**Abstract.** Aerosol liquid water (ALW) is a unique reaction medium, but its chemistry is poorly understood. For example, little is known of photooxidant concentrations – including hydroxyl radicals ( $\cdot\text{OH}$ ), singlet molecular oxygen ( $^1\text{O}_2^*$ ), and oxidizing triplet excited states of organic matter ( $^3\text{C}^*$ ) – even though they likely drive much of ALW chemistry. Due to the very limited water content of particles, it is difficult to quantify oxidant concentrations in ALW directly. To predict these values, we measured photooxidant concentrations in illuminated aqueous particle extracts as a function of dilution and used the resulting oxidant kinetics to extrapolate to ALW conditions. We prepared dilution series from two sets of particles collected in Davis, California: one from winter (WIN) and one from summer (SUM). Both periods are influenced by biomass burning, with dissolved organic carbon (DOC) in the extracts ranging from 10 to 495 mg C L<sup>-1</sup>. In the winter sample, the  $\cdot\text{OH}$  concentration is independent of particle mass concentration, with an average value of  $5.0 (\pm 2.2) \times 10^{-15}$  M, while in summer  $\cdot\text{OH}$  increases with DOC in the range  $(0.4\text{--}7.7) \times 10^{-15}$  M. In both winter and summer samples,  $^3\text{C}^*$  concentrations increase rapidly with particle mass concentrations in the extracts and then plateau under more concentrated conditions, with a range of  $(0.2\text{--}7) \times 10^{-13}$  M. WIN and SUM have the same range of  $^1\text{O}_2^*$  concentrations,  $(0.2\text{--}8.5) \times 10^{-12}$  M, but in WIN the  $^1\text{O}_2^*$  concentration increases linearly with DOC, while in SUM  $^1\text{O}_2^*$  approaches a plateau.

We next extrapolated the relationships of oxidant formation rates and sinks as a function of particle mass concentration from our dilute extracts to the much more concentrated condition of aerosol liquid water. Predicted  $\cdot\text{OH}$  concentrations in ALW (including mass transport of  $\cdot\text{OH}$  from the gas phase) are  $(5\text{--}8) \times 10^{-15}$  M, similar to those in fog/cloud waters. In contrast, predicted concentrations of  $^3\text{C}^*$  and  $^1\text{O}_2^*$  in ALW are approximately 10 to 100 times higher than in cloud/fogs, with values of  $(4\text{--}9) \times 10^{-13}$  M and  $(1\text{--}5) \times 10^{-12}$  M, respectively. Although  $\cdot\text{OH}$  is often considered the main sink for organic compounds in the atmospheric aqueous phase, the much higher concentrations of  $^3\text{C}^*$  and  $^1\text{O}_2^*$  in aerosol liquid water suggest these photooxidants will be more important sinks for many organics in particle water.

## 1 Introduction

The chemical processing of organic compounds in cloud/fog water and aerosol liquid water comprises an important source and sink of secondary organic aerosol (SOA) (Carlton et al., 2020; Ervens et al., 2011; Gilardoni et al., 2016; Lim et al., 2010; McNeill, 2015). Aerosol liquid water (ALW), i.e., the liquid-phase water on airborne particles, is much less abundant (in terms of liquid water content) and contains much higher concentrations of solutes compared to clouds and fogs. ALW appears to be an efficient and important medium for the production of aqueous SOA (aqSOA) (Ervens and Volkamer, 2010; Faust et al., 2017; Volkamer et al., 2007; Wu et al., 2018; Zhang et al., 2011), and ALW chemistry is often different from that in more dilute cloud and fog drops (Ervens, 2018; Mekic et al., 2018; Zhou et al., 2019). For example, reactions in ALW can more efficiently produce high-molecular-weight compounds like oligomers and brown carbon (De Haan et al., 2020; Lim et al., 2010; Renard et al., 2014; Tan et al., 2012; Xia et al., 2018). Modeled rates of aqSOA formation in ALW vary enormously, likely because reactant concentrations and chemical processes in particle water are poorly understood (Ervens and Volkamer, 2010; Ervens, 2018; Lin et al., 2014; Washenfelder et al., 2011).

A key driver of ALW reactivity is likely the concentrations of photochemically generated oxidants (Herrmann et al., 2015; Lim et al., 2010). Important aqueous photooxidants include hydroxyl radicals ( $\cdot\text{OH}$ ), oxidizing triplet excited states of organic compounds ( ${}^3\text{C}^*$ ), and singlet molecular oxygen ( ${}^1\text{O}_2^*$ ) (Kaur et al., 2019).  $\cdot\text{OH}$  is the most widely studied oxidant due to its ubiquity and high reactivity: it reacts with most organics with near-diffusion-controlled rate constants (Herrmann et al., 2015). The main sources of aqueous  $\cdot\text{OH}$  include mass transfer from the gas phase; the photo-Fenton reaction; and photolysis of nitrate, nitrite, and other species (Anastasio and McGregor, 2001; Arakaki and Faust, 1998; Badali et al., 2015; Herrmann et al., 2010; Tilgner and Herrmann, 2018), while the main sinks of  $\cdot\text{OH}$  are dissolved organic compounds (Anastasio and Newberg, 2007; Arakaki et al., 2013). Based on lab studies of rainwater, clouds/fogs, and aqueous particle extracts, concentrations of  $\cdot\text{OH}$  in atmospheric waters (including calculated rates of gas-to-particle partitioning of  $\cdot\text{OH}$ ) are typically  $10^{-16}$ – $10^{-15}$  M (Albinet et al., 2010; Anastasio and McGregor, 2001; Anastasio and Newberg, 2007; Arakaki et al., 2013; Faust and Allen, 1993; Kaur et al., 2019; Leresche et al., 2021; Zhou et al., 2008). In contrast, modeled  $\cdot\text{OH}$  concentrations in aqueous aerosol are generally  $10^{-13}$  to  $10^{-12}$  M (Ervens et al., 2014; Tilgner and Herrmann, 2018; Tilgner et al., 2013), but these are likely overestimates, in part because of missing  $\cdot\text{OH}$  sinks (Arakaki et al., 2013; Arciva et al., 2022).

When organic chromophores (i.e., brown carbon) absorb sunlight, the molecules are promoted to their more reactive

triplet excited states, some of which are oxidants (Kaur et al., 2019; McNeill and Canonica, 2016). These oxidizing triplets can transform numerous atmospheric species, including converting phenols and biogenic volatile compounds to aqSOA and oxidizing sulfite to sulfate (González Palacios et al., 2016; Monge et al., 2012; Rossignol et al., 2014; Smith et al., 2014; Wang et al., 2020). Triplets can be important oxidants in atmospheric and surface waters, with concentrations of  $10^{-15}$ – $10^{-13}$  M (Kaur and Anastasio, 2018; Kaur et al., 2019; McNeill and Canonica, 2016). In comparison, triplet concentrations in ALW are expected to be higher because the production rate of  ${}^3\text{C}^*$  increases with dissolved organic carbon (Cannonica and Freiburghaus, 2001; McCabe and Arnold, 2017), although organic compounds can also be important sinks for  ${}^3\text{C}^*$ , suppressing its steady-state concentration (Gemayel et al., 2021; Wenk et al., 2013). This dual effect of organic compounds makes it difficult to predict  ${}^3\text{C}^*$  concentrations in ALW. Kaur et al. (2019) estimated a concentration of oxidizing  ${}^3\text{C}^*$  in ALW of  $10^{-13}$ – $10^{-11}$  M based on measurements in dilute particle extracts, while Tilgner et al. (2021) estimated the ALW concentration of triplets as  $10^{-11}$  M.

