Abstract. Atmospheric age reflects how long particles have been suspended in the atmosphere, which is closely associated with the evolution of air pollutants. Severe regional haze events occur frequently in China, influencing air quality, human health, and regional climate. Previous studies have explored the characteristics of mass concentrations and compositions of fine particulate matter (PM₂.₅) during haze events, but the evolution of atmospheric age remains unclear. In this study, the age-resolved University of California, Davis/California Institute of Technology (UCD/CIT) model was developed and applied to simulate the concentration and age distribution of PM₂.₅ during a severe regional haze episode in eastern China. The results indicated that PM₂.₅ concentrations in the North China Plain (NCP) gradually accumulated due to stagnant weather conditions during the beginning stage of the haze event. Accordingly, the atmospheric age of nitrate (NO₃⁻) particles decreased. During the regional transport stage, aged particles from the NCP moved to the downwind Yangtze River Delta (YRD) region, leading to a sharp increase in PM₂.₅ concentrations and the average age of EC, POA, SO₄²⁻, and SOA in YRD. In contrast, the average age of NO₃⁻ and ammonium remained unchanged or even slightly decreased due to continuous local formation in the YRD region. Different evolution of the atmospheric age among these components provides a unique perspective on the formation of PM₂.₅ during the regional haze event. The information can also be used for designing effective control strategies for different components of PM₂.₅.

1 Introduction

Haze pollution is a chronic environmental issue in China, influencing atmospheric visibility (Li et al., 2019; Pui et al., 2014), human health (C. Wang et al., 2021; Lelieveld et al., 2015; Cohen et al., 2017), ecosystems (Xie et al., 2020; Gu et al., 2002; Cirino et al., 2014), and climate (Ramanathan et al., 2001; Seinfeld et al., 2016; IPCC, 2021). Fine particulate matter, also known as PM$_{2.5}$, the major pollutant during haze days, is either directly emitted into the atmosphere or formed from precursor gases through chemical processes. Although the annual mean PM$_{2.5}$ concentrations in Chinese megacities have been substantially reduced in recent years because of the strict emission control measures (Wang et al., 2019; Q. Zhang et al., 2019), severe regional haze pollution (PM$_{2.5}$ > 150 µg m$^{-3}$) still frequently occurs in densely populated regions, such as the North China Plain (NCP) and the Yangtze River delta (YRD; An et al., 2019).

Intensive pollutant emissions and unfavorable meteorology are two key factors controlling haze formation. NCP and YRD are two major city clusters in eastern China with intensive anthropogenic emissions. Previous studies have revealed that severe winter haze events in the NCP were initialized by the accumulation of local emissions under stable weather conditions and further deteriorated by rapid secondary formation (An et al., 2019; Zheng et al., 2015). Polluted air masses in the NCP are rapidly eliminated by the strong prevailing northwesterly wind and moved downwind to the YRD regions (X. Wang et al., 2021). During the long-range transport, freshly emitted particles gradually age and mix with secondary inorganic and organic species, further influencing regional climate and air quality through aerosol–planetary boundary layer (PBL) interaction (Huang et al., 2020; Zhang et al., 2021).

The atmospheric age of an air pollutant, defined as the time since it is emitted or formed, provides a unique perspective on the evolution of pollutants in the atmosphere (Wagstrom and Pandis, 2009; Ying et al., 2021; H. Zhang et al., 2019). Unlike the lifetime or residence time of pollutants, atmospheric age refers to the time that a single particle remains in the atmosphere at a given location and time, which can better reflect its instantaneous physical and chemical properties (Chen et al., 2017). However, measuring and calculating the atmospheric age of air pollutants is difficult because of their chemical nonlinearity and process complexity. Previous studies have attempted to track particle age distributions by adding tracers in Lagrangian trajectory models such as FLEXPART (Stohl et al., 2003). However, due to the simplified chemistry, this method cannot accurately determine the age distributions of secondary species. Some other studies estimated the photochemical age of an air mass using the ratio of hydrocarbons, including toluene / benzene and ethylbenzene / benzene (Chu et al., 2021; Parrish et al., 2007).

Since the oxidation rates of these hydrocarbons by hydroxyl (OH) radicals vary widely, the hydrocarbon ratios change with photochemical aging (Chen et al., 2021). By this definition, the photochemical age determines the degree of photochemical processing associated with OH radicals rather than the physical age of pollutants (Irei et al., 2016).

