Abstract. Organosulfates (OSs) are ubiquitous aerosol components, which has seen intense research over years. However, spatial and diurnal variations in OS formation in polluted atmospheres remain poorly understood. In this study, 130 OS species were quantified (or semi-quantified) in ambient fine particulate matter (PM_{2.5}) collected in urban and suburban Shanghai (East China) in the summer of 2021. Isoprene- and monoterpene-derived OSs were dominant OS groups (averaging 51 % and 19 % of total quantified OSs, respectively), likely indicating a large biogenic contribution to OS formation in summer. Most OSs peaked during daytime, while monoterpene-derived nitrooxy-OSs (NOS_m) increased during nighttime. Accordingly, OSs were largely produced via daytime formation processes, rather than nighttime chemistry, except for NOS_m. Additionally, although OS formation in the urban and suburban areas exhibited similar diurnal variations, the average concentrations of biogenic and anthropogenic OSs decreased significantly from the urban site to the suburban site. Furthermore, we concretized daytime OS formation based on the interactions among OSs, ultraviolet (UV), ozone (O₃), and sulfate (SO₄²⁻). Indeed, the concentrations of most OSs were significantly correlated with the values of UV[O₃][SO₄²⁻] during daytime in both urban and suburban Shanghai. In particular, the correlation between major OSs and UV[O₃][SO₄²⁻] was stronger than the correlation of major OSs with O₃ and SO₄²⁻; moreover, there was no significant correlation between major OSs and UV. Thus, higher urban OS events were attributed to the enhanced photochemical processes and sulfate level in the urban area. Overall, this study provides field evidence for the influence of photochemical processes and anthropogenic sulfate on OS formation and has important implications for the mitigation of organic particulate pollution.

1 Introduction

Organosulfates (OSs) are ubiquitous constituents in secondary organic aerosol (SOA) and can contribute up to ~30% of organic mass in atmospheric fine particles (PM_{2.5}) (Tolocka and Turpin, 2012; Surratt et al., 2008; Hettiyadura et al., 2018). OSs affect the formation, hygroscopicity, light-absorbing property, and acidity of organic aerosols, as well as biogeochemical cycles of sulfur (Estillore et al., 2016; Riva et al., 2019; Fleming et al., 2019), which are tightly associated with air quality, human health, and regional climate (Ramanathan et al., 2001; Menon et al., 2008). Thus, understanding the mechanisms and key influencing factors of OS formation in the ambient atmosphere is of great significance for an effective assessment of environment and climate effects of OSs.

Many laboratory studies have suggested that heterogeneous and multiphase reactions involving biogenic and anthropogenic volatile organic compounds (VOCs), their oxidation intermediates, and sulfate or gas-phase sulfur dioxide (SO₂) are important pathways for the formation of OSs (Blair et al., 2017; Riva et al., 2016b; Ye et al., 2018). For example, the formation of 2-methyltetrol sulfate ester (2-MT-OS) and 2-methylglyceric acid sulfate ester (2-MGA-OS) can be attributed to the reactive uptake of isoprene epoxydiols (IEPOX) and isoprene-derived hydroxymethyl-methyl- α -lactone (HMML) by acidic particles, respectively (Surratt et al., 2010; Nguyen et al., 2015). The ozonolysis of α -pinene and limonene in the presence of SO₂ can contribute to the production of monoterpene-derived OSs (e.g., C₉H₁₅O₇S⁻ and C₁₀H₁₇O₇S⁻) (Ye et al., 2018). Chamber experiments by Riva et al. (2016b) showed that the photooxidation of C₁₀–C₁₂ alkanes is associated with the formation of aliphatic OSs. More recently, the aliphatic OSs have been identified based on the uptake experiments of SO₂ by oleic acid and other unsaturated fatty acids (Shang et al., 2016; Passananti et al., 2016). In addition, the gas-phase oxidation of polycyclic aromatic hydrocarbons was found to be an important source of aromatic OSs (Riva et al., 2015).

Furthermore, OSs have been identified in different ambient atmospheres, including suburban (Surratt et al., 2007b), rural (Hettiyadura et al., 2017, 2018; Budisulistiorini et al., 2015), urban (Kanellopoulos et al., 2022; Stone et al., 2012; Surratt et al., 2007b), marine (Hawkins et al., 2010), polar (Hansen et al., 2014), and forest areas (Iinuma et al., 2007a). In particular, Chen et al. (2021) investigated aerosol OSs across the Interagency Monitoring of Protected Visual Environments (IMPROVE) network of the USA (20 sites). Owing to different levels of precursors and atmospheric pollution, the abundance and formation pathways of OSs change substantially in temporal and spatial scales (Wang et al., 2021; Ding et al., 2022; Jiang et al., 2022; Nozière et al., 2010; O'Brien et al., 2014). Patently, field observations are valuable for verifying the mechanistic understanding of OS formation obtained in the laboratory studies. The importance of atmospheric oxi-

dants and sulfate (or SO₂) in the OS formation was proposed in field observations according to a correlation analysis of OSs with ozone (O₃) (or the sum of O₃ and NO₂ concentrations) and sulfate (or SO₂) (Nguyen et al., 2014; Hettiyadura et al., 2019; Wang et al., 2018). Notably, these observation-based studies also highlighted the role of photochemistry of OS precursors. However, the interactions among ultraviolet (UV), O₃, and sulfate have not been well investigated. In particular, few studies were performed to systematically reveal the difference in the formation processes of OSs in polluted and clean areas, as well as during daytime and nighttime.

Shanghai is a megacity in the Yangtze River Delta (YRD) region of China. Locally varied ambient conditions such as O₃, SO₂, and NO_x, relative humidity (RH), and aerosol acidity affect the formation of OSs significantly (Cai et al., 2020; Wang et al., 2021). Here, 130 OS species were quantified (or semi-quantified) in PM_{2.5} samples collected in urban and suburban Shanghai in summer 2021 to investigate the relative influence of photochemistry and nighttime chemistry on OS formation and their linkages with anthropogenic sulfate pollution. In addition, the potential impacts of aerosol acidity and aerosol liquid water (ALW) on OS formation were discussed. This study can help to deepen the understanding of photochemical process and nighttime chemistry of OSs in the atmosphere.

2 Materials and methods

2.1 Site description and sample collection

Ambient PM_{2.5} samples were continuously collected in the urban center and suburban area in Shanghai from 11 to 23 July 2021 (Fig. S1 in the Supplement). The sampling site in the urban center is located on the roof of a building (~20 m above the ground) in the Xuhui Campus of Shanghai Jiao Tong University. The site is characterized by a typical urban environment with heavy traffic and dense population (~24.76 million people in Shanghai). The aerosol sampler in the suburban area was placed on the roof of a ~20 m high building in a monitoring station of Pudong Huinan. This site is closer to the coastline than the urban sampling site (Fig. S1). Thus, the suburban site is expected to be more affected by clean air mass from the sea. PM_{2.5} was sampled onto the prebaked (550 °C for ~8 h) quartz fiber filters (Whatman) using a high-volume air sampler (HiVol 3000, Ecotech) at a flow rate of 67.8 m³ min⁻¹. The duration of each sample collection in both urban and suburban areas was approximately 11 h during the daytime (08:30–19:30 LT) and 12 h during the nighttime (20:00–08:00 LT). Two blank filter samples were collected at each site during the campaign. A total of 50 filter samples were collected, which were stored at -30 °C until analysis. It should be pointed out that the concentrations of detected OSs could be impacted by the sampling process without denuding SO₂ (Kristensen et al., 2016; Brüggemann et al., 2021). However, if SO₂ can heteroge-

neously react with organic species on filters to form OSs, these processes should also occur on ambient particle matter before the sample was collected. Thus, we did not consider the potential impact of PM_{2.5} collection without denuding SO₂ on OS measurements in this study. In the future, the relative importance of the heterogeneous sulfation reactions on filter and ambient particle matter should be further evaluated for different environments.