Most or all of atmospheric triplets (i.e., both oxidizing and non-oxidizing triplets) also transfer energy to dissolved oxygen to form another important photooxidant, singlet molecular oxygen. Concentrations of  ${}^1\text{O}_2^*$  in fog/cloud drops and dilute extracts of ambient particles and lab SOA are higher than concentrations of  $\cdot\text{OH}$  and  ${}^3\text{C}^*$ , typically  $10^{-14}$  to  $10^{-12}$  M (Anastasio and McGregor, 2001; Bogler et al., 2022; Faust and Allen, 1992; Kaur and Anastasio, 2017; Kaur et al., 2019; Li et al., 2019; Manfrin et al., 2019). Though  ${}^1\text{O}_2^*$  is generally less reactive than  $\cdot\text{OH}$  and  ${}^3\text{C}^*$ , it can react quickly with certain alkenes, furans, nitrogen heterocycles, polycyclic aromatic hydrocarbons, and other organics (Barrios et al., 2021; Wilkinson et al., 1995) and can be a competitive oxidant because of its high concentration (Bogler et al., 2022; Kaur et al., 2019; Manfrin et al., 2019). Kaur et al. (2019) estimated  ${}^1\text{O}_2^*$  might be as high as  $10^{-10}$  M under ALW conditions due to increased  ${}^3\text{C}^*$  concentrations, which would make it an important oxidant in particle water (Ma et al., 2021).

Due to its limited water content, it is difficult to study chemistry in ALW directly. To get around this problem, Kaur et al. (2019) measured  $\cdot\text{OH}$ ,  ${}^3\text{C}^*$ , and  ${}^1\text{O}_2^*$  kinetics as a function of dilution in extracts of a single particulate matter (PM) sample and extrapolated the results to aqueous aerosol conditions. However, there are large uncertainties with this extrapolation, since the PM extracts were approximately 1000 times more dilute than ALW conditions. In addition, these authors only examined a single sample collected during winter and were unaware that triplet measurements can be impacted by probe inhibition from organic compounds. To build on this past work, here we apply the same method but with

higher dissolved organic matter concentrations in particle extracts and with correction for triplet probe inhibition. Moreover, in this work we study both a winter PM sample and summer wildfire particles to explore differences in oxidant kinetics.

## 2 Experimental methods

### 2.1 Chemicals

Furfuryl alcohol (FFA, 98%), benzoic acid (BA,  $\geq 99.5\%$ ), *p*-hydroxybenzoic acid (*p*-HBA, 99%), (phenylthio)acetic acid (PTA, 96%), syringol (SYR, 99%), 3,4-dimethoxybenzaldehyde (DMB, 99%), and deuterium oxide (99.9% D atom) were received from MilliporeSigma. All chemical solutions and particulate matter extracts were prepared using air-saturated ultrapure water (Milli-Q water) from a Milli-Q Advantage A10 system (Millipore;  $\geq 18.2\text{ M}\Omega\text{ cm}$ ) with an upstream cartridge to remove organics.

### 2.2 Particle collection and extraction

Fine particles ( $\text{PM}_{2.5}$ ) were collected on the roof of Ghausi Hall on the campus of the University of California, Davis, in February and August 2020. Davis air quality in winter is often impacted by residential wood combustion, while the August 2020 samples were impacted by northern California wildfires.  $\text{PM}_{2.5}$  was collected using a high-volume sampler equipped with a  $\text{PM}_{10}$  inlet (Graseby Andersen) to remove PM larger than  $10\ \mu\text{m}$  followed by two offset, slotted impactor plates (Tisch Environmental, Inc., 230 series) to remove PM above  $2.5\ \mu\text{m}$ . The resulting fine particles were collected onto Teflon-coated borosilicate glass microfiber filters (Pall Corporation, Emfab™ filters, 8 in.  $\times$  10 in.) that were pre-cleaned by gently shaking in Milli-Q water for 8 h and then drying at  $100\ ^\circ\text{C}$ . During sampling, the airflow rate was maintained at  $68 (\pm 2)\ \text{m}^3\ \text{h}^{-1}$ . Particles were collected for either 24 h or up to a week; see Table S1 for details. Upon collection, each sample was wrapped in aluminum foil (baked previously at  $500\ ^\circ\text{C}$  for 8 h), sealed in a Ziploc bag, and frozen at  $-20\ ^\circ\text{C}$ . Field blanks were obtained in an identical manner to samples, including loading the clean filters into the sampler and turning on the pump for 2 min.

To prepare particulate matter extracts (PMEs), filters were cut into  $2\ \text{cm} \times 2\ \text{cm}$  squares on the day of extraction. Each square was placed in an individual, sealed, 20 mL amber glass vial and extracted with Milli-Q water by shaking for 4 h in the dark. The extracts from the same filter sample were combined, filtered ( $0.22\ \mu\text{m}$  PTFE; Pall), and adjusted to pH 4.2 with sulfuric acid or sodium hydroxide to mimic the acidity of winter particle water in the Central Valley of California (Parworth et al., 2017). The pH of each extract was measured by a pH microelectrode (MI-414 series, protected tip; Microelectrodes, Inc.). The UV–Vis spectrum of each

PME was measured in a 1 cm cuvette immediately after pH adjustment with a Shimadzu UV-2501PC spectrophotometer. Rates of sunlight absorption between 300 and 450 nm were calculated for midday winter-solstice sunlight in Davis, as described by Kaur et al. (2019). PMEs were divided into 4 mL HDPE bottles and flash-frozen in liquid nitrogen immediately after preparation and were later thawed on the day of experiments. Filter squares were weighed by a microbalance (Sartorius M2P) before and after extraction to determine the PM mass extracted; the resulting PM mass / water mass ratios in the filtered extracts might be overestimated because of removal of insoluble material during filtration. Dissolved organic carbon (DOC) and major ion concentrations (Table S2) in PMEs were measured by a Shimadzu TOC-VCPH analyzer and Metrohm ion chromatographs (881 Compact IC Pro) equipped with conductivity detectors, respectively.

To investigate the relationship between particle dilution and oxidant concentration, filter squares from the same sample were extracted with five different volumes of Milli-Q water: 10, 2, 0.7, 0.4, and 0.3 mL. To obtain enough filter squares for this dilution series, for both the winter (WIN) and the summer (SUM) samples we combined extracts from 180 filter squares cut from three sheets of filter that were collected on consecutive days. The same number of squares was cut from each of the three filters in a given sample. We use “PME name-water volume” (e.g., WIN-0.7) to denote the sample and extraction volume. Because it is difficult to extract squares with only 0.4 or 0.3 mL of Milli-Q, for these dilutions we extracted each filter square with 1 mL of Milli-Q and then used a rotary evaporator (Buchi Rotavapor R-110; temperature set no higher than  $65\ ^\circ\text{C}$ ) to remove water until we obtained the equivalent of a 0.4 or 0.3 mL extract. We define the concentration factor (CF) of an extract as the inverse of the volume used for extraction. For example, WIN-10 has a concentration factor of 0.1.

### 2.3 Sample illumination and chemical analysis

We illuminated samples with light from a 1000 W xenon arc lamp passed through a water filter, an AM1.0 air mass filter (AM1D-3L, Sciencetech), and a 295 nm long-pass filter (20CGA-295, Thorlabs) to simulate tropospheric sunlight (Kaur and Anastasio, 2017). We first transferred the extract into a silicone-plugged GE 021 quartz tube (5 mm inner diameter, 1.0 mL volume) and then spiked it with the photooxidant probe and mixed it. The entire tube was illuminated at  $20\ ^\circ\text{C}$  and was not stirred. Dark control samples were wrapped in aluminum foil and kept in the same photoreactor chamber. During illumination, aliquots of approximately 150  $\mu\text{L}$  were removed from the illuminated and dark tubes at specific time intervals to measure concentrations of probes with high-performance liquid chromatography (HPLC, Shimadzu LC-20AB pump, Thermo Scientific Accucore XL C18 column ( $50 \times 3\ \text{mm}$ ,  $4\ \mu\text{m}$  bead), and Shimadzu-M20A UV–Vis detector). The photon flux on each experiment day

was determined by measuring the photolysis rate constant of a 10  $\mu\text{M}$  2-nitrobenzaldehyde (2NB) solution in the same type of container as samples (Galbavy et al., 2010).