A few attempts were made to track the age distribution of aerosols using chemical transport models (CTMs; Han and Zender, 2010; Wagstrom and Pandis, 2009; Wu et al., 2017). CTMs can reproduce the evolution of pollutants in the atmosphere (including emission, transport, deposition, and chemical transformation). H. Zhang et al. (2019) introduced a dynamic age-bin-updating algorithm in the source-oriented University of California, Davis/California Institute of Technology (UCD/CIT) air quality model to track the age distribution of primary PM$_{2.5}$. In their study, chemical variables in the UCD/CIT model were expanded by adding an additional dimension to represent pollutants with varying atmospheric ages, and the evolution of particle concentrations between different age bins was dynamically updated at a fixed frequency. The dynamic age-bin-updating algorithm can be represented in Eq. (1).

\[
\begin{align*}
C^{t+1}_n &= C^n_t + C^{n-1}_t, \\
C^n_0 &= C^n, \quad t = 1, \ldots, n,
\end{align*}
\]

where $t$ is the age bin index, and $n$ is the total number of age bins. More recently, this dynamic age-bin-updating algorithm was used to determine the age distribution of primary and secondary inorganic compounds in the Community Multiscale Air Quality (CMAQ) model (Ying et al., 2021). In this study, we further developed the age-resolved UCD/CIT model to track the atmospheric age distribution of various primary and secondary components of PM$_{2.5}$, based on the method used by H. Zhang et al. (2019). Different from that of Ying et al. (2021), the atmospheric age of secondary aerosols is calculated based on the time they are formed in the atmosphere. Then we applied the model to investigate the evolution of the concentrations and ages of the major PM$_{2.5}$ components during a typical winter haze episode in eastern China.

2 Methods

2.1 Description of UCD/CIT model

The source-oriented UCD/CIT air quality model (Held et al., 2004; Hu et al., 2014, 2015; Kleeman and Cass, 2001; Ying et al., 2007; Ying and Kleeman, 2006) was used in this study to simulate air quality in eastern China. The UCD/CIT model is a 3-dimensional Eulerian regional CTM with detailed chemistry and aerosol mechanisms. Details about the fundamental algorithms used in the UCD/CIT model can be found in the above references. Briefly, gas-phase chem-
istry is modeled by the SAPRC-11 chemical mechanism (Carter and Heo, 2013). Aerosols are represented using a sectional approach, with 15 log-spaced size bins encompassing 10 nm–10 µm. Thermodynamic equilibrium for inorganic aerosols is calculated by ISORROPIA (Nenes et al., 1998). Secondary organic aerosol (SOA) treatment is based on the two-product model used in the Community Multiscale Air Quality (CMAQ) model, including a total of 19 semivolatile or nonvolatile species from seven precursors (Carlton et al., 2010).

In most existing air quality models, particles from diverse emission sources are mixed. However, the UCD/CIT model applies a source-oriented framework in which primary and secondary particles from each source category are tracked separately through the calculation of all major atmospheric processes, such as advection, diffusion, deposition, and gas particle partitioning. Thus, the source contributions to regional particle concentrations can be evaluated. H. Zhang et al. (2019) expanded the source-oriented UCD/CIT model to track the age distribution of elemental carbon (EC) in the atmosphere. In this study, we implemented the atmospheric age distribution modeling framework to track the age distribution of both primary and secondary aerosols. The age distribution of SOA was added to the framework, making it possible to have complete age-resolved modeling of secondary aerosols.

The age-resolved UCD/CIT model employs a sectional approach to track particles of different atmospheric ages (n age bins). Freshly emitted or formed particles at each model time step are set to the lowest age bin. At a fixed age-bin-updating frequency (Δτ), particles in the lower age bin would be moved to the higher age bin successively. Particles in the last age bin represent those older than the highest explicit age. The average age of particles in the i-th age bin (τ_i) is approximately equal to the middle of that period.

\[
τ_i = \left( i - \frac{1}{2} \right) Δτ, \quad i = 1, 2, \ldots, n. \tag{2}
\]

The average age of particles can be calculated by

\[
\bar{τ} = \frac{\sum τ_i C_i}{\sum C_i}. \tag{3}
\]

2.2 Model setup

The age-resolved UCD/CIT model was run from 21 December 2017 to 2 January 2018, with the first 4 d as the spin-up period to minimize the impact of initial conditions. The model domain has a horizontal resolution of 36 km that encompasses eastern China (Fig. 1) and a vertical structure of 16 layers with 10 layers below 1 km. Hourly meteorological inputs were generated by the Weather Research Forecasting (WRF) model version 4.2 with initial and boundary conditions from the 1.0° × 1.0° National Centers for Environmental Prediction Final (NCEP FNL) operational global analyses dataset. More details on the WRF model configuration can be found in Xie et al. (2023).