2.2 Chemical analysis and prediction of aerosol acidity and ALW

A portion of the filter ($\sim 15.9\text{ cm}^2$) was extracted with 3 mL methanol in an ultrasonic bath for 30 min, twice. The sodium camphor sulfonate (1 ppm) was spiked on the filter punches as an internal standard before extracting. The extracts obtained each time were combined and filtered through a 0.22 μm Teflon syringe filter (CNW Technologies GmbH) and then concentrated to 300 μL under a gentle stream of ultra-high-purity nitrogen gas. Subsequently, 300 μL ultra-pure water was added into the concentrated samples, followed by centrifugation to get the supernatant for analysis. OSs were analyzed using an Acquity UPLC (Waters, USA) coupled to a Xevo G2-XS Quadrupole time-of-flight mass spectrometer (ToF-MS, Waters, USA) equipped with an electrospray ionization (ESI) source operated in the negative ion mode. The chromatographic conditions and analytical procedures were detailed in our recent publication (Wang et al., 2021).

A total of 212 OSs were identified by UPLC-MS analysis, in which 130 OS species were quantified (or semi-quantified) (Tables 1 and S1). The quantified (or semi-quantified) species included isoprene-derived OSs (OS_i), monoterpene-derived OSs (OS_m), C₂–C₃ OSs, aliphatic OSs, and aromatic OSs (Hettiyadura et al., 2019). It is worth noting that most of identified OSs were semi-quantified using surrogate standards because of the lack of authentic standards (Staudt et al., 2014; Hettiyadura et al., 2015). The surrogate OS standards included potassium phenyl sulfate (98 %, Tokyo Chemical Industry), methyl sulfate (99 %, Macklin), sodium octyl sulfate (95 %, Sigma-Aldrich), glycolic acid sulfate (artificial synthesis), lactic acid sulfate (artificial synthesis), limonaketone sulfate (artificial synthesis), and α -pinene sulfate (artificial synthesis) (Olson et al., 2011; Wang et al., 2017; Hettiyadura et al., 2019, 2017; Wang et al., 2018), as detailed by our previous study (Wang et al., 2021). Considering that OSs with similar structures of carbon backbone typically have similar MS responses (Wang et al., 2021, 2017), the selection of surrogate standard for a given OS was primarily based on the similarities in the carbon chain structure of the standard and targeted OS species (Hettiyadura et al., 2017). Furthermore, the similarities of the sulfur-containing fragment ions in the MS/MS spectra of the standard and targeted OS species have also been adopted (Wang et al., 2021; Hettiyadura et al., 2019). For OSs that have

been reported in previous studies, MS/MS can further support their structural identifications (Table 1). However, most of OSs without identified structural information were classified and semi-quantified according to their molecular formulas and correlation analysis with known OSs and unidentified OSs (Sect. S1) (Bryant et al., 2021; Hettiyadura et al., 2019). Details about the standards used for quantitative OS species, as well as about the classification or identification of OSs, are shown in Tables 1 and S1, and the Supplement (Sect. S1). We found that most of OSs without identified structural information in previous studies and this study had significantly lower peak intensity compared to those listed in Table 1, implying that these OS compounds have weak impact on total OS abundance in ambient aerosols. In general, the differential ionization efficiencies and fragmentation patterns in the OS measurement may introduce biases (Hettiyadura et al., 2017). Consequently, the OS species shown in Tables 1 and S1 should not be regarded as an accurate measure of OS compounds, but a best solution in the absence of authentic OS standards (Hettiyadura et al., 2015, 2017, 2019; Wang et al., 2021). The recoveries of OS standards ranged from 84 % to 94 % ($87\% \pm 4\%$). Thus, we assumed that there is a high extraction efficiency for major OS species in this study, as indicated by previous studies (Wang et al., 2021; Hettiyadura et al., 2015). Detailed data quality control was described in our recent publication (Wang et al., 2021).

The mass concentrations of organic carbon (OC) and elemental carbon (EC) were determined via an OC/EC analyzer (DRI Model 2015). The mass concentrations of OC were converted to those of organic matter (OM) using a conversion factor of 1.6 (Turpin and Lim, 2001; Wang et al., 2021, 2018). The mass concentrations of inorganic ions in PM_{2.5} samples, including Na⁺, NH₄⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, NO₃⁻, and SO₄²⁻, were measured using an ion chromatograph system (ICS-5000+, Thermo, USA).

A thermodynamic model (ISORROPIA-II) was used to predict the mass concentration of ALW and pH (Guo et al., 2015; Hennigan et al., 2015). The model was operated with particle-phase concentrations of Na⁺, SO₄²⁻, NH₄⁺, NO₃⁻, Cl⁻, Ca²⁺, K⁺, and Mg²⁺, as well as ambient temperature (T) and RH as the inputs. Moreover, the forward mode with the thermodynamically metastable state was selected. The detailed descriptions on ALW and pH predictions were shown in our previous studies (Wang et al., 2021; Xu et al., 2020). In particular, we compared different outputs of the pH values calculated by ISORROPIA-II between the cases with and without considering OSs as additional sulfates to investigate potential impact of OSs on pH prediction (Riva et al., 2019). The pH values predicted from these two cases (2.55 ± 0.93 vs. 2.65 ± 0.94 at the urban site and 2.17 ± 0.68 vs. 2.23 ± 0.74 at the suburban site) have an insignificant difference. Thus, OSs were expected to have a considerably small contribution to pH prediction in this study.

and UV irradiation, as well as the concentrations of NO, NO₂, O₃, SO₂, and PM_{2.5} at the urban and suburban sites were obtained from the environmental monitoring stations of Xuhui (~ 4 km away from the sampling site) and Pudong Huinan (~ 10 m away from the sampling site), respectively. The ventilation coefficient (VC) can be used to characterize the state of atmospheric dilution in pollutant concentrations (Gani et al., 2019). The VC value can be expressed as a product of wind speed and planetary boundary layer height (PBLH).

3 Results and discussion

3.1 Molecular compositions and concentrations of OSs

The mass concentrations and mass fractions of the OS species in PM_{2.5} collected in Shanghai were shown in Fig. 1, with a focus on their spatial and diurnal differences. On average, isoprene-derived OSs (i.e., OS_i) were the dominant components at both urban and suburban sites (Fig. 1a, d), which accounted for 53.9 ± 0.1 % and 48.1 ± 0.1 % of the total OS masses, respectively. The mass fractions and concentrations of C₃H₁₁O₇S⁻ were the highest among all kinds of OS_i. In

contrast, OS_i containing nitrogen atoms only accounted for a small proportion of OS_i in both urban and suburban areas (Fig. 1a, d and Table S2). Monoterpene-derived OSs (OS_m) were the second most abundant OS components, whose concentrations averaged 30.6 ± 46.4 and 19.3 ± 25.7 ng m⁻³ in the urban and suburban areas, respectively. Moreover, the abundance of OS_m was also less controlled by nitrogen-containing OS_m. On average, the OS species with two or three carbon atoms (C₂–C₃ OSs) and anthropogenic OSs (OS_a) together contributed to 26.8 % and 33.1 % of total OS concentrations in the urban and suburban areas, respectively (Fig. 1a, d and Table S3). A similar pattern in the relative abundance of different groups of OSs was also observed at the same sites in summer 2020 (Fig. S2). The predominance of OS_i was well documented by many previous observations in Beijing, China (Wang et al., 2018), Guangzhou, China (Bryant et al., 2021), and Atlanta, Georgia, USA (Hettiyadura et al., 2019), Hong Kong, China (Wang et al., 2022), Copenhagen, Denmark (Nguyen et al., 2014), Centreville, AL, USA (Hettiyadura et al., 2017), Zion, Illinois, USA (Hughes et al., 2021), Birmingham, Alabama, USA (Rattanavaraha et al., 2016), Yorkville, GA, USA (Lin et al., 2013), Look Rock, TN, USA (Budisulistiorini et al., 2015). A

reasonable explanation for these cases is that there is a large biogenic emission of isoprene, particularly during summer days with higher temperature than in other seasons (Bryant et al., 2021). Interestingly, we found that the mass concentrations of all types of OSs (i.e., total OS_i, OS_m, C₂–C₃ OSs, and OS_a) tended to decrease from the urban area to the suburban area. This spatial difference in OS concentrations can be attributed to varied atmospheric oxidation capacity and aerosol properties (e.g., sulfate, acidity, and ALW) (Wang et al., 2021), which will be discussed in detail below.