## 2.4 Photooxidant measurements

Details about determining photooxidant concentrations are provided in past papers (Anastasio and McGregor, 2001; Kaur and Anastasio, 2017; Kaur et al., 2019) and are only discussed briefly here.

### 2.4.1 Hydroxyl radical ( $\bullet\text{OH}$ )

The production rate, rate constant for loss, and steady-state concentration of  $\bullet\text{OH}$  were quantified using benzoic acid (BA) and a competition kinetics technique. A 0.020 M stock solution of benzoic acid/benzoate was prepared and adjusted to pH 4.2. For each sample, four 1.0 mL aliquots of PME were spiked with different final concentrations (100–1200  $\mu\text{M}$ ) of BA, keeping PME dilution by the addition of probe solution to less than 10%. We then illuminated each PME and used HPLC to monitor the formation of *p*-hydroxybenzoic acid (*p*-HBA), which is formed from BA oxidation by  $\bullet\text{OH}$ . The initial rate of *p*-HBA formation was determined from a regression between concentration and illumination time, using either a linear regression or, for plots with curvature, a three-parameter exponential fit:

$$[p\text{-HBA}]_t = [p\text{-HBA}]_0 + a(1 - e^{-bt}), \quad (1)$$

where  $[p\text{-HBA}]_t$  and  $[p\text{-HBA}]_0$  are the concentrations at illumination times  $t$  and zero, respectively, and  $a$  and  $b$  are regression fit parameters. For exponential kinetics data, the initial formation rate of *p*-HBA,  $R_{\text{P,EXP}}$ , was calculated with

$$R_{\text{P,EXP}} = a \times b. \quad (2)$$

Rates of *p*-HBA formation were normalized to sunlight conditions at midday local time on the winter solstice at Davis (solar zenith angle = 62°;  $j_{2\text{NB,win}} = 0.0070 \text{ s}^{-1}$ ; Anastasio and McGregor, 2001), and were corrected for internal light screening due to sample absorption, using

$$R_{\text{P,norm}} = \left[ \frac{R_{\text{P,EXP}}}{S_\lambda \times j_{2\text{NB,EXP}}} \right] \times j_{2\text{NB,win}}, \quad (3)$$

where  $S_\lambda$  is the internal light screening factor in an individual sample (Table S1) and  $j_{2\text{NB,EXP}}$  is the photolysis rate constant of 2NB measured on the experiment day.

We then fitted  $1/R_{\text{P,norm}}$  versus  $1/[\text{BA}]$  with a linear regression and used the slope and  $y$  intercept to calculate the initial production rate of  $\bullet\text{OH}$  ( $P_{\text{OH}}$ ), the pseudo-first-order rate constant of  $\bullet\text{OH}$  loss by natural sinks ( $k'_{\text{OH}}$ ), and the

steady-state  $\bullet\text{OH}$  concentration:

$$P_{\text{OH}} = \frac{1}{y \text{ intercept} \times Y_{p\text{-HBA}}}, \quad (4)$$

$$k'_{\text{OH}} = k_{\text{BA}+\bullet\text{OH}} \left( \frac{\text{slope}}{y \text{ intercept}} \right), \quad (5)$$

$$[\bullet\text{OH}] = \frac{1}{k_{\text{BA}+\bullet\text{OH}} \times \text{slope} \times Y_{p\text{-HBA}}}. \quad (6)$$

Here  $Y_{p\text{-HBA}}$  (0.18) is the yield of *p*-HBA from the reaction of BA with  $\bullet\text{OH}$  (Anastasio and McGregor, 2001) and  $k_{\text{BA}+\bullet\text{OH}}$  is the second-order rate constant of BA reacting with  $\bullet\text{OH}$  at pH 4.2 ( $5.1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ ) (Ashton et al., 1995; Wander et al., 1968).  $\bullet\text{OH}$  measurements are in Table S3.

### 2.4.2 Oxidizing triplet excited states of organic matter ( $^3\text{C}^*$ )

Oxidizing triplets were measured employing syringol (SYR) and (phenylthio)acetic acid (PTA) as probes (Kaur and Anastasio, 2018; Ma et al., 2023b). These probes only quantify the subset of triplets that can oxidize organic molecules. SYR captures both weakly and strongly oxidizing triplets, but its decay can be inhibited by dissolved organic matter (DOM) in PME (Canonica and Laubscher, 2008; Ma et al., 2023b; Wenk and Canonica, 2012; Wenk et al., 2015). In contrast, PTA is less sensitive to inhibition by DOM, but it only reacts appreciably with strongly oxidizing triplets (Ma et al., 2023b). Two 1.0 mL aliquots of PME were spiked with 10  $\mu\text{M}$  of SYR or PTA and then illuminated to determine the pseudo-first-order rate constants for the loss of each probe ( $k'_{\text{P,EXP}}$ ). Next,  $k'_{\text{P,EXP}}$  values were normalized to Davis winter sunlight conditions and corrected for light screening using an equation that is analogous to Eq. (3) to obtain rate constant  $k'_\text{P}$ . The contributions of direct photodegradation,  $\bullet\text{OH}$ , and  $^1\text{O}_2^*$  to probe decay were then subtracted to determine the rate constant for loss of the probe due to triplets,  $k'_{\text{P},^3\text{C}^*}$ :

$$k'_{\text{P},^3\text{C}^*} = k'_\text{P} - \left( j_\text{P} + k_{\text{P}+\text{OH}}[\bullet\text{OH}] + k_{\text{P}+^1\text{O}_2^*} \left[ ^1\text{O}_2^* \right] \right). \quad (7)$$

Here  $j_\text{P}$  is the probe direct photodegradation rate constant under Davis winter sunlight, and  $k_{\text{P}+\text{OH}}$  and  $k_{\text{P}+^1\text{O}_2^*}$  are the bimolecular rate constants of triplet probes reacting with  $\bullet\text{OH}$  and  $^1\text{O}_2^*$ , respectively (Table S4).  $\bullet\text{OH}$  accounts for 2%–35% and 3%–17% of the decay of SYR and PTA, respectively, while  $^1\text{O}_2^*$  accounts for 3%–45% and 2%–10% for SYR and PTA (Tables S5 and S6). Since triplets in PMEs represent the excited states of a complex mixture of brown carbon, there is no single value for the second-order rate constant of  $^3\text{C}^*$  reacting with probes ( $k_{\text{P},^3\text{C}^*}$ ). To estimate triplet concentrations, we assume that triplets ( $^3\text{C}^*$ ) in PME have the same average reactivity as the triplet state of 3,4-dimethoxybenzaldehyde,  $^3\text{DMB}^*$  (Fleming et al., 2020; Kaur and Anastasio, 2018; Kaur et al., 2019). Unlike in our

past work (Kaur et al., 2019), we corrected for DOM inhibiting the decays of SYR and PTA, which can cause an underestimate of  $^3\text{C}^*$  concentrations. To do this, we measured the inhibition factor (IF) in samples (Canonica and Laubscher, 2008; Ma et al., 2023b; Wenk et al., 2011) and used it to correct the  $^3\text{C}^*$  concentration. Details about inhibition factor measurements and [ $^3\text{C}^*$ ] corrections are in Sect. S1 in the Supplement. The  $^3\text{C}^*$  concentration after inhibition correction is

$$[{}^3\text{C}^*]_{\text{P}} = \frac{k'_{\text{P},{}^3\text{C}^*}}{k_{\text{P}+{}^3\text{DMB}^*} \times \text{IF}_{\text{P,corr}}}, \quad (8)$$

where  $k_{\text{P}+{}^3\text{DMB}^*}$  is the second-order rate constant of the probe with  $^3\text{DMB}^*$  (Table S4) and  $\text{IF}_{\text{P,corr}}$  is the inhibition factor of the probe in that extract (Table S7). Concentrations of  $^3\text{C}^*$  in the main text are values after IF correction. While our past work indicates that  $^3\text{DMB}^*$  is a good surrogate for the average oxidizing triplet in Davis drops and particles (Kaur and Anastasio, 2018; Kaur et al., 2019), it is possible that  $k_{\text{P}+{}^3\text{DMB}^*}$  is higher than the rate constant for the probe with natural triplets. This is the case for surface waters, where the 2,4,6-trimethylphenol (TMP) +  $^3\text{DMB}^*$  rate constant (Ma et al., 2023b) is 3 times higher than the TMP +  $^3\text{CDOM}^*$  rate constant (Erickson et al., 2018). If this were also the case for our PM extracts, we would be underestimating oxidizing triplet concentrations by roughly a factor of 3.