Anthropogenic emissions were taken from the MEIC (Multi-resolution Emission Inventory for China) v1.3, with a spatial resolution of 0.25° × 0.25° (Zheng et al., 2018). FINN (Fire INventory from NCAR) v1.5, with 1 km resolution (Wiedinmyer et al., 2011), and MEGAN (Model of Emissions of Gases and Aerosols from Nature) v2.10 (Guenther et al., 2006), driven by meteorological inputs from WRF, were used to provide wildfire and biogenic emissions, respectively. Total particle-phase emissions from the above-mentioned sources were transformed into size-resolved emissions, based on measured source profiles (Hu et al., 2015; Kleeman et al., 2008; Robert et al., 2007a, b). The fraction of total particulate emissions assigned to each size bin is shown in Table S1 in the Supplement. In addition, sea salt and dust emissions were calculated online within the model, based on wind speed and land use type, as described in Hu et al. (2015).

A total of nine age bins were configured to determine the age distribution of particles in this study. The age-bin-updating frequency was set to 12 h in our base simulation so that we could explicitly track particle ages up to 96 h. However, PM_{2.5} concentrations can grow explosively during our study period within several hours. Thus, another four simulations with age-bin-updating intervals of 1, 3, 6, and 8 h were also conducted to better reflect the age distribution of particles (Table S2). Results from different simulations were combined by replacing the low-time-resolution simulations with the corresponding high-time-resolution results (Ying et al., 2021). The simulated concentrations of PM_{2.5} and its major components from the age-resolved model show good agreement with the original UCD/CIT model (Fig. S1), confirming that the dynamic age-bin-updating algorithm will not change the concentration prediction. The computational burden of the age-resolved UCD/CIT model with nine age bins is ∼3 times higher than the original model.

2.3 Field observations

Hourly meteorological data, including 2 m air temperature (T_{2m}), 10 m wind speed (WS) and wind direction (WD), and 2 m relative humidity (RH) were collected from 171 routine weather stations in eastern China (Fig. 1) from the Chinese National Meteorological Center (http://data.cma.cn/en, last access: 16 September 2023). Surface PM_{2.5} observations were acquired from the national air quality monitoring network developed by the China National Environmental Monitoring Center (http://www.cnemc.cn, last access: 16 September 2023). Measurements of the aerosol composition were conducted at four main cities in eastern China, including Beijing, Jinan, Nanjing, and Shanghai. Water-soluble inorganic ions (WSIIs; including nitrate, NO_3^-, sulfate, SO_{4}^{2-}, and ammonium, NH_4^+) were measured by an online analyzer (MARGA, Monitor for AeRosols and Gases in Ambient Air, model ADI 2080: Applikon Analytical B. V., the Netherlands) with a PM_{2.5} cyclone inlet in Jinan, Nan-
The condition of low wind speed (\(\sim\)) from 25–28 December 2017 under NCP (see red lines in Fig. 2c–e; in the following sections, IMR (Fig. S2), which is identified as the accumulation stage. Se-

China indicates that PM\(_{2.5}\) during the PM\(_{2.5}\) episode. Briefly, the IMR of a certain component \(i\) can be found in the corresponding references.

The incremental mass ratio (IMR) proposed by Tan et al. (2018) was adopted in this study to determine the aerosol concentration growth during the haze episode. Briefly, the IMR of a certain component \(i\) (IMR\(_i\)) is calculated as the ratio of the increment of component \(i\) (\(\Delta C_i\)) to the increment of PM\(_{2.5}\) (\(\Delta M_{2.5}\)) total mass during the PM\(_{2.5}\) growth stage.

\[
\text{IMR}_i = \frac{\Delta C_i}{\Delta M_{2.5}} \times 100
\]  

Thus, the contribution of each chemical composition to the PM\(_{2.5}\) increment can be calculated.

3 Results

3.1 Episode description and model evaluation

Figure 2 shows a severe regional haze episode over eastern China spanning from 25 December 2017 to 2 January 2018. The time series of PM\(_{2.5}\) concentrations in eastern China indicates that PM\(_{2.5}\) gradually accumulated in the NCP (see red lines in Fig. 2c–e; in the following sections, NCP refers to this region) from 25–28 December 2017 under the condition of low wind speed (\(\sim 2\) m s\(^{-1}\)) and rising RH (Fig. S2), which is identified as the accumulation stage. S
Figure 2. Time series and spatial distributions of wind fields and PM$_{2.5}$ during this haze episode. (a, b) Observed wind and PM$_{2.5}$ concentrations in the NCP (red lines in panels c–e) and YRD (blue lines in panels c–e). Shaded areas represent the 25th–75th percentile range of observation. Solid dots mark the simulated PM$_{2.5}$ concentrations. (c–e) Observed PM$_{2.5}$ concentrations, WRF-simulated wind fields, and sea level pressure before, during, and after regional transport (RT).