Table S4 gives an overview of OSs in PM_{2.5} in different regions around the world. The concentrations of total OSs in our study (more than 102.3 ng m⁻³) were higher than those in Copenhagen, Denmark (59.0 ng m⁻³) (Nguyen et al., 2014) and Beijing, China (48.7 ng m⁻³) (Wang et al., 2018). However, the OSs showed a lower concentration in Shanghai compared to the observations in Guangzhou (486.4 ng m⁻³) (Wang et al., 2022) and Atlanta, USA (Hettiyadura et al., 2019) (1249.4 ng m⁻³). The concentrations of OS_i in this study were lower than those observed in summertime Atlanta, USA (1123.0 ng m⁻³) (Hettiyadura et al., 2019), Guangzhou, China (460.2 ng m⁻³) (Wang et al., 2022), and Hong Kong, China (163.2 ng m⁻³) (Wang et al., 2022), Yorkville, GA, USA (115.11 ng m⁻³) (Lin et al., 2013), Look Rock, TN, USA (180.90 ng m⁻³) (Budisulistiorini et al., 2015), Birmingham, Alabama, USA (176.30 ng m⁻³) (Rattanavaraha et al., 2016), Manaus, Brazil (390.00 ng m⁻³) (Cui et al., 2018), but higher than Copenhagen, Denmark (11.3 ng m⁻³) (Nguyen et al., 2014), Seashore, CA, USA (22.00 ng m⁻³) (Chen et al., 2021), National Park, CO, USA (19.00 ng m⁻³) (Chen et al., 2021), National Monument, AZ, USA (3.00 ng m⁻³) (Chen et al., 2021). For OS_m and C₂–C₃ OSs, their concentrations also showed a variable range in different regions (Table S4). The concentrations of OS_a in this study were much higher than those in previous observations (Hettiyadura et al., 2017; Kanellopoulos et al., 2022), which is likely explained by more OS_a species being quantified or higher air pollution level in this study. It should be noted that these spatial comparisons for OS levels mentioned above involved more or less uncertainty due to the lack of authentic standards for precise quantification of OSs. However, our semi-quantitative data provides at least literature reference for future research on these OSs. At the same study site, the abundances of biogenic OSs (OS_i + OS_m) were typically higher than those of other types of OSs, particularly during the summertime when vegetation grows vigorously (Table S4). Thus, the yield of summertime OSs in the investigated areas largely depends on the emission level of biogenic VOCs and the air pollution status.

We found that the contributions of total OSs to OM were 1.3 ± 0.5 % and 1.9 ± 0.5 % at urban and suburban sites in summer 2021, respectively, which were similar to the cases observed in Birmingham, Alabama, USA (1.7 %) (Rattanavaraha et al., 2016) and Manaus, Brazil (1.3 %) (Cui et al., 2018). These proportions of total OSs in OM were

larger than those observed in Beijing, China (0.3 %) (Wang et al., 2018) and Centreville, USA (0.2 %) (Hettiyadura et al., 2017). However, a significantly higher contribution of total OSs to OM was observed in Look Rock, TN, USA (36.3 %) (Budisulistiorini et al., 2015), Great Smoky Mountains National Park, TN, USA (7.0 %) (Chen et al., 2021), Shining Rock Wilderness, NC, USA (5.0 %) (Chen et al., 2021), Bondville, IL, USA (6.2 %) (Chen et al., 2021), and Atlanta, USA (10.3 %) (Hettiyadura et al., 2019), where the formation of OSs was largely impacted by the oxidation of biogenic VOCs. In particular, total OSs contributed to 1.2 ± 0.8 % of OM in summer 2015 and 1.1 ± 0.8 % of OM in summer 2019 in urban Shanghai (Wang et al., 2021). Thus, although anthropogenic emission reduction has been vigorously promoted by the local government in recent years (Guo et al., 2022; Pei et al., 2022), the contribution of SOA to OM in Shanghai has not decreased significantly (Wang et al., 2021).

Figure 1b, e shows diurnal differences in the mass concentrations and mass fractions of the OS components in PM_{2.5} collected at the urban site. The OS_i was the dominant sulfur-containing species regardless of in daytime and nighttime. However, the concentrations of OS_i exhibited a significant decrease from the daytime (117.8 ± 148.1 ng m⁻³) to the nighttime (43.9 ± 62.0 ng m⁻³), except for isoprene-derived nitroxyorganosulfates (NOS_i). Moreover, the variations in OS_i mass concentrations (~ 2 times) were much larger than those in OS_i mass fractions (< 1.2 times). These results indicate that the production of major OS_i (e.g., C₅H₁₁O₇S⁻, C₅H₉O₇S⁻ and C₅H₇O₇S⁻) was weakened during the nighttime. In contrast, the higher concentration for these OS_i in the daytime can be attributed to the increased levels of precursors (e.g., isoprene) (Bryant et al., 2021) and oxidants (e.g., O₃) (Table S5), as well as the strong photochemistry in the daytime. Although the average fraction of NOS_i was higher in the nighttime than in the daytime, their concentration was similar between daytime and nighttime. This is because several special NOS_i (e.g., C₅H₁₀NO₉S⁻, C₅H₈NO₁₀S⁻, C₄H₈NO₇S⁻, and C₅H₈NO₇S⁻) peaked in the daytime, although C₅H₉N₂O₁₁S⁻ showed a maximum in the nighttime (Table S2). Previous laboratory studies have suggested that the formation of C₅H₁₀NO₉S⁻ is mainly related to •OH oxidation processes (Hamilton et al., 2021). Thus, a strong photochemical oxidation during daytime can be responsible for the increases in concentrations of these NOS_i (particularly C₅H₁₀NO₉S⁻) from nighttime to the daytime. Overall, the diurnal variations of other OSs including OS_m, C₂–C₃ OSs, and OS_a were similar to that of OS_i, with a higher level in the daytime than in the nighttime, except for NOSs (Fig. 1 and Tables S2 and S3). It is noteworthy that the fractions and concentrations of monoterpene-derived NOSs (NOS_m) were higher in the nighttime than in the daytime (Table S2). This case can be attributed to NO₃•-related nighttime chemistry (Wang et al., 2018). Thus, these findings further emphasize the importance of photochemistry for daytime OS formation