#### 2.4.3 Singlet molecular oxygen ( $^1\text{O}_2^*$ )

We used furfuryl alcohol (FFA) as a probe to determine  $^1\text{O}_2^*$  concentrations (Anastasio and McGregor, 2001; Haag et al., 1984). A total of 1.0 mL of PME sample was divided into two 0.5 mL aliquots, and then one was diluted with 0.5 mL  $\text{H}_2\text{O}$  while the other was diluted with 0.5 mL deuterium oxide ( $\text{D}_2\text{O}$ ). A final concentration of 10  $\mu\text{M}$  FFA was spiked into each solution, and then both were illuminated. The pseudo-first-order rate constant of FFA loss in  $\text{H}_2\text{O}$ - and  $\text{D}_2\text{O}$ -diluted PME ( $k'_{\text{FFA},\text{H}_2\text{O}}$  and  $k'_{\text{FFA},\text{D}_2\text{O}}$ ) during illumination was determined as the negative slope of a linear regression between  $\ln([\text{FFA}]_t / [\text{FFA}]_0)$  and illumination time ( $t$ ). The  $^1\text{O}_2^*$  concentration in the undiluted PME was determined from the difference in FFA loss rates in  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  using (Anastasio and McGregor, 2001)

$$[{}^1\text{O}_2^*]_{\text{EXP}} = \frac{k'_{\text{FFA},\text{D}_2\text{O}} - k'_{\text{FFA},\text{H}_2\text{O}}}{D \times k_{\text{FFA}+{}^1\text{O}_2^*} \times \left( \frac{k'_{\text{H}_2\text{O}}}{k'_{\text{H}_2\text{O}}\chi_{\text{H}_2\text{O}} + k'_{\text{D}_2\text{O}}\chi_{\text{D}_2\text{O}}} - 1 \right)}, \quad (9)$$

where  $D$  is the sample dilution factor (i.e., 0.5 for our experiments);  $k_{\text{FFA}+{}^1\text{O}_2^*}$  is the second-order rate constant of FFA reacting with  $^1\text{O}_2^*$  at 20 °C,  $0.96 (\pm 0.04) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$  (Appiani et al., 2017);  $k'_{\text{H}_2\text{O}}$  and  $k'_{\text{D}_2\text{O}}$  are the first-order rate constants for loss of  $^1\text{O}_2^*$  in 100 %  $\text{H}_2\text{O}$  ( $2.2 \times 10^5 \text{ s}^{-1}$ ) and  $\text{D}_2\text{O}$  ( $1.6 \times 10^4 \text{ s}^{-1}$ ), respectively (Bilski et al., 1997); and

$\chi_{\text{H}_2\text{O}}$  and  $\chi_{\text{D}_2\text{O}}$  are the mole fractions of  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  in the  $\text{D}_2\text{O}$ -diluted solution. Analogously to Eq. (3), we normalized the experimentally determined  $^1\text{O}_2^*$  concentrations using the light screening factor of each PME and adjustment to Davis winter sunlight conditions. Measurements of  $^1\text{O}_2^*$  are in Table S8.

## 3 Results and discussions

### 3.1 Testing extraction and rotary evaporation

Our winter particle filters were collected in February 2020, when Davis was influenced by residential wood combustion; the average  $\text{PM}_{2.5}$  concentration during our sampling was  $9.2 \mu\text{g m}^{-3}$ . The summer particles were collected in August 2020, when severe wildfires were occurring approximately 30 km from Davis, resulting in an average  $\text{PM}_{2.5}$  concentration of  $54 \mu\text{g m}^{-3}$ . While we label our filter composites as “summer” and “winter” as a shorthand, since we have only one sample for each season, our results say little about the seasonality of photooxidants in PM. We explore the issue of oxidant seasonal variations in two other papers (Jiang et al., 2023; Ma et al., 2023a). Figure 1 shows the dissolved organic carbon (DOC) concentrations and rates of light absorption ( $R_{\text{abs}}$ ) as a function of dilution in the winter (WIN) and summer (SUM) particle extracts. We express dilution as the ratio of dry particle mass to liquid water mass in our extracts, since we can experimentally measure these quantities for our PMEs and can estimate values for both clouds/fogs and airborne particles. Both DOC and  $R_{\text{abs}}$  are directly proportional to the particle mass / water mass ratio, indicating that the extractions of filter squares with varying volumes of water achieved the same extraction efficiency. The DOC values of the most concentrated extracts ( $-0.4$  and  $-0.3$ ) also follow a linear relationship, showing that the rotary evaporation process used for these dilutions did not lead to significant loss of brown carbon or other organic compounds. As shown in Fig. S1, UV–Vis spectra of the  $-0.4$  and  $-0.3$  extracts before and after rotovapping are essentially the same, indicating that evaporation did not change the brown carbon (BrC) composition significantly. We also checked inorganic concentrations as a function of the concentration factor (Fig. S2): most of the ions exhibit good linearity, indicating consistency in extraction efficiency.

We also examined if rotovapping affects photooxidant concentrations. First, we extracted one filter with either 0.7 mL water per square (sample PME-NR) or 2 mL water per square followed by rotovapping to the equivalent of 0.7 mL water per square (sample PME-R). In a second test, we diluted a rotovapped sample (WIN-0.3) by a factor of 6.7 with water to obtain an extract equivalent to 2 mL Milli-Q per square (WIN-0.3D); this diluted, rotovapped sample should be equivalent to WIN-2, a non-rotovapped sample with the same overall dilution. Figure S3 presents photooxidant concentrations in the two tests. In each test, the concen-

**Figure 1.** Dependence of dissolved organic carbon (DOC, circles) and the rate of sunlight absorption between 300–450 nm ( $R_{\text{abs}}$ , diamonds) on the particle mass / water mass ratio (i.e., aqueous particle concentration) in summer (red) and winter (blue) particle extracts.

trations are essentially the same in the rotovapped and non-rotovapped samples, indicating a negligible effect of rotary evaporation on photooxidant kinetics.