The UCD/CIT model reproduces the observed temporal variations in the hourly PM$_{2.5}$ concentrations averaged over the NCP and the YRD well during this haze episode, with a high correlation coefficient ($R > 0.85$) and a low normalized mean bias ($\text{NMB} < 15\%$; Fig. 2b). High PM$_{2.5}$ concentrations (> 150 µg m$^{-3}$) with low wind speed over the southern Hebei, Shandong, Henan, northern Jiangsu, and Anhui provinces are well captured by the model (Fig. S5). The simulated PM$_{2.5}$ compositions (SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, EC, and OM) also agree well with the daily averaged measurements in Beijing, Jinan, Nanjing, and Shanghai (Fig. S6), with the model performance statistics being comparable to those in other studies (Shi et al., 2017; Hu et al., 2016; Q. Zhang et al., 2019). Detailed model evaluation about meteorological parameters and concentrations of PM$_{2.5}$ and its major chemical compositions can be found in the Supplement. Note that there are currently no techniques to measure particle age quantitatively. Therefore, no observational age data are available to directly evaluate the predicted age results. Nevertheless, the evolution of particle chemical compositions over time is related to the ages, so we assume that the validated chemical composition results can also provide confidence in the predicted age information.

3.2 Evolution of particle chemical compositions

Figure 3 shows the observed chemical composition evolution in Beijing, Jinan, Nanjing, and Shanghai. SO$_4^{2-}$, NO$_3^-$, and NH$_4^+$ (denoted SNA hereafter) increased rapidly and became the major component of PM$_{2.5}$ during the PM$_{2.5}$ growth stage in all four cities, while the mass fraction of EC and OM in PM$_{2.5}$ decreased. In Beijing and Jinan, located in the NCP, the daily averaged SNA concentrations increased from 10 and 22 µg m$^{-3}$ on 25 December to 110 and 157 µg m$^{-3}$ on 29 December, and their mass fraction in PM$_{2.5}$ increased from $\sim 40\%$ to $\sim 75\%$. Particularly, NO$_3^-$ exhibited the highest levels among SNA in all four cities. The peak value of NO$_3^-$ was 49, 57, 80, and 51 µg m$^{-3}$ for Bei-
Nitrogen-, 3-Jin, Nanjing, and Shanghai, respectively, contributing to 25%–41% of PM$_{2.5}$ mass concentrations. The IMR of NO$_3^-$ (29%–33%) was much higher than that of other components in Beijing, Nanjing, and Shanghai (Figs. 3e and S7), indicating that NO$_3^-$ was the driving component during the PM$_{2.5}$ growth stage. In Nanjing, the IMR of SO$_4^{2-}$ (26%) was slightly higher than that of NO$_3^-$ (24%). Nevertheless, the mass fraction of NO$_3^-$ in PM$_{2.5}$ during the PM$_{2.5}$ growth stage (25–29 December) was 26%, significantly larger than that of SO$_4^{2-}$ (16%) and NH$_4^+$ (15%). The higher fraction of NO$_3^-$ in PM$_{2.5}$ and its dominant contribution to the PM$_{2.5}$ growth stage have also been pointed out by recent observation and modeling studies conducted in eastern China during winter haze periods (Shao et al., 2018; Xu et al., 2019; Xie et al., 2022).

During 25–29 December, the NCP region was under the control of a uniform pressure field with low horizontal winds (Fig. S3), and pollutants gradually accumulated under such stagnant conditions. The observed RH gradually increased, and the maximum exceeded 80% on 28–29 December, which facilitated the chemical formation of secondary aerosols and accelerated the hygroscopic growth of particles (Cheng et al., 2016; Sun et al., 2014; Yang et al., 2015). Process analysis also indicates that chemical formation is the driving process for the growth of SNA in the NCP, with its net production rate being ~3 times larger than that of vertical mixing and horizontal advection during the accumulation stage (Fig. 4a and b). For YRD cities, Nanjing and Shanghai, daily SNA concentrations increased sharply by 3–6 times within 2 d (30–31 December) and accounted for 78% of the peak PM$_{2.5}$. Horizontal advection played a dominant role during the explosive growth of air pollutants, with a maximum production rate of 8.1 and 2.7 µg m$^{-3}$ h$^{-1}$ for NO$_3^-$ and SO$_4^{2-}$, respectively (Fig. 4c and d). The chemical process also contributed obviously to NO$_3^-$ and SO$_4^{2-}$ in Nanjing during the regional transport, indicating the continuous local formation in the YRD regions.