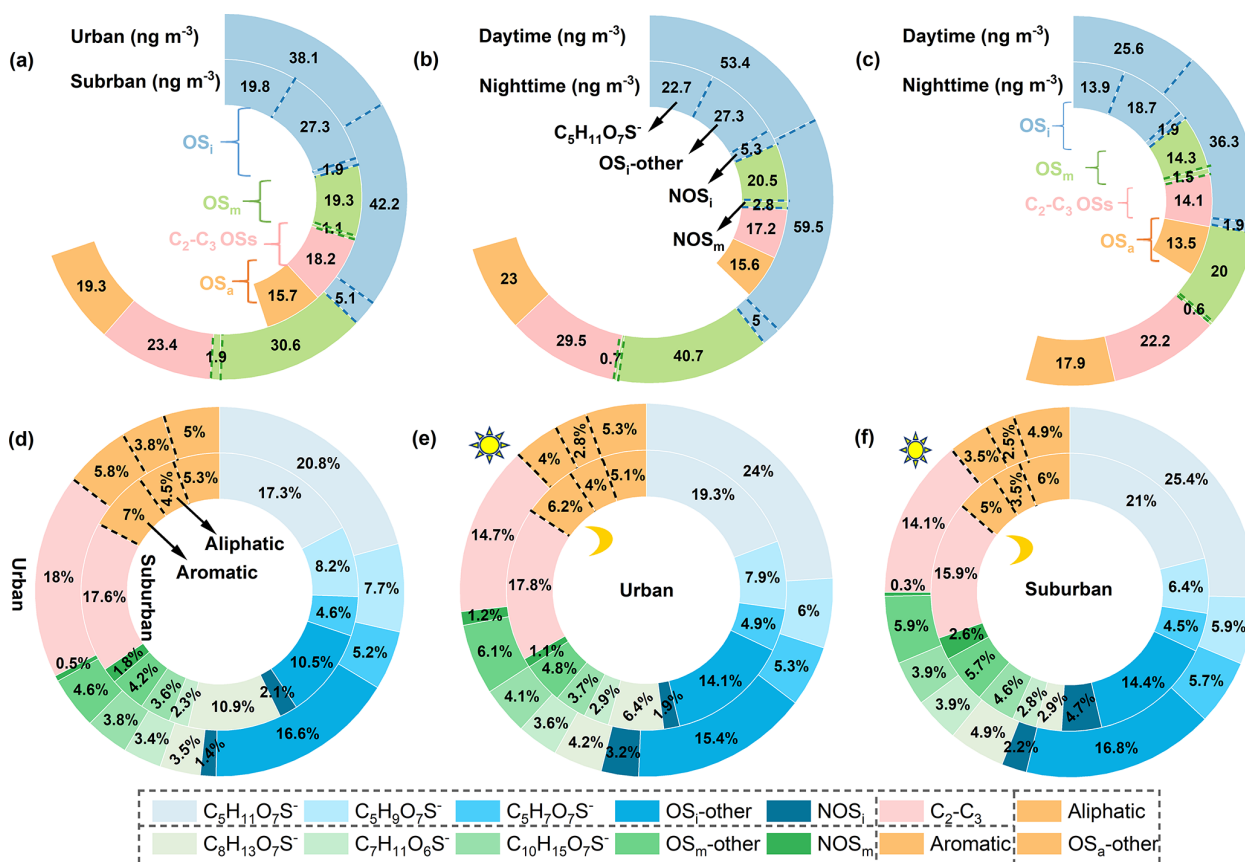

Figure 1. Average distributions in the mass concentrations and mass fractions of various OSs in PM_{2.5} in different cases: (a, d) urban vs. suburban for all data, (b, e) daytime vs. nighttime in the urban area, as well as (c, f) daytime vs. nighttime in the suburban area. The areas divided by dashed lines in panels (a)–(c) indicate $C_5H_{11}O_7S^-$, OS_i-other, NOS_i, and NOS_m in sequence, as illustrated in panel (b). The areas divided by dashed lines in panels (d)–(f) indicate aromatic and aliphatic OSs in sequence, as illustrated in panel (d).

and nighttime chemistry for NOS (in particular NOS_m) formation in urban Shanghai.

The concentrations of various types of OSs at the suburban site were lower than those at the urban site in both daytime and nighttime (Fig. 1b, c). However, the characteristics of diurnal difference in various OSs at the suburban site were similar to those observed at the urban site, which showed a substantially higher OS level in the daytime. A similar case was also found in Beijing in 2016 (Wang et al., 2018) and in Shanghai in 2017 (Cai et al., 2020). Clearly, the aerosol OS abundance in Shanghai was mainly controlled by the OS formation process in the daytime rather than in the nighttime.

3.2 Time series of the major OSs

Figure 2a–h compares the time series of the major OS species and inorganic ions in PM_{2.5} collected at urban and suburban sites. The OS_i concentrations peaked during daytime on 11 and 12 July, with maximum values of 479.8 and 309.5 ng m⁻³ at urban and suburban sites, respectively. Owing to the high proportion of OS_i in total OSs, total OS

concentrations also showed maximum values during 11 and 12 July. The mass concentrations of total OSs, OS_i, and $C_5H_{11}O_7S^-$ (a major OS_i component) decreased from 11 to 14 July (period A; i.e., a relatively polluted period) in both urban and suburban areas, whereas their concentrations exhibited a quite small fluctuation after 14 July (period B; i.e., a clean period). As a result, the mean concentrations of total OSs and OS_i were ~ 4 times higher in the period A than in the period B. The temporal variations in the concentrations of OS_m, $C_8H_{13}O_7S^-$ (a major component of OS_m) (Schindelka et al., 2013), OS_a, and C₂–C₃ OSs were similar to those of total OSs and OS_i. However, the dissimilarities in the diurnal variations of OSs in period A and period B suggest that the sources or levels of precursors and oxidants associated with OS formation differed between these two periods. This consideration was further supported by decreasing O₃ and NO₂ levels from period A to period B (Table S5 and Fig. 2i, j).

Sulfate showed a temporal variation similar to total OSs, OS_i, and OS_m concentrations on most days (Fig. 2g, h). We observed several abnormally high sulfate events during period B (from the evening of 17 to 18 July). The transport dis-

tance of air mass on 18 July was found to be shorter than that in other days (Fig. S3); moreover, the VC value was lower on 18 July than on other days (Fig. S4). Thus, this high sulfate case can be partly attributed to the special meteorological conditions on 18 July. In general, sulfate concentrations showed a strong correlation with total OSs, OS_i, and OS_m concentrations at both sites ($P < 0.01$, $r = 0.76$ – 0.78). These results indicate that the abundances of OSs in these two study areas were tightly associated with sulfate-related particle-phase chemistry (Surratt et al., 2008).

The concentrations of total OSs, OS_i, and OS_m exhibited a distinct diurnal variation during period A at both sites, with a higher concentration in the daytime. The diurnal variation pattern of OSs was similar to those of O₃ and sulfate. These findings imply an important role of atmospheric oxidation capacity and sulfate in daytime OS formation. Exceptionally, although a clear diurnal pattern was also observed for NOS_m, their concentrations peaked in the nighttime, suggesting that the formation of NOS_m was highly affected by the NO₃•-related nighttime chemistry (Inuma et al., 2007a; Surratt et al., 2008). In the period B, the concentrations of various OSs showed a weak diurnal variation, with a slightly higher level in the daytime.

As mentioned above, the ambient levels of oxidants (e.g., O₃ and NO₂) and sulfates showed a significant difference in period A and period B, which were tightly associated with the formation of OSs (Wang et al., 2021). Cluster analysis of backward trajectories showed that air masses arriving at both urban and suburban sites in the period A mainly originated from the continental region, with significant influences of anthropogenic emissions (e.g., NO_x and SO₂) from southern YRD. Furthermore, considering the distinct and similar diurnal variation of O₃, NO₂, SO₂, sulfate, and OSs during period A at both sites, aerosol OSs can be assumed to be mainly formed in local areas. In contrast, these two sampling sites were primarily affected by air masses transported from the East China Sea in the period B. Moreover, the average VC value in the period A was two times lower than that in the period B (Table S5), implying relatively weaker diffusion and dilution of air pollutants in the period A. These factors can be partly responsible for the higher oxidant and sulfate concentrations in period A than in period B. Similarly, since the suburban site is closer to the East China Sea with a decreased influence from anthropogenic emissions (Fig. 3), the levels of O₃, NO_x, and sulfate were higher at the urban site than at the suburban site (Fig. 2 and Table S5). The differences in the concentration of oxidants and sulfate might provide an explanation for the difference in the concentrations of OSs between periods A and B, as well as between urban and suburban sites.

