ammonium and no change in organic aerosol, resulting in a marginal decrease in PM2.5 concentrations during the lockdown period.

Based on our findings, we suggest that additional emission control measures aimed at reducing ozone pollution be implemented, which should also help reduce PM. A concurrent reduction of NOx and VOC emissions should occur. Otherwise, ozone levels will rise as NOx emissions drop, increasing oxidizing capacity, until a NOx-limited ozone production regime is reached. We also addressed the annual

spring PM$_{2.5}$ pollution episodes in German metropolitan areas, which are associated with high NH$_3$ concentrations. Northwest Germany is a hot-spot of NH$_3$ emissions, primarily emitted from livestock farming and intensive agricultural activities (fertilizer application), with high NH$_3$ concentrations in the early spring and summer months. Winter and spring meteorological conditions are more favorable for PM$_{2.5}$ formation from NH$_3$ than summer. Unsurprisingly, low temperature (and low boundary layer height) is shown to be a favorable meteorological condition for the formation of PM$_{2.5}$ from NH$_3$. Regulation of NH$_3$ emissions, primarily from agriculture, has the potential to reduce PM$_{2.5}$ pollution significantly in German metropolitan areas.

In this study, a COVID-19 emission reduction scenario was created using proxy pollutant concentration changes with meteorology accounted for, assuming that observed proxy pollutant concentration changes are due to the combined direct effects of emission and meteorology changes. Our GC modeling study work reflects the assumed direct relationship between changes in NO$_2$ concentration with meteorology accounted for and changes in NO$_x$ emission. This work also shows a direct relationship between changes in SO$_2$ (and CO) concentration with meteorology accounted for.)
and changes in SO$_2$ (and CO) emission. However, due to the non-linear feedback system in atmospheric chemistry, this assumption should be investigated further. Because of their similar sources, we use CO concentration as a proxy for anthropogenic VOC concentration. However, this is debatable because VOCs are more reactive than CO. We call for further advancements in estimating the emission changes during the lockdown period, which would allow us to estimate the precise sensitivity of PM$_{2.5}$ to changes in emissions from various sources and comparison of VOC emission inventories with observations. This will help in the implementation of appropriate air quality regulation strategies in the future. Organic aerosol accounts for nearly 30% of total PM$_{2.5}$, which could be influenced by both primary/secondary biogenic and anthropogenic sources. However, our study is limited to examining the effects of NO$_x$ emission changes on PM$_{2.5}$ formation. Therefore, future studies on VOC emission changes on OA formation during high-PM-pollution episodes, particularly in the spring, will be more important in mitigating PM pollution.

Figure C1. Mean changes in in situ O\(_X\) with meteorology accounted for between 2020 and 2019 (a). Diurnal cycle of GC O\(_X\) concentration changes with emissions accounted for between 2020 lockdown and 2020 BAU (no lockdown) scenarios \(fX_{(GC,emi)}\) (b). Error bars represent the 1 \(\sigma\) of the mean of 10 metropolitan areas.
Appendix D

Figure D1. Mean relative contributions of PM$_{2.5}$ species simulated by GC for 2019.

Appendix E

Figure E1. Mean relative contributions of PM$_{2.5}$ species simulated by GC for 2020 (no lockdown).

Appendix F

Figure F1. Mean relative contributions of PM$_{2.5}$ species simulated by GC for 2020 (lockdown).

Author contributions. VB and XB obtained the measurement data. ZQ performed the modeling work. VB analyzed the data and wrote the manuscript draft. JC and FNK supervised the work and data. VB and XB obtained the measurement (Copernicus Climate Change Service, 2022).

Competing interests. The contact author has declared that neither they nor their co-authors have any competing interests.

Disclaimer. Publisher’s note: Copernicus Publications remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Acknowledgements. The authors thank the European Environment Agency, Copernicus Services, the Aeris data infrastructure, and the Copernicus Climate Change Service for providing access to the various datasets used in this study.

Financial support. This research has been supported by the Institute for Advanced Study, Technical University of Munich (grant no. 291763) and the German Research Foundation (grant no. 419317138).

This work was supported by the German Research Foundation (DFG) and the Technical University of Munich (TUM) in the framework of the Open Access Publishing Program.

Review statement. This paper was edited by Theodora Nah and reviewed by Ke Li and two anonymous referees.