3.3 Evolution of particle age distribution

The age distribution evolutions of the major PM$_{2.5}$ compositions (EC, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, POA, and SOA) in Beijing and Shanghai are illustrated in Figs. 5 and 6. High concentrations of EC, POA, and SO$_4^{2-}$ typically occurred at low atmospheric ages, with obvious diurnal variations in both cities. The bimodal distribution of fresh particles (defined as particles with atmospheric age < 24 h) was mainly related to the variations in local emissions and the evolution of PBL. Generally, the atmospheric age decreased in the early morning before sunrise (Fig. S8). This is because of the increased traffic emissions during the morning rush hour and the weakened vertical dispersion due to the low boundary layer height. The mean atmospheric age increased during the daytime because freshly emitted particles were mixed to a more developed boundary layer. In the late afternoon, the mean atmospheric age decreased again. The increased traffic and residential emissions during the evening rush hour and decreased mixing layer height both contribute to the reduction in the mean atmospheric age. From Figs. 5 and 6, some diagonal stripes can be easily observed, which indicate that the concentrations of particles dropped rapidly after being released due to the atmospheric dilution process such as advection and deposition. Nevertheless, under stable weather conditions with low wind speeds, the dilution effect was weak, and EC, POA, and SO$_4^{2-}$ particles could accumulate in the atmosphere for a longer time. This can be seen in Beijing from 25–29 December, with a gradually increasing mean atmospheric age of EC, POA, and SO$_4^{2-}$. During this time, relatively high concentrations of aged EC, POA, and SO$_4^{2-}$ particles (with atmospheric age > 24 h) together with large contributions from fresh particles can also be observed (e.g., 12:00 to 18:00 LT on 28 December). On 30 December, aged EC, POA, and SO$_4^{2-}$ particles in Beijing were removed sharply by strong northwesterly wind, leading to a steep decrease (from ~40 h to less than 6 h) in their mean atmospheric age. Subsequently, in Shanghai, the concentration of aged particles increased rapidly during the period from 14:00 LT on 30 December to 02:00 LT on 31 December, indicating the influence of regional transport. As a result, the mean atmospheric age of EC, POA, and SO$_4^{2-}$ increased from 3–6 to 47–52 h.

For both Beijing and Shanghai, the average age of SOA is generally larger than that of EC and POA, with a maximum average age of 55 and 69 h, respectively. Similar to that of EC, POA, and SO$_4^{2-}$, the average age of SOA gradually increased during the accumulation stage in Beijing, and then decreased sharply on 30 December due to the sweeping effect of the strong northwesterly wind. In Shanghai, the average age of SOA increased from ~20 to ~60 h within several hours during the regional transport. Oligomers of anthropogenic SOA (AOLGA), xylene, toluene, long-chain alkanes, and monoterpenes were found to be the most important precursors, contributing over 95% of the total SOA in Beijing, Nanjing, and Shanghai (Figs. S9 and S10). The contribution of AOLGA increased with atmospheric age in all four cities, while the contributions of xylene, toluene, and long-chain alkanes decreased with age. In the NCP cities, the contribution of AOLGA to total SOA concentrations increased from 35% in the accumulation stage to 48% in the stabilization stage. This is because semivolatile SOA would not immediately form AOLGA after being released into the atmosphere, and the oligomerization reactions take time.

NO$_3^-$ and NH$_4^+$ exhibited different age distributions compared to EC, POA, SO$_4^{2-}$, and SOA during the PM$_{2.5}$ growth stage in all the four cities. The mean atmospheric age of NO$_3^-$ and NH$_4^+$ did not show an increasing trend and even decreased on some occasions during the accumulation stage in Beijing and Nanjing (Figs. S11 and S12). Such a low atmospheric age was mainly due to the continuous formation of...
Figure 3. Mass concentrations and fractions (a–d) and incremental mass ratio (e) of the major PM$_{2.5}$ chemical compositions (SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, EC, and OM) in Beijing, Jinan, Nanjing, and Shanghai.