3.3 Formation mechanisms of OSs

3.3.1 Isoprene-derived OSs

Previous laboratory studies have suggested that isoprene can react with •OH to form IEPOX in the gas phase under low NO_x conditions (Fabien et al., 2009). In the daytime, ambient O₃ can be rapidly photolyzed to generate •OH under the influence of UV (Kourtchev et al., 2015). Thus, O₃ and UV could serve as a proxy of •OH. Considering a significant role of photochemistry and sulfate-related heterogeneous chemistry in the formation of OSs, OS_i production is expected to be closely associated with isoprene, O₃, UV, and sulfate. Specifically, the simplified pathways leading to the formation of OS_i in the atmosphere can be derived as follows.

where J_{O_3} is the photolysis rate constant, k_{1-4} is the second-order rate coefficient, M is N₂ or O₂, and X represents the potential products (e.g., IEPOX and HMML) of isoprene oxidation by •OH.

Assuming the concentrations of O(¹D) and •OH are in the steady state, we can derive the following equations (Seinfeld and Pandis, 2016).

$$[\text{O}(^1\text{D})] = \frac{J_{\text{O}_3} [\text{O}_3]}{k_1 [\text{H}_2\text{O}] + k_2 [M]}, \quad (1)$$

$$[\cdot\text{OH}] = 2\tau_{\text{OH}} k_1 [\text{O}(^1\text{D})] [\text{H}_2\text{O}], \quad (2)$$

where τ_{OH} is the average lifetime of •OH. In general, J_{O_3} is linearly dependent on the UV radiation, i.e., $J_{\text{O}_3} = \varphi \text{UV}$, where φ is the slope of the linear fitting between J_{O_3} and UV radiation (Li et al., 2022). Combining Eqs. (1) and (2), the steady-state •OH concentration can be expressed as:

$$[\cdot\text{OH}] = \frac{2\tau_{\text{OH}} k_1 [\text{H}_2\text{O}] J_{\text{O}_3} [\text{O}_3]}{k_1 [\text{H}_2\text{O}] + k_2 [M]} = \alpha \varphi \tau_{\text{OH}} \text{UV} [\text{O}_3], \quad (3)$$

$$\alpha = \frac{2k_1 [\text{H}_2\text{O}]}{k_1 [\text{H}_2\text{O}] + k_2 [M]}. \quad (4)$$

Also, assuming a steady-state to the oxygenated organic intermediates (i.e., X), we can derive:

$$\begin{aligned} [X] &= k_3 \tau_X [\text{Isoprene}] [\cdot\text{OH}] \\ &= \alpha \varphi k_3 \tau_X \tau_{\text{OH}} [\text{Isoprene}] \text{UV} [\text{O}_3], \end{aligned} \quad (5)$$

where τ_X is the average lifetime of X in the atmosphere.

During the strong formation of OS_i via the heterogeneous reactions of X on acidic sulfate, the change in the abundance

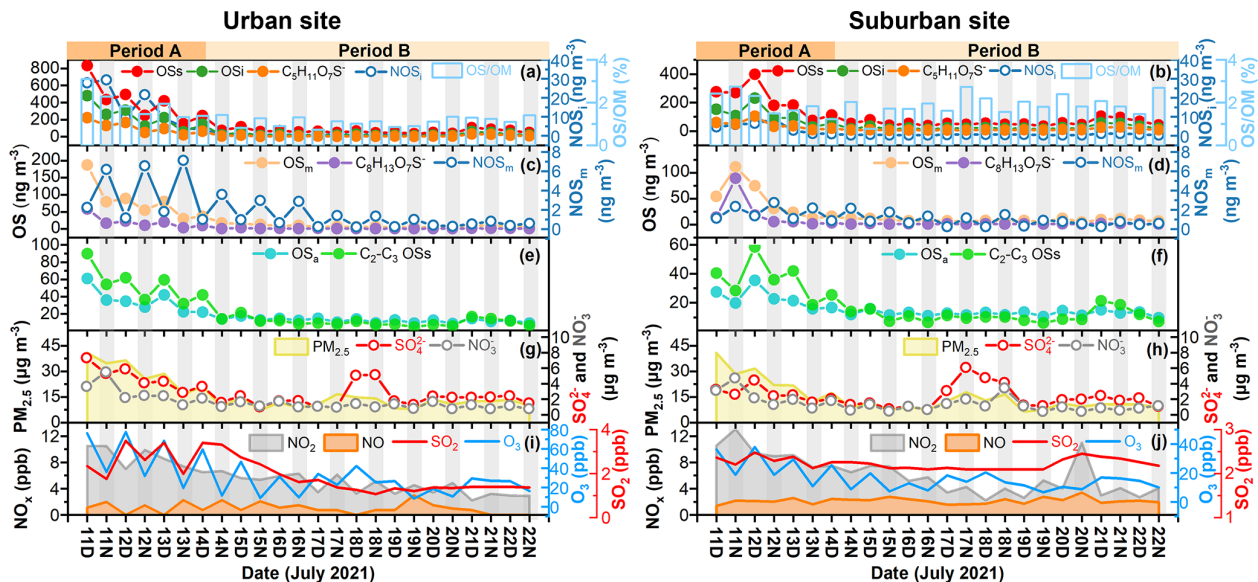

Figure 2. Temporal variations of OSs and other chemical components in $\text{PM}_{2.5}$ as well as other data measured in urban and suburban Shanghai in summer. (a–b) OSs, OS_i , $\text{C}_5\text{H}_{11}\text{O}_7\text{S}^-$ (major OS_i species), NOS_1 , and OS/OM (%); (c–d) OS_m , $\text{C}_8\text{H}_{13}\text{O}_7\text{S}^-$, and NOS_m ; (e–f) OS_a and $\text{C}_2\text{--C}_3$ OSs; (g–h) $\text{PM}_{2.5}$, SO_4^{2-} , and NO_3^- ; and (i–j) NO_2 , NO , SO_2 , and O_3 . The sampling periods A and B indicate the relatively polluted period and the cleaner period, respectively.

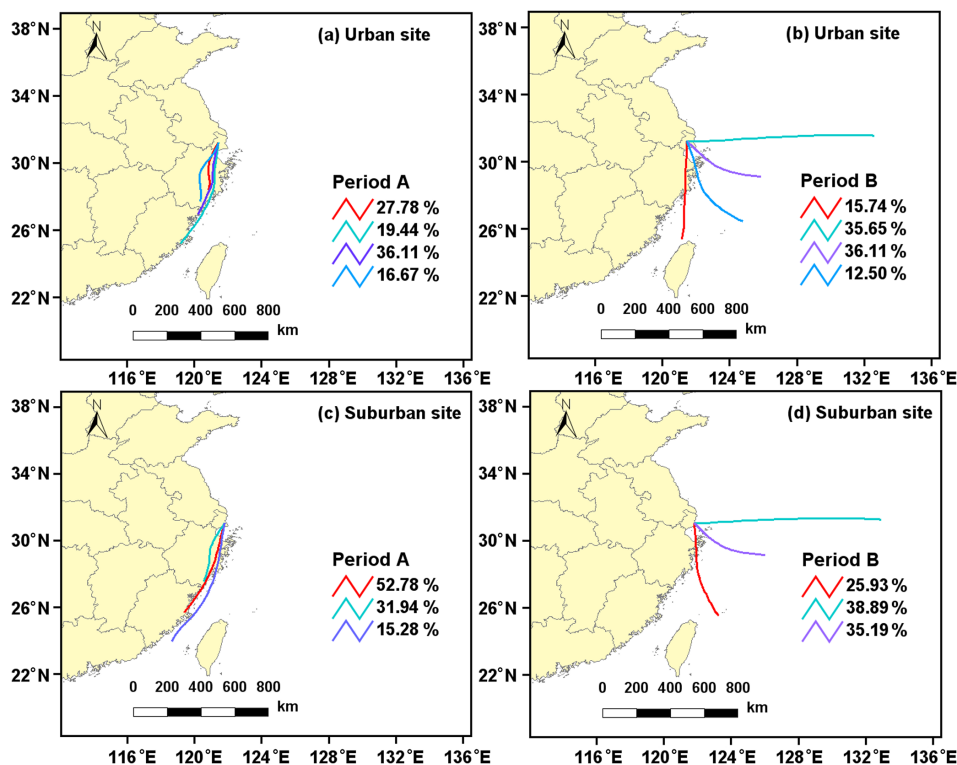

Figure 3. Air mass backward trajectories of the major clusters in different periods in the (a–b) urban and (c–d) suburban areas.