### 3.2 Ions and light absorption

Figure 1 shows that summer and winter PMEs have DOC concentrations in the range of 16–495 and 10–336  $\text{mg C L}^{-1}$ , respectively, but WIN has slightly higher particle mass / water mass ratios of  $(0.05\text{--}1.6) \times 10^{-3} \mu\text{g PM} / \mu\text{g H}_2\text{O}$  compared to  $(0.04\text{--}1.4) \times 10^{-3} \mu\text{g PM} / \mu\text{g H}_2\text{O}$  for SUM. The particle mass / water mass ratios indicate that our extracts have particle concentrations that are equivalent to dilute to concentrated cloud/fog waters. The summer sample of relatively fresh wildfire emissions shows a higher average fraction of organic carbon (OC) to PM mass,  $0.37 (\pm 0.02)$ , compared to winter ( $0.20 \pm 0.01$ ). But both are lower than the typical OC / PM ratio near 0.5 for biomass burning particles (Reid et al., 2005; Schauer et al., 2001), probably because our water extracts do not capture non-polar organic compounds. The winter sample has lower organic carbon but higher concentrations of ions, including nitrate ( $\text{NO}_3^-$ ), sulfate ( $\text{SO}_4^{2-}$ ), and ammonium ( $\text{NH}_4^+$ ) (Table S2). For example, nitrate concentrations in WIN range from 0.18 to 5.2 mM and contribute on average ( $\pm 1\sigma$ )  $20 (\pm 2) \%$  of the total extracted PM mass. In contrast,  $\text{NO}_3^-$  concentrations in SUM are about 5 times lower (0.03–1.0 mM) at the same concentration factor and only contribute an average of  $4.4 (\pm 0.4) \%$  of the SUM PM mass. The sulfate in WIN accounts for  $11 (\pm 4) \%$  of extracted PM mass, with concentrations (0.03–2.3 mM) that are around 4 times higher than in SUM (0.02–0.6 mM, accounting for an average of  $4.2 (\pm 0.6) \%$  of extracted PM mass).  $\text{NH}_4^+$  is also higher in WIN (0.20–3.6 mM) compared to SUM (0.10–1.3 mM). Concentrations of potassium, a tracer of biomass burning

(Andreae, 1983), are 0.03–0.7 mM in both WIN and SUM, with a K / PM mass ratio of  $0.02 (\pm 0.004)$ , which is in the range reported for biomass burning aerosols of 0.02 to 0.05 (Reid et al., 2005; Urban et al., 2012).

For all PMEs, absorbance declines exponentially with wavelength (e.g., Fig. S1), and WIN and SUM samples have the same average absorption Ångström exponent (AAE, 300–450 nm) of 7.2 (Table S1), comparable to AAE values (6–8) previously reported in water extracts of biomass burning particles (Hecobian et al., 2010; Hoffer et al., 2006; Kaur et al., 2019). The pathlength-normalized absorption coefficient at 300 nm ( $\alpha_{300}$ ) for the summer samples ( $0.2\text{--}6.7 \text{ cm}^{-1}$ ) is about 2 times higher than winter samples at the same concentration factor ( $0.1\text{--}3.0 \text{ cm}^{-1}$ ) (Table S1). Thus, summer extracts absorb sunlight at approximately twice the rate as winter extracts (Fig. 1). We also calculated the dissolved-organic-carbon-normalized mass absorption coefficient ( $\text{MAC}_{\text{DOC}}$ ) of each extract by dividing the absorbance at 300 or 365 nm by the DOC concentration (Kaur et al., 2019). SUM average  $\text{MAC}_{\text{DOC}}$  values across all dilutions are  $3.1 (\pm 0.1)$  and  $1.0 (\pm 0.1) \text{ m}^2 (\text{g C})^{-1}$  at 300 and 365 nm, respectively, which are approximately 1.5 times higher than the WIN values (Table S1). This difference is likely because the SUM sample is dominated by fresh wildfire organic aerosols that are composed of organic compounds with a higher degree of unsaturation, increasing light absorption (Fleming et al., 2020). Meanwhile, the WIN sample may contain a lower fraction of fresh biomass burning aerosols due to oxidation and photobleaching of the brown carbon (Forrister et al., 2015; Wong et al., 2019). Our MAC value for WIN is similar to the average MAC value in the previous Davis winter samples (Kaur et al., 2019).

### 3.3 Photooxidants in PM extracts

In this section we first present our measured oxidant concentrations as a function of particle dilution in the WIN and SUM extracts. We use DOC as the independent variable in our plots because BrC likely dominates the production of  $^3\text{C}^*$  and  $^1\text{O}_2^*$  and DOC is proportional to the concentration factor in each extract series. We then examine how the production rate ( $P_{\text{OX}}$ ) and pseudo-first-order rate constant for loss ( $k'_{\text{OX}}$ ) for each oxidant vary as a function of dilution. These parameters are related to the oxidant steady-state concentration, [OX], by

$$[\text{OX}] = \frac{P_{\text{OX}}}{k'_{\text{OX}}}. \quad (10)$$

In Sect. 3.4, we extrapolate these kinetic parameters to aerosol liquid water conditions to predict photooxidant concentrations in ALW.

### 3.3.1 Hydroxyl radicals in PM extracts

As shown in Fig. 2a, the most dilute sample in the WIN dilution series, WIN-10, has the lowest  $^{\bullet}\text{OH}$  concentration, while in the other dilutions  $^{\bullet}\text{OH}$  is noisy but appears to be independent of DOC. This result, i.e., that  $^{\bullet}\text{OH}$  concentration is essentially independent of particle mass concentration, is similar to what Kaur et al. (2019) observed for winter samples (green points in Fig. 2), although our  $^{\bullet}\text{OH}$  concentrations are approximately 10 times higher.

Kaur et al. (2019) found that the  $^{\bullet}\text{OH}$  photoproduction rate ( $P_{\text{OH}}$ ) and sink ( $k'_{\text{OH}}$ ) both linearly increase with the concentration factor, leading to a roughly constant  $^{\bullet}\text{OH}$  concentration, since the concentration is equal to the ratio  $P_{\text{OH}}/k'_{\text{OH}}$  (Eq. 10). To explore this in our samples, we determined  $P_{\text{OH}}$  and  $k'_{\text{OH}}$  in all of the WIN and SUM extracts; we start by considering the WIN results. As shown in Fig. 3a,  $P_{\text{OH}}$  and  $k'_{\text{OH}}$  both increase linearly with DOC, which is consistent with the winter PM extract observations of Kaur et al. (2019), though our samples have a higher slope for  $P_{\text{OH}}$  and a lower one for  $k'_{\text{OH}}$ . This higher  $^{\bullet}\text{OH}$  production rate, coupled with a lower rate constant for  $^{\bullet}\text{OH}$  loss, is responsible for the roughly 10 times higher  $^{\bullet}\text{OH}$  in this work, but we do not know why these parameters are so different between the previous and current winter particle samples.  $P_{\text{OH}}$  in WIN ranges from  $0.02 \times 10^{-8}$  to  $4.8 \times 10^{-8} \text{ M s}^{-1}$ , significantly higher than typical values (approximately  $10^{-10} \text{ M s}^{-1}$ ) in rainwater, cloud, and fog waters (Albinet et al., 2010; Arakaki et al., 2013; Hong et al., 2018; Kaur and Anastasio, 2018; Tilgner and Herrmann, 2018). In Davis fog samples, the major source of  $^{\bullet}\text{OH}$  is photolysis of nitrate and nitrite (Anastasio and McGregor, 2001; Kaur and Anastasio, 2017). However, in our winter PM extracts, nitrate accounts for 10% or less of  $P_{\text{OH}}$  (Table S3), while the nitrite contribution is negligible. Instead, we hypothesize that our samples might contain higher concentrations of transition metals, contributing to  $^{\bullet}\text{OH}$  production (Li et al., 2022; Vidrio et al., 2009). While DOC photoreactions can also be a source of  $^{\bullet}\text{OH}$  (Badali et al., 2015), it seems likely that  $P_{\text{OH}}$  is correlated with DOC primarily because DOC is a proxy for the concentration factor in the extracts. As for  $^{\bullet}\text{OH}$  sinks in our WIN extracts,  $k'_{\text{OH}}$  is in the range  $(0.2\text{--}9.9) \times 10^6 \text{ s}^{-1}$ , which is higher than previous Davis fog values  $((0.4\text{--}1.3) \times 10^6 \text{ s}^{-1}$ ; Kaur and Anastasio, 2017). The lowest  $k'_{\text{OH}}$  (in WIN-10, the most dilute extract) is comparable to the field blank values (Table S3), suggesting that  $^{\bullet}\text{OH}$  in WIN-10 may be artificially low because of background contamination. We also calculated the rate constant of organics reacting with  $^{\bullet}\text{OH}$  ( $k_{\text{DOC}+\text{OH}}$ ) for the winter samples; our average WIN value,  $2.4 (\pm 0.7) \times 10^8 \text{ L (mol C)}^{-1} \text{ s}^{-1}$ , is similar to the one determined by Arakaki et al. (2013) for general atmospheric waters,  $3.8 (\pm 1.9) \times 10^8 \text{ L (mol C)}^{-1} \text{ s}^{-1}$ . In contrast, the average winter  $k_{\text{DOC}+\text{OH}}$  in Kaur et al. (2019) is approximately 3 times higher than our current winter sample; i.e., the past organics were more reactive with  $^{\bullet}\text{OH}$ .