secondary NH$_4$NO$_3$ particles locally (Fig. S13), which increased the concentrations of fresh particles and decreased the mean age of NO$_3^-$ and NH$_4^+$. High concentrations of fresh NO$_3^-$ combined with a moderate contribution of aged NO$_3^-$ can also be seen during the explosive growth stage (e.g., 16:00 to 23:00 LT on 30 December 2017) in Nanjing and Shanghai, indicating that the continuous local formation with additional help from regional transport together contribute to the high concentrations of NO$_3^-$. The average atmospheric age of NO$_3^-$ in Jinan, Nanjing, and Shanghai decrease significantly with RH, and low average ages are often observed with a high concentration of NO$_3^-$ (Fig. S15). This confirms our speculation that the rapid chemical formation of NO$_3^-$ under high RH conditions (Fig. S2) leads to a high concentration of fresh NO$_3^-$ and decreases the mean age of NO$_3^-$. The vertical cross sections of the concentrations and mean ages for EC and NO$_3^-$ along the transport route from Beijing to Shanghai (see solid white lines in Fig. 1) are shown in Figs. 7 and 8, while those for SO$_4^{2-}$ and SOA are illustrated in Figs. S16 and S17. Before the regional transport (e.g., 16:00 LT on 28 December 2017), aged particles mainly accumulated in the NCP under slow wind speed (~2 m s$^{-1}$). The average age of EC, SO$_4^{2-}$, NO$_3^-$, and SOA was approximately 30–50, 50–60, 20–45, and 50–60 h, respectively, which is larger than that in the YRD (15–30 h for EC, 30–50 h for SO$_4^{2-}$, 8–24 h for NO$_3^-$, and 35–45 h for SOA). An obvious vertical gradient of particle age occurred in the YRD, with a lower age near the surface and higher age aloft. Compared to YRD, the vertical distribution of particle ages was more uniform in the NCP due to the accumulation of aged pollutants in the atmosphere under stable weather conditions. When the cold front passed through, the vertical distribution in the NCP appears to be more uniform. This is because the upward motion ahead of the cold front enhanced the vertical mixing of air pollutants. Additionally, polluted air masses carrying aged particles gradually moved from the NCP to the YRD under strong northwesterly wind (>5 m s$^{-1}$). During this period, high PM$_{2.5}$ concentrations occurred in eastern China and vertically extended up to 1.2 km, as they were forced by the upward motion along the cold front. For EC, SO$_4^{2-}$, and SOA, the average age in the YRD increased significantly within the whole PBL due to the regional transport from the NCP. The maximum age reached 48, 60, and 65 h for EC, SO$_4^{2-}$, and SOA, respectively. For NO$_3^-$, the highest concentration reached 180 µg m$^{-3}$ for regions between Jinan and Nanjing at 08:00 LT on 30 December 2017, which was 2 times the peak value in the NCP before the regional transport (~90 µg m$^{-3}$). Moreover, the average age of NO$_3^-$ was relatively low (6–24 h) for high-concentration NO$_3^-$ particles, indicating the significant contribution from the local chemical formation.

The age distribution of the major PM$_{2.5}$ chemical compositions (EC, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, and SOA) in Beijing, Jinan, Nanjing, and Shanghai is shown in Fig. 9.
Figure 4. The contributions of physicochemical processes (CHEM is the gas-phase, aerosol, and cloud chemistry; VMIX is the vertical mixing and dry deposition; HTRA is the horizontal advection; EMIS is the emission) to $\text{NO}_3^-$ and $\text{SO}_4^{2-}$ concentrations within the first 10 layers in Beijing, Jinan, Nanjing, and Shanghai. The stacked bar graphs inserted in each panel represent the total contribution during the corresponding period. A, S, and D indicate the accumulation, stabilization, and dilution stage in Beijing and Jinan. B, D, and A represent the period before, during, and after regional transport in Nanjing and Shanghai.