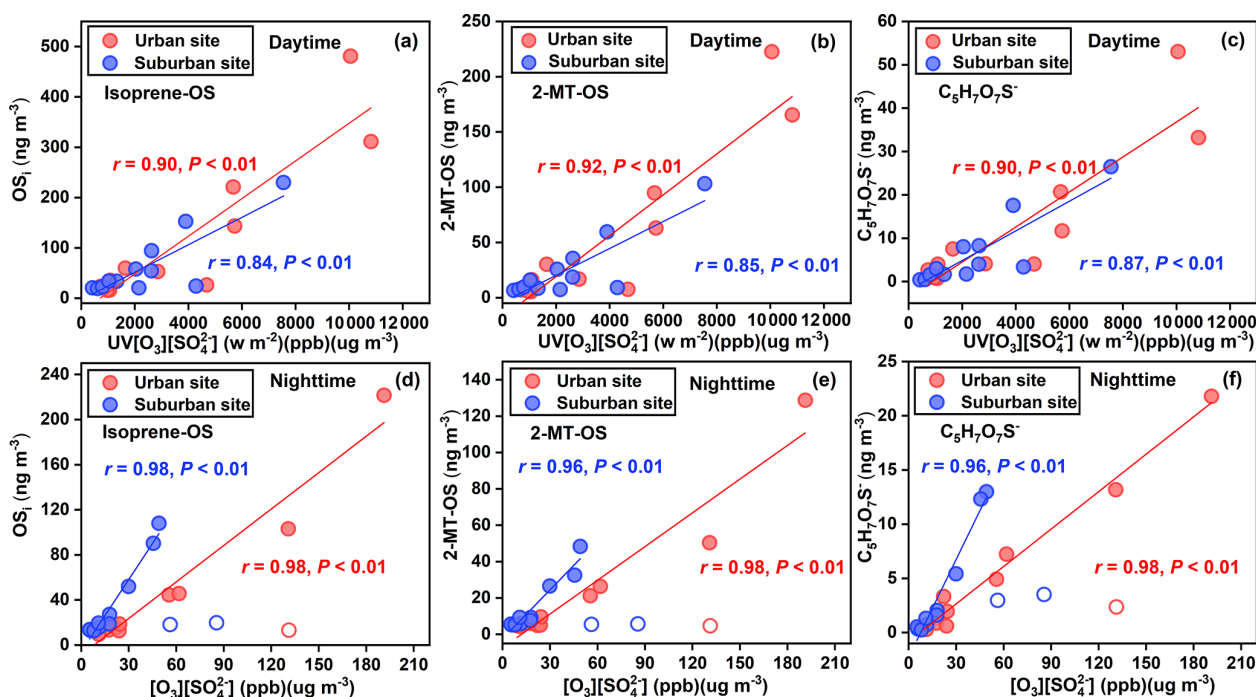

Figure 4. Mass concentrations of (a, d) OS_i, (b, e) 2-MT-OS, and (c, f) C₅H₇O₇S⁻ as functions of UV[O₃][SO₄²⁻] and [O₃][SO₄²⁻] during daytime and nighttime in the urban (solid red circles) and suburban sites (solid blue circles). The open circles represent outliers, which was attributed to several particularly high sulfate events.

of OS_i is expected to be proportional to its formation rate:

$$\frac{d[\text{OS}_i]}{dt} \propto k_4[\text{SO}_4^{2-}][X] \propto \alpha\phi k_3 k_4 \tau_X \tau_{\text{OH}} [\text{Isoprene}] \text{UV}[\text{O}_3] [\text{SO}_4^{2-}]. \quad (6)$$

It should be noted that the above equations are derived based on the assumption that the reaction between O(¹D) and H₂O is a major source of summertime •OH in the areas studied. Given that a linear relationship was observed between atmospheric •OH and J_{O(¹D)} in different atmospheres (Stone et al., 2012), such an assumption seems to be reasonable. When isoprene is in a steady state in the atmosphere, OS_i production is expected to be proportional to the product of O₃, UV, and sulfate.

$$\frac{d[\text{OS}_i]}{dt} \propto \text{UV}[\text{O}_3] [\text{SO}_4^{2-}]. \quad (7)$$

It should be noted that Eq. (7) did not consider the influences of aerosol acidity, ALW, and other factors (e.g., •OH production from the photolysis of nitrous acid and aldehydes during the daytime). However, the deduction can at least suggest that the secondary production of OS_i is positively correlated with the value of UV[O₃][SO₄²⁻]. Indeed, the concentrations of daytime OS_i and major OS_i species showed a linear positive relationship with the value of UV[O₃][SO₄²⁻] at both urban and suburban sites ($r = 0.84\text{--}0.92$, $P < 0.01$) (Fig. 4a–c). We found that the correlation between major OS_i species and

UV[O₃][SO₄²⁻] was stronger than the correlation of major OS_i species with O₃ and SO₄²⁻ ($r < 0.82$, $P < 0.01$); moreover, there was no significant correlation between major OSs and UV ($P > 0.05$). Thus, our results provide field evidence that the formation of daytime OS_i in these two study areas was mainly controlled by •OH oxidation of isoprene; moreover, the higher concentration of OS_i in the urban area can be attributed to the stronger atmospheric oxidation capacity (i.e., higher UV[O₃] value) and more serious anthropogenic sulfate pollution (particularly during period A). We also observed that the OS concentrations did not significantly increase in several high sulfate events in the period B. One possible explanation is that these abnormal high sulfate events resulted in excessive SO₄²⁻ in the formation of OSs.

2-MT-OS and 2-MGA-OS have been identified as important tracers of isoprene-derived SOA (Hettiyadura et al., 2019; Cai et al., 2020). During isoprene oxidation by •OH, these two OS species are produced under low (i.e., IEPOX pathway) and high (i.e., HMML or methacrylic acid epoxide (MAE) pathways) NO_x conditions, respectively (Surratt et al., 2010; Nguyen et al., 2015). The ratios of 2-MT-OS concentration to 2-MGA-OS concentration in the daytime were 9.7 ± 3.1 and 12.1 ± 5.5 at urban and suburban sites, respectively (Fig. S5b). A 2-MT-OS/2-MGA-OS ratio of larger than 1 was also found in observations in summer 2020 (Fig. S5a), suggesting that low NO_x channel dominated the formation of daytime OS_i in the two

study areas. This finding was similar to previous observations in Beijing (3.2) (Wang et al., 2020) and Guangzhou (7.6) (Bryant et al., 2021). Other abundant OS_i compounds including C₅H₇O₇S⁻, C₄H₇O₆S⁻, and C₅H₉O₇S⁻ can be produced by the photooxidation of isoprene, heterogeneous oxidative aging of 2-MT-OS, or sulfate radical-initiated reaction with methacrolein and methyl vinyl ketone in the aqueous phase (Schindelka et al., 2013; Wach et al., 2019; Hettyadura et al., 2015). These OSs showed strong correlations ($r = 0.74\text{--}0.90$, $P < 0.01$) with UV[O₃][SO₄²⁻], which further highlights the significance of the photochemistry in OS_i formation.