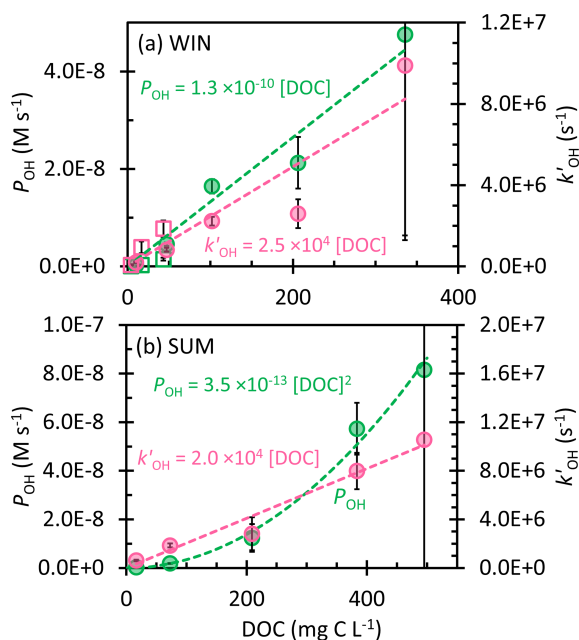

**Figure 2.** Steady-state concentrations of (a) hydroxyl radicals, (b, c) oxidizing triplet excited states of brown carbon determined by (b) syringol (SYR) and (c) (phenylthio)acetic acid (PTA), and (d) singlet molecular oxygen in WIN (blue) and SUM (red) samples as a function of dissolved organic carbon. WIN-0.3D results are also included. Previous measurements in Davis winter particle extracts are shown in green (Kaur et al., 2019). Error bars represent  $\pm 1$  standard error propagated from linear regression and uncertainties in rate constants. Dashed lines represent linear or hyperbolic regression fits for WIN and SUM samples.

Unlike in WIN,  $^{\bullet}\text{OH}$  in the summer samples linearly increases with the concentration factor or DOC, with an  $^{\bullet}\text{OH}$  concentration range of  $(0.4\text{--}7.7) \times 10^{-15} \text{ M}$  (Fig. 2a). This indicates that either  $P_{\text{OH}}$  or  $k'_{\text{OH}}$  does not increase linearly with DOC. As shown in Fig. 3b,  $k'_{\text{OH}}$  is linear with DOC, but  $P_{\text{OH}}$  is proportional to the DOC concentration squared. Our interpretation is that  $^{\bullet}\text{OH}$  production in SUM is a bimolecular reaction rather than a first-order photolysis reaction. The most likely candidate is the photo-Fenton reaction involving soluble reduced iron and hydrogen peroxide (or organic peroxides) (Paulson et al., 2019; Zepp et al., 1992), where the concentrations of both reactants increase with the concentration factor, as does [DOC]. Therefore, although WIN and SUM have roughly similar  $^{\bullet}\text{OH}$  concentrations, they apparently have different mechanisms governing  $^{\bullet}\text{OH}$  formation.  $P_{\text{OH}}$  in SUM is in the range  $(0.03\text{--}8.2) \times 10^{-8} \text{ M s}^{-1}$ , with the value in SUM-0.3 nearly double that of WIN-0.3. In contrast,  $^{\bullet}\text{OH}$  sinks for the summer and winter samples are similar (Fig. 3) and the average  $k_{\text{DOC}+\text{OH}}$  value in SUM is  $2.9 (\pm 1.1) \times 10^8 \text{ L (mol C)}^{-1} \text{ s}^{-1}$ , not significantly different from the WIN value.

### 3.3.2 Oxidizing triplet excited states of organic matter in PM extracts

We determined oxidizing triplet concentrations using two probes. Syringol (SYR) is highly reactive towards both strongly and weakly oxidizing triplets, but its decay by  $^3\text{C}^*$  can be inhibited by antioxidant moieties in DOM, leading

**Figure 3.** Dependence of the rate of  $\cdot\text{OH}$  photoproduction ( $P_{\text{OH}}$ ; green, left y axis) and rate constant for loss of  $\cdot\text{OH}$  due to natural sinks ( $k'_{\text{OH}}$ ; pink, right y axis) on dissolved organic carbon in the (a) winter and (b) summer samples. Error bars represent  $\pm 1$  standard error propagated from the error in regressions and rate constants; error bars for the 0.3 mL extracts (highest DOC) extend past the plot borders. Dashed lines represent linear regression fits, except the dashed green line in (b) SUM, which is derived from the linear regression of  $P_{\text{OH}}$  with  $[\text{DOC}]^2$ . Previous measurements in Davis winter particle extracts are shown as open squares in panel (a) (Kaur et al., 2019).

to an underestimate of  $^3\text{C}^*$  concentrations (Canonica and Laubscher, 2008; Ma et al., 2023b; Maizel and Remucal, 2017; Wenk et al., 2011). (Phenylthio)acetic acid (PTA) has a higher oxidation potential (1.47 V vs. SHE (standard hydrogen electrode), estimated using the Marcus equation) than SYR ( $\sim 1.17$  V vs. SHE) (Canonica et al., 2000; Chellamani and Sengu, 2008), is less reactive than SYR with weakly oxidizing triplets, and thus does not capture the whole oxidizing triplet pool. But the advantage of PTA is that it is more resistant to inhibition by DOM (Klein et al., 2006; Ma et al., 2023b). For both probes, we correct for probe inhibition by measuring the inhibition factor (IF) and using it to correct  $^3\text{C}^*$  concentrations (Sect. S1 and Table S7). Inhibition factors of SYR are as low as  $0.13 (\pm 0.03)$  in the most concentrated sample (WIN-0.3), indicating that approximately  $87 (\pm 20)\%$  of SYR decay is inhibited by DOM in this sample, which would lead to a  $^3\text{C}^*$  concentration that is  $7.5 (\pm 1.7)$  times lower than the actual value if there were no correction for inhibition. This significant inhibition of syringol oxidation is likely due to the high phenolic content of biomass burning particles, whether from residential wood burning (WIN) or wildfires (SUM) (Huo et al., 2021; Schauer

et al., 2001; Wenk and Canonica, 2012). As for PTA, IF values are all greater than 0.9, indicating little inhibition. For simplicity, we only show  $^3\text{C}^*$  concentrations after inhibition factor correction; uncorrected values are given in Tables S5 and S6.