exhibited larger atmospheric age than other PM$_{2.5}$ components, with a maximum average age of 84 and 81 h, respectively. This can also be observed in other regions (Figs. S18 and S19). In the NCP cities, Beijing and Jinan, more aged particles occurred in the stabilization stage. The average age in Beijing was 45, 76, 55, 61, and 71 h for EC, $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, and SOA, respectively, which is higher than that in the accumulation and dilution stages. It is worth noting that a large fraction (50%–60%) of $\text{NO}_3^-$ and $\text{NH}_4^+$ particles with an age younger than 12 h occurred in Jinan during the stabilization stage, indicating a rapid local formation. In the YRD cities, Nanjing and Shanghai, the mass fraction of aged EC, $\text{SO}_4^{2-}$, and SOA particles increased significantly during the regional transport; their average ages were even larger than that in the NCP cities (Fig. S19). This is mainly because of the strong northwesterly wind that brought abundant aged particles from the NCP. $\text{NO}_3^-$ and $\text{NH}_4^+$ showed a smaller atmospheric age than $\text{SO}_4^{2-}$ and SOA, with an average age of 20–30 h during the regional transport. Fresh $\text{NO}_3^-$ and $\text{NH}_4^+$ particles with an atmospheric age of less than 24 h accounted for more than 70% of the total mass. As can be seen from Fig. S19, the low atmospheric age of $\text{NO}_3^-$ and $\text{NH}_4^+$ was found in YRD, while high atmospheric age occurred in NCP.

Figures 10 and S20 show the size distribution of the major PM$_{2.5}$ chemical compositions in Beijing and Shanghai. Both EC and POA exhibited bimodal size distributions, with a fine-mode peak at 0.2–0.4 µm and a coarse-mode peak at 1–4 µm, respectively. SOA, $\text{SO}_4^{2-}$, $\text{NO}_3^-$, and $\text{NH}_4^+$ were mainly concentrated in the fine mode, with a peak at 3–4 µm. The size distribution of particles with different atmospheric ages was quite different. Aged particles were mainly concentrated in a larger size range, especially for SOA, $\text{SO}_4^{2-}$, and $\text{NO}_3^-$. For example, $\text{SO}_4^{2-}$ with a diameter > 0.4 µm in both Beijing and Shanghai showed an atmospheric age of > 96 h. When the accumulation stage evolved into the stabilization stage, the size of SOA, $\text{SO}_4^{2-}$, and $\text{NO}_3^-$ increased slightly in Bei-
Figure 5. Hourly atmospheric age distribution of EC, SO$_2^-$, and NO$_3^-$ in Beijing and Shanghai during this haze episode. White lines represent the average atmospheric age, and red lines (right y axis) indicate total mass concentrations. The results were combined from simulations with age-bin-updating intervals of 1, 3, 6, 8, and 12 h. The black lines in panels (a)–(c) indicate 12:00 to 18:00 LT on 28 December.

Figure 6. Same as Fig. 5 but for POA, SOA, and NH$_4^+$.
Fig. 7. Vertical cross section of the average atmospheric age (color contours; h) and concentrations (solid blue lines; µg m⁻³) of EC along the transport route from Beijing to Shanghai (see solid white lines in Fig. 1) at (a) 16:00 LT on 28 December; (b) 20:00 LT on 29 December; (c–e) 08:00, 14:00, and 20:00 LT on 30 December; and (f) 08:00 LT on 31 December 2017. Note that the vertical wind speed was multiplied by 500 for the illustration of vertical circulations. The location of Jinan and Nanjing are marked as solid red lines.

**Discussion**

Our results indicate that the atmospheric age of EC, POA, SO₄²⁻, and SOA increased gradually during the accumulation stage in the NCP due to air stagnation. The regional transport from the NCP to the YRD brought in high concentrations of aged primary particles, such as EC and POA. As a result, the simulated average atmospheric age of EC was ~40 h during the regional transport, which was much higher than the “experimental” aging timescale to achieve complete morphology modification and absorption enhancement of BC in Beijing (4.6 h) and Houston, Texas, USA (18 h; Peng et al., 2016). It could be speculated that the aged EC or POA particles are coated continuously by the newly formed fresh SNA particles along the transport route, which could further enhance the light absorption of particles (Bond et al., 2013). Using transmission electron microscopy (TEM), Zhang et al. (2021) observed abundant spherical primary OM particles coated with secondary aerosols in the YRD during the regional transport, which is consistent with our findings. Previous studies have confirmed the crucial role of aerosol–PBL interaction in altering the vertical structure of the PBL and the formation and accumulation of haze in eastern China (Huang et al., 2020; Li et al., 2017). Thus, the potential absorption enhancement of aged black or brown carbon particles during the regional transport could amplify...
Another interesting finding is that the atmospheric age of NO$_3^-$ remained unchanged or even slightly decreased during the regional transport from NCP to YRD, contrary to the age evolution of SO$_2^{4-}$. This indicates that SO$_2^{4-}$ is mainly formed in the upwind NCP region and then transported to YRD, while there is a large fraction of NO$_3^-$ formed locally in YRD. SO$_2^{4-}$ concentrations have been dramatically reduced during the last decade due to desulfurization devices vigorously promoted in coal-fired facilities, and NO$_3^-$ has become the dominant inorganic component of PM$_{2.5}$ in most regions of eastern China (Sun et al., 2022). Our previous study for January 2013 suggested that NO$_x$ emissions from local sources and adjacent Jiangsu province contributed to nearly 30% of NO$_3^-$ in Shanghai, respectively (Xie et al., 2021). Therefore, NO$_3^-$ reduction can be achieved by cooperative emission controls within the YRD region. Moreover, emission reduction actions should be taken a few days in advance to mitigate severe haze pollution under unfavorable weather conditions.