In the nighttime, the formation of •OH can be primarily attributed to the reactions of olefins and O₃ (Paulson and Orlando, 1996). As shown in Fig. 4d–f, total OS_i and major OS_i compounds were significantly correlated with the product of O₃ and SO₄²⁻ concentrations ($r = 0.96\text{--}0.98$, $P < 0.01$). Since the nighttime oxidant level (including O₃ and •OH) was substantially lower than that in the daytime (Table S5), the production of OS_i was weakened in the nighttime (Table S2). It is interesting to note the 2-MT-OS / 2-MGA-OS mean ratio in the nighttime was 13.1–15.0 (Fig. S5b), which is significantly higher than the mean ratio (9.7–12.1) in the daytime, indicating that the IEPOX pathway may be a potential mechanism to generate OS_i in the nighttime. Another possible explanation for the decreased OS concentration in the nighttime is that these OSs were mainly formed during the daytime but had a lower abundance in the nighttime due to deposition and weak nighttime formation. Namely, considering the strong diffusion effect during the daytime and the weak diffusion effect at the nighttime (Fig. S4), the nighttime OSs may be partially derived from OSs formed via photochemical processes during the daytime. This is because the enhanced diffusion effect during the daytime can result in a decrease in the amount of OS produced during the daytime to deposit into the nighttime.

Furthermore, NO₃• chemistry in the nighttime was another possible pathway to form OS_i, particularly NOSs. The nighttime NOS concentration was linearly correlated with the product of NO₂ and O₃ ([NO₂][O₃], i.e., a proxy of NO₃•) (Fig. S6). Interestingly, most of NOS_i (e.g., C₅H₁₀NO₉S⁻, C₅H₈NO₁₀S⁻, C₄H₈NO₇S⁻, and C₅H₈NO₇S⁻) have higher concentrations in the daytime, except for C₅H₉N₂O₁₁S⁻. Thus, although nighttime NO₃• chemistry was important, the NOS_i formed via photochemistry under the influence of NO_x in the daytime was still the dominant contributor to the total NOS_i in our study areas. Regarding C₅H₉N₂O₁₁S⁻, its formation pathway is mainly the NO₃• oxidation of C₅H₉NO₅, as illustrated in Fig. S7 (Hamilton et al., 2021). Accordingly, the abundance of C₅H₉N₂O₁₁S⁻ peaked during the nighttime (Fig. S8). It should be pointed out that the •OH oxidation of C₅H₉NO₅ can also contribute to the production of C₅H₁₀NO₉S⁻ (Fig. S7). Clearly, this mechanism can be responsible for the higher C₅H₁₀NO₉S⁻ concentrations in the daytime, as mentioned above. In general, increased OS_i

level in the daytime demonstrated that the formation of OS_i in urban and suburban areas was largely controlled by photooxidation of isoprene in the presence of sulfate in the daytime, rather than nighttime NO₃• chemistry. Moreover, a decrease in average OS_i level from the urban area to the suburban area can be explained by the weakened photooxidation of isoprene and the decreased anthropogenic sulfate pollution (particularly in the relatively polluted period).

3.3.2 Monoterpene-derived OSs

The concentrations of the most abundant OS_m species (C₁₀H₁₅O₇S⁻ and C₈H₁₃O₇S⁻) showed a strong correlation with the value of UV[O₃][SO₄²⁻] (and UV[O₃][SO₂]) in the daytime at both urban and suburban sites ($r = 0.82\text{--}0.86$, $P < 0.01$), indicating that the photooxidation of monoterpenes was a significant source for OS_m. Previous studies also demonstrated that C₁₀H₁₅O₇S⁻ can be produced through the photooxidation of monoterpenes or sulfate radical reaction with α-pinene (Surratt et al., 2008; Nozière et al., 2010).

In the nighttime, the concentrations of nitrogen-free OS_m species decreased significantly with a decrease in the O₃ levels (Wang et al., 2020). However, NOS_m species increased in concentration in the nighttime and showed a significant correlation with the value of [O₃][NO₂] (the proxy of NO₃•, as mentioned above) ($r = 0.90\text{--}0.95$, $P < 0.01$). Accordingly, nighttime NO₃• chemistry exerted a significant influence on the abundance of NOS_m in these study areas. A study by Hamilton et al. (2021) has reported that NO₃• chemistry plays an important role in the production of NOS_m. However, the overall lower OS_m level in the nighttime (Table S2) suggests that daytime OS_m production via monoterpenes photooxidation was still the dominant contributor to total OS_m throughout the day. Although several field studies have reported the abundance of various NOS_m (e.g., C₁₀H₁₆NO₇S⁻ and C₉H₁₄NO₈S⁻) (Wang et al., 2018; Bryant et al., 2021; Cai et al., 2020), their structures, formation mechanisms, and relevant diurnal variations remain large uncertainties, which need to be deeply explored in future research.

3.3.3 C₂–C₃ and anthropogenic OSs

The OS species with two or three carbon atoms (C₂–C₃ OSs) are generally considered to originate from both biogenic and anthropogenic emissions (Wang et al., 2020). The abundant C₂–C₃ OS species, including C₂H₃O₆S⁻ (glycolic acid sulfate; GAS), C₃H₅O₅S⁻ (hydroxyacetone sulfate; HAS), and C₃H₅O₆S⁻ (lactic acid sulfate; LAS), were significantly correlated with the values of UV[O₃][SO₄²⁻] in the daytime at both urban and suburban sites ($r = 0.79\text{--}0.91$, $P < 0.01$), indicating that the photochemical processes largely contributed to the formation of C₂–C₃ OSs. Recently, the heterogeneous •OH oxidation of particulate 2-MT-OS has been shown to generate a series of C₂–C₃ OSs (e.g., C₂H₃O₆S⁻, C₃H₅O₆S⁻, and C₂H₃O₅S⁻) (Chen et al., 2020). Moreover,

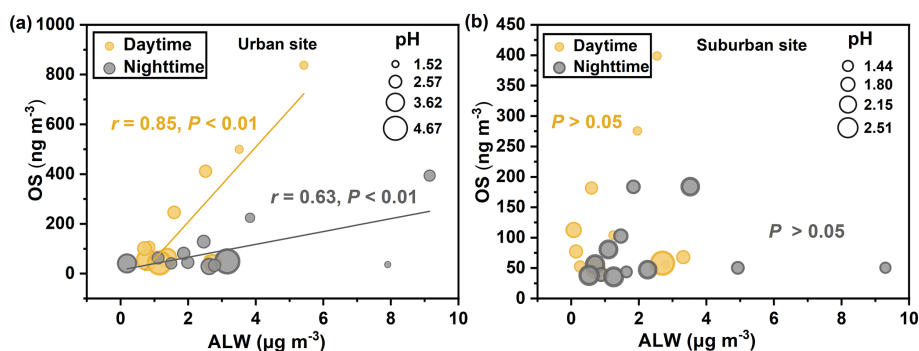

Figure 5. Scatterplots of the ALW concentrations with the mass concentrations of total OSs in $\text{PM}_{2.5}$ collected in the (a) urban and (b) suburban areas. Yellow and gray lines show regression lines in the daytime and nighttime, respectively.

$\text{C}_3\text{H}_5\text{O}_4\text{S}^-$ and $\text{C}_3\text{H}_7\text{O}_5\text{S}^-$ have previously been reported to be produced by the photooxidation of diesel vehicle exhausts (Blair et al., 2017).