Concentrations of  $^3\text{C}^*$  as a function of DOC are in Fig. 2. With SYR as the triplet probe (Fig. 2b), the  $[\text{C}^*]_{\text{SYR}}$  range is  $(0.5\text{--}7.1) \times 10^{-13}$  M in WIN and  $(1.6\text{--}6.8) \times 10^{-13}$  M in SUM. At the same DOC,  $[\text{C}^*]_{\text{SYR}}$  values in summer and winter are similar, despite the differences in sample composition (Table S5). Oxidizing triplet concentrations in our samples are generally higher than those from Kaur et al. (2019) (Fig. 2c, green points), which can be attributed to higher DOC in our samples and our correction for SYR inhibition. From PTA, the  $[\text{C}^*]_{\text{PTA}}$  range is  $(0.2\text{--}3.9) \times 10^{-13}$  M in WIN and  $(0.4\text{--}2.9) \times 10^{-13}$  M in SUM, with WIN having higher values than SUM at the same concentration factor (Fig. 2c). The  $[\text{C}^*]_{\text{PTA}}$  value is lower than  $[\text{C}^*]_{\text{SYR}}$  in every dilution, with an average  $[\text{C}^*]_{\text{PTA}}/[\text{C}^*]_{\text{SYR}}$  ratio of  $0.67 (\pm 0.22)$  in WIN and  $0.36 (\pm 0.09)$  in SUM. Since PTA appears to only capture highly oxidizing triplets (Ma et al., 2022), the ratio of  $[\text{C}^*]_{\text{PTA}}/[\text{C}^*]_{\text{SYR}}$  should represent the highly oxidizing fraction of the total oxidizing triplet pool (i.e., 67 % in WIN and 36 % in SUM). Highly oxidizing triplets are typically formed from aromatic ketone or carbonyl precursors, such as 3,4-dimethoxybenzaldehyde, while precursors for weakly oxidizing  $^3\text{C}^*$  include polycyclic aromatic structures (e.g., 2-acetonaphthone) (McNeill and Canonica, 2016). Our oxidizing triplet concentrations are approximately 100 times higher than  $[\cdot\text{OH}]$  (Fig. 2), indicating the likely importance of  $^3\text{C}^*$  as an oxidant in atmospheric drops and particles.

For both probes, the  $^3\text{C}^*$  concentration initially increases with DOC but then approaches or reaches a plateau under more concentrated conditions. Kaur et al. (2019) observed the same trend. Their interpretation was that in dilute solutions  $\text{O}_2$  is the dominant sink for triplets, while under more concentrated conditions DOM becomes the major sink. Therefore,  $^3\text{C}^*$  production and loss are both functions of DOC, as described by

$$[\text{C}^*] = \frac{a[\text{DOC}]}{1 + b[\text{DOC}]} \quad (11)$$

The dashed lines in Fig. 2b and c show the regression fitting results of Eq. (11) to the experimental data. From the fitted parameter  $b$  (Table S9), we can determine  $k_{\text{rxn}+\text{Q},3\text{C}^*}$  (Eq. S6), the total rate constant of physical quenching and chemical reaction of oxidizing triplets with DOC. Values from our Fig. 2 fittings are  $7.6 (\pm 6.8) \times 10^7 \text{ L (mol C)}^{-1} \text{ s}^{-1}$  for WIN and  $1.2 (\pm 0.5) \times 10^8 \text{ L (mol C)}^{-1} \text{ s}^{-1}$  for SUM (Table S10). Kaur et al. (2019) obtained  $9.3 (\pm 1.3) \times 10^7 \text{ L (mol C)}^{-1} \text{ s}^{-1}$  for Davis winter particle extracts, but they did not correct for SYR inhibition, which should be more significant at higher DOC, leading to an earlier plateau and higher appar-

ent rate constant. Despite this, the three values are not significantly different, possibly because the Kaur et al. (2019) samples had much lower DOC and thus were less affected by SYR inhibition. Wenk et al. (2013) obtained a range of values of  $(1.3\text{--}3.9) \times 10^7 \text{ L}(\text{mol C})^{-1} \text{ s}^{-1}$  for surface water DOM quenching and reacting with 2-acetonaphthone and 3-methoxyacetophenone triplets; their lower values imply that atmospheric DOM, at least in our samples, more efficiently quenches triplets than does DOM in surface waters.

The DOC quenching and reaction rate constants from our PTA-derived triplet concentrations are  $5.7 (\pm 1.2) \times 10^7$  and  $6.6 (\pm 1.0) \times 10^7 \text{ L}(\text{mol C})^{-1} \text{ s}^{-1}$  for WIN and SUM, respectively. These values are lower than those obtained using SYR, as reflected by the weaker curvature of the PTA dashed lines (Fig. 2c) compared to SYR (Fig. 2b). The similar values of  $k_{\text{rxn}+\text{Q},^3\text{C}^*}$  from PTA in WIN and SUM suggest that this rate constant is insensitive to particle type. Therefore, the higher  $[^3\text{C}^*]_{\text{PTA}}$  in WIN compared to SUM at the same DOC level can be attributed to differences in  $^3\text{C}^*$  production. This is consistent with the differences in apparent quantum yields: the WIN yield of triplets is  $1.8 (\pm 0.3) \%$ , more than double the SUM value of  $0.8 (\pm 0.1) \%$  (Table S6).

### 3.3.3 Singlet molecular oxygen in PM extracts

The final photooxidant we measured was singlet molecular oxygen. As shown in Fig. 2d, winter and summer samples have similar  $^1\text{O}_2^*$  concentrations, in the range of  $(0.2\text{--}8.5) \times 10^{-12} \text{ M}$ , with values increasing with DOC. The lowest values, in the most dilute extracts, are comparable to fog water concentrations, while our highest concentrations are approximately 4 times higher than those in previous Davis winter particle extracts (Anastasio and McGregor, 2001; Kaur and Anastasio, 2017; Kaur et al., 2019). Singlet oxygen is the most abundant oxidant in our PMEs, with concentrations roughly 10 times higher than  $^3\text{C}^*$  and 1000 times higher than  $\cdot\text{OH}$ . In both series of samples, the  $^1\text{O}_2^*$  concentration increases with DOC, as seen in Kaur et al. (2019). Since brown carbon is the source of  $^1\text{O}_2^*$ , the  $^1\text{O}_2^*$  production rate increases with DOC. In contrast, the dominant sink for  $^1\text{O}_2^*$  is water, whose concentration is independent of the sample concentration factor. All three sets of samples in Fig. 2d exhibit very similar relationships between  $^1\text{O}_2^*$  and DOC, suggesting DOC concentration might be a good predictor of  $^1\text{O}_2^*$  concentrations in atmospheric waters.

Apparent quantum yields of  $^1\text{O}_2^*$  are  $3.0 (\pm 0.2) \%$  for WIN and  $2.0 (\pm 0.4) \%$  for SUM (Table S8), which are in the range of typical values for atmospheric waters (Bogler et al., 2022; Kaur and Anastasio, 2017; Kaur et al., 2019; Leresche et al., 2021; Manfrin et al., 2019) and surface waters (Ossola et al., 2021). As described by Ossola et al. (2021), the most accurate determination of quantum yields with simulated sunlight uses a rate of light absorption that accounts for all of the sunlight wavelengths, i.e., out to roughly 700–800 nm. Consistently with our past work (Kaur et al., 2019),

we determined our quantum yields based on sample light absorption from 300–450 nm; as shown in Table S1, rates of light absorption over this range represent  $78 (\pm 3) \%$  of  $R_{\text{abs}}$  calculated based on the total sunlight absorption. Thus, our  $^1\text{O}_2^*$  and  $^3\text{C}^*$  quantum yields would be roughly  $29 (\pm 1) \%$  smaller if calculated using the entire range of solar light absorption.