This study is subject to a few limitations. The UCD/CIT model includes SO$_2^{4-}$ formation mechanisms through the gas-phase oxidation of SO$_2$ by OH radicals and the in-cloud aqueous oxidation. However, recent field observations indicated a large contribution from other pathways during winter haze events in China, such as manganese-catalyzed oxidation on aerosol surfaces (W. Wang et al., 2021) and aqueous oxidation of SO$_2$ by NO$_2$ (Cheng et al., 2016; G. Wang et al., 2016). The missing mechanism in the current model leads to a substantial underestimation of SO$_2^{4-}$ (42.3%), which will further affect the age distribution of SO$_2^{4-}$ particles. Since SOA is universally underestimated in current CTMs (Hu et al., 2017), uncertainties may also occur with SOA. Additionally, the discretization of atmospheric age in our model can lead to some uncertainties, especially for the calculation of the aerosol–PBL interactions and further exacerbate air pollution.

Figure 8. Same as Fig. 7 but for NO$_3^-$. 
Figure 9. The mass fractional contributions of different age bins to EC, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, and SOA in Beijing, Jinan, Nanjing, and Shanghai. The red circle with a black dot indicates the average atmospheric age (in hours; right y axis). A, S, and D indicate the accumulation, stabilization, and dilution stage in Beijing and Jinan. B, D, and A represent the period before, during, and after regional transport in Nanjing and Shanghai.

Figure 10. The size distribution of EC, POA, SOA, SO$_4^{2-}$, NO$_3^-$, and NH$_4^+$ in Shanghai (a) before, (b) during, and (c) after regional transport.
of average atmospheric age (Xie et al., 2023). Thus, in this study, we run five different simulations with Δτ of 1, 3, 6, 8, and 12 h, respectively, and combine the results to minimize the effect of discrete age representation.

5 Conclusions

In this study, the age-resolved UCD/CIT model was used to investigate the age distribution of PM$_{2.5}$ during a severe regional haze episode in eastern China in December 2017. A comparison with surface observations shows that the model reasonably captured the spatiotemporal variations in the PM$_{2.5}$ and its major chemical compositions. Our results indicate that at the beginning stage of the haze event (25–29 December 2017), the stagnant weather conditions characterized by weak surface wind and high RH facilitated the accumulation and secondary formation of air pollutants, leading to increased PM$_{2.5}$ concentrations in the NCP region. NO$_3^-$ was found to be the dominant chemical composition during this haze episode, contributing to ~30% of the PM$_{2.5}$ concentration growth in Beijing, Jinan, Nanjing, and Shanghai. Both the concentration and atmospheric age of EC, POA, SO$_4^{2-}$, and SOA increased gradually during the accumulation stage in the NCP due to the weakened atmospheric diffusion capacity, while the atmospheric age of NO$_3^-$ and NH$_4^+$ remained unchanged because of continuous local formation. During the regional transport stage (30 December), a cold front moved from north to south, bringing aged particles from the NCP to the YRD region and increasing the PM$_{2.5}$ concentrations rapidly within hours. Accordingly, the average atmospheric age of EC, POA, SO$_4^{2-}$, and SOA particles in the YRD increased from 5–20 to 50–60 h. In contrast, continuous local chemical formation resulted in an unexpected decrease in the atmospheric age of NO$_3^-$ and NH$_4^+$ in the YRD, although the concentrations of aged particles with old atmospheric age increased due to regional transport. The age information provided in this study enhances our understanding of the formation mechanism of haze events and helps us design cost-effective control strategies for different PM$_{2.5}$ components.

**Code and data availability.** Hourly PM$_{2.5}$ data used in this study are freely available from http://www.cnemc.cn/en (China National Environmental Monitoring Centre, 2023). Meteorological observations used in this study are available from http://data.cma.cn/en/?r=data/detail&dataCode=A.0012.0001 (China Meteorological Data Service Centre, 2023).