Most of the quantified OS_a compounds, including $\text{C}_{13}\text{H}_{25}\text{O}_5\text{S}^-$, $\text{C}_9\text{H}_{15}\text{O}_7\text{S}^-$, $\text{C}_8\text{H}_{17}\text{O}_4\text{S}^-$, benzyl sulfate ($\text{C}_7\text{H}_7\text{O}_4\text{S}^-$), phenyl sulfate ($\text{C}_6\text{H}_5\text{O}_4\text{S}^-$), as well as $\text{C}_6\text{H}_9\text{O}_6\text{S}^-$, $\text{C}_5\text{H}_7\text{O}_6\text{S}^-$, and $\text{C}_4\text{H}_7\text{O}_4\text{S}^-$, exhibited a strong correlation ($P < 0.01$) with the values of $\text{UV}[\text{O}_3][\text{SO}_4^{2-}]$ in the daytime. $\text{C}_{13}\text{H}_{25}\text{O}_5\text{S}^-$ has been detected in diesel exhaust (Cui et al., 2019), which is the homologous compound of $\text{C}_{12}\text{H}_{23}\text{O}_5\text{S}^-$ produced from dodecane photooxidation (Riva et al., 2016b). A chamber study has detected $\text{C}_9\text{H}_{15}\text{O}_7\text{S}^-$ in decalin SOA and speculated that it was produced via $\cdot\text{OH}$ oxidation of a C_9 -carbonyl hydroperoxide ($\text{C}_9\text{H}_{16}\text{O}_3$) and subsequent reaction on acidic sulfate aerosols (Riva et al., 2016b). In addition, photooxidation of diesel fuel vapor in the presence of SO_2 has been suggested to be an important source of $\text{C}_6\text{H}_9\text{O}_6\text{S}^-$, $\text{C}_5\text{H}_7\text{O}_6\text{S}^-$, and $\text{C}_4\text{H}_7\text{O}_4\text{S}^-$ species (Blair et al., 2017). The formation of $\text{C}_7\text{H}_7\text{O}_4\text{S}^-$ and $\text{C}_6\text{H}_5\text{O}_4\text{S}^-$ can also be attributed to the photooxidation of naphthalene and 2-methylnaphthalene (Riva et al., 2015).

We note that the concentrations of most of C_2 – C_3 OS and OS_a species decreased significantly from the daytime to the nighttime (Tables S2 and S3). As discussed above, the OSs observed in the nighttime may partially come from the OSs generated during the daytime. Thus, the deposition effect from the daytime to the nighttime was an important factor controlling nighttime levels of C_2 – C_3 OSs and OS_a . In addition, the nighttime gas-phase oxidation process was also likely associated with C_2 – C_3 and anthropogenic OS formation at both urban and suburban sites, as suggested by the significant correlations of C_2 – C_3 OSs and OS_a with O_3 and $[\text{O}_3][\text{NO}_2]$ in the nighttime ($r = 0.89$ – 0.91 , $P < 0.01$). Overall, these results further highlight the importance of photochemistry in controlling the all-day abundance of OSs, as discussed earlier.

3.3.4 The effects of ALW and pH on OS formation

We have demonstrated that the atmospheric oxidation capacity (e.g., $\text{UV}[\text{O}_3]$ and $[\text{O}_3 + \text{NO}_2]$), sulfate pollution, and nighttime $\text{NO}_3\cdot$ chemistry exerted considerable influences on the formation of OSs in both urban and suburban areas. In addition, laboratory and field studies have suggested that aerosol properties including acidity and ALW also play important roles in OS formation (Iinuma et al., 2007b; Surratt et al., 2007b; Wang et al., 2020, 2018, 2022). The aerosol pH in Shanghai in summer averaged 2.7 ± 0.9 and 2.2 ± 0.7 in urban and suburban areas, respectively. The mean pH value was similar to that in northern China (summer) (Ding et al., 2019; Wang et al., 2018), but higher than that in the Pearl River Delta (PRD) region (Fu et al., 2015). In this study, only the 2-MT-OS concentration showed an evidently negative correlation with the pH value ($r = 0.58$, $P < 0.05$), suggesting the aerosol acidity is not a limiting factor for the formation of most OS species.

A positive correlation was observed between the concentrations of OSs and ALW only in the urban area during both daytime and nighttime (Fig. 5), consistent with our previous observations in urban Shanghai (Wang et al., 2021). It is interesting to note that although higher ALW concentrations and lower pH values were observed at the suburban site, the OS concentrations were significantly higher at the urban site (Table S5). This result further confirms that atmospheric oxidation capacity and sulfate pollution level governed the formation of OSs in urban and suburban Shanghai (particularly in the relatively polluted period), although ALW and aerosol acidity also played a role. Therefore, a synergistic regulation of atmospheric oxidation capacity and anthropogenic SO_2 emissions would be important for the mitigation of OS and SOA pollution in the megacity Shanghai.

4 Conclusions

We investigated the spatial and diurnal variations of aerosol OS formation in Shanghai in summer. Isoprene- and monoterpene-derived OSs were found to be the dominant OS

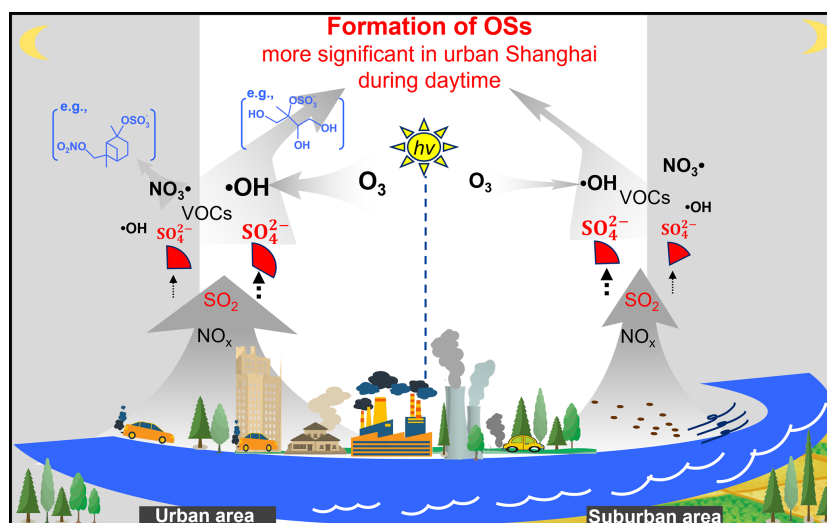

Figure 6. Conceptual picture showing the characteristic and atmospheric process of OSs in urban and suburban Shanghai.

groups during the entire sampling campaign, likely suggesting that the formation of OSs was largely controlled by biogenic VOCs. Most OSs decreased from the daytime to the nighttime, while NOS_m peaked during nighttime. These findings suggested that OSs were mainly produced via daytime formation processes in both urban and suburban areas, except for NOS_m . Moreover, the average abundance of various types of OSs showed a decreasing trend from the urban area to the suburban area, which can be explained by weakened atmospheric oxidation capacity and sulfate pollution in the suburban area (primarily in the relatively polluted period). Further, daytime OS formation was concretized according to the interactions among OSs, UV, O_3 , and SO_4^{2-} , suggesting that the concentrations of most OSs were significantly correlated with the values of $\text{UV}[\text{O}_3][\text{SO}_4^{2-}]$ during daytime in both urban and suburban Shanghai. We concluded that an enhancement in the photochemical process and sulfate level can exacerbate OS pollution in the urban area. These findings were summarized in a diagram (Fig. 6). Generally, our study not only deepens the understanding about the importance of photochemical process and anthropogenic sulfate pollution in controlling OS formation but also provides potential management strategies to decrease the abundance of particulate OSs.