For WIN,  $^1\text{O}_2^*$  is linearly related to DOC throughout the dilution series, but in SUM the singlet oxygen concentration exhibits a linear relationship at low DOC and then starts to level off in the more concentrated extracts (Fig. 2d). This curvature has at least two possible explanations. One, as proposed by Kaur et al. (2019), is that  $[^1\text{O}_2^*]$  stops rising under concentrated solution conditions because organics become the dominant  $^1\text{O}_2^*$  sink. The second possibility is that under more concentrated conditions, the concentration of  $^3\text{C}^*$  plateaus, a result of DOC becoming the dominant sink for triplets (e.g., Fig. 2b). Thus, as the solution becomes more concentrated, the production rate of  $^1\text{O}_2^*$  rises more slowly, causing  $[^1\text{O}_2^*]$  to start to bend over. In the summer sample of Fig. 2d, the curvature of  $^1\text{O}_2^*$  is more likely due to this second explanation (i.e.,  $[^3\text{C}^*]$  plateauing) rather than DOC becoming an important  $^1\text{O}_2^*$  sink because  $^1\text{O}_2^*$  generally has lower reactivity than triplets with most organics (Arnold, 2014; Canonica et al., 2000; Wilkinson et al., 1995). Based on rough estimates of the composition and reactivity of particulate organics from biomass burning (Kaur et al., 2019), we estimate that DOC accounts for less than 2% of the  $^1\text{O}_2^*$  sink in our extracts.

Assuming the leveling-off of  $[^3\text{C}^*]$  is responsible for the  $^1\text{O}_2^*$  curvature in the SUM sample, we can derive a kinetic equation for  $[^1\text{O}_2^*]$  as a function of DOC (Eq. S8), which is analogous to Eq. (11) and is derived in Sect. S2. This equation gives a good fit to the SUM data, as shown by the dashed red line in Fig. 2d. From the parameter  $b$ , we calculate that the rate constant for DOC reacting and physically quenching  $^1\text{O}_2^*$ -producing triplet states ( $k_{\text{rxn}+\text{Q},^3\text{C}^*}$ ) is  $2.1 (\pm 0.3) \times 10^7 \text{ L}(\text{mol C})^{-1} \text{ s}^{-1}$ . This is lower than the values acquired from  $[^3\text{C}^*]_{\text{SYR}}$  and  $[^3\text{C}^*]_{\text{PTA}}$ , which is reasonable since the  $^1\text{O}_2^*$ -derived value represents the whole triplet pool (i.e., all triplets that can undergo energy transfer with dissolved oxygen), which is a larger pool than oxidizing triplets. Our results suggest that the non-oxidizing triplets are less reactive with organics than are oxidizing triplets, leading to a lower rate constant for reaction and quenching by DOC, as seen previously by Canonica et al. (2000).

### 3.4 Extrapolating photooxidant concentrations to ALW conditions

In the dilution experiments above, we investigated oxidant kinetics and concentrations as a function of the concentration factor, i.e., particle mass / water mass ratio. In this section we extrapolate these relationships from our dilute extract conditions (with PM mass / water mass ratios of (0.04–

$1.6) \times 10^{-3} \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ) to the much more concentrated conditions of aerosol liquid water (up to  $\sim 1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ).

### 3.4.1 Hydroxyl radicals in ALW

To estimate  $[\cdot\text{OH}]$  in particle water for WIN, we apply the linear relationships of  $P_{\text{OH}}$  and  $k'_{\text{OH}}$  with DOC that we determined in our extracts (Fig. 3a), along with the relationship of  $[\text{DOC}]$  to the particle mass / water mass ratio, to predict kinetics under more concentrated particle water conditions. Parameters used in the extrapolation are provided in Table S11. Extrapolating to an ALW of  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$  yields an estimated  $P_{\text{OH}}$  of  $2.7 \times 10^{-5} \text{ M s}^{-1}$  and  $k'_{\text{OH}}$  of  $5.0 \times 10^9 \text{ s}^{-1}$ . However, since our aqueous experiments do not include  $\cdot\text{OH}$  transferred from the gas phase ( $P_{\text{OH,gas}}$ ), we added  $P_{\text{OH,gas}}$  estimated by Kaur et al. (2019) to our extrapolated  $P_{\text{OH}}$  to calculate  $P_{\text{OH,tot}}$ . We then estimate  $[\cdot\text{OH}]$  as  $P_{\text{OH,tot}}$  divided by  $k'_{\text{OH}}$  (Eq. 10). Estimating  $[\cdot\text{OH}]$  for the SUM sample is more complicated, since  $P_{\text{OH}}$  initially increases with DOC squared. We simulate the  $\cdot\text{OH}$  production rate as a function of DOC by using photo-Fenton reaction rate constants and setting soluble iron and hydrogen peroxide concentrations to fit measured values (Sect. S3). We then apply this simple model to predict  $P_{\text{OH}}$  for SUM from fog/cloud to ALW conditions. For  $k'_{\text{OH}}$  in SUM, we use the measured linear dependence on DOC (Fig. 3b).

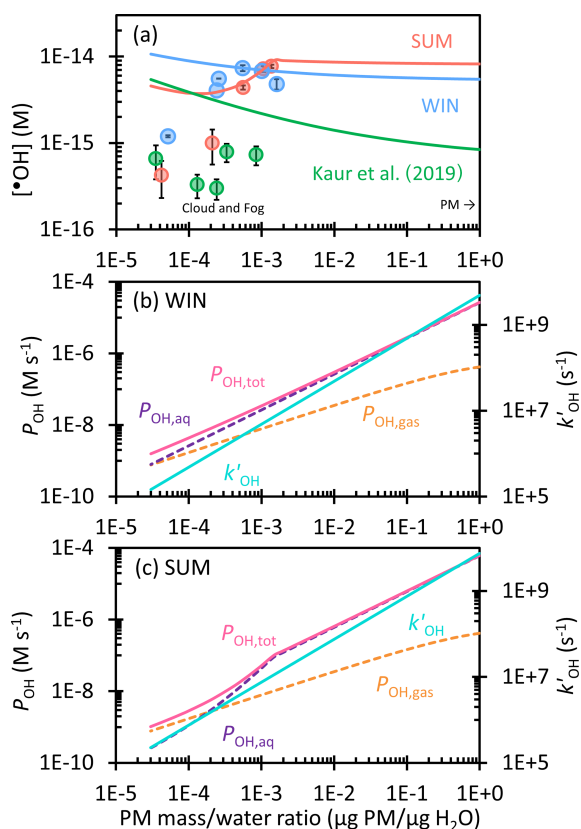

Figure 4a shows the predicted hydroxyl radical steady-state concentrations for SUM and WIN across a wide range of liquid water content, from dilute cloud/fog drops to concentrated aqueous particle conditions. We also include the winter PM  $\cdot\text{OH}$  predictions from Kaur et al. (2019) for comparison. For WIN,  $[\cdot\text{OH}]$  slowly decreases from  $1 \times 10^{-14} \text{ M}$  in cloud/fog waters (at  $3 \times 10^{-5} \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ) to  $6 \times 10^{-15} \text{ M}$  in ALW (at  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ). Calculated  $[\cdot\text{OH}]$  values are higher than measured values, especially under the most dilute conditions, because  $\cdot\text{OH}$  from gas-phase mass transfer is included in our extrapolation. The  $\cdot\text{OH}$  trend for WIN is consistent with the result of Kaur et al. (2019), but our concentrations are 6–12 times higher. This is because WIN has a slope of  $P_{\text{OH}}$  vs. DOC around 4 times higher than that in Kaur et al. (2019), while the slope for  $k'_{\text{OH}}$  in WIN is slightly lower (Fig. 3a). For our winter sample under dilute conditions, aqueous processes are as important an  $\cdot\text{OH}$  source as gas-phase transfer (Fig. 4b). However, the aqueous production rate rises more rapidly with PM mass concentration than does gas-phase mass transfer, making aqueous reactions the dominant source of  $\cdot\text{OH}$  under ALW conditions, where they account for more than 90 % of  $\cdot\text{OH}$  production. This slower increase in  $P_{\text{OH,gas}}$  is also responsible for the decreasing  $[\cdot\text{OH}]$  with increasing PM mass concentration.

For SUM, predicted  $[\cdot\text{OH}]$  is approximately constant at  $4 \times 10^{-15} \text{ M}$  under dilute conditions (Fig. 4a), with gas-phase mass transport being the major source of  $\cdot\text{OH}$  (Fig. 4c).  $[\cdot\text{OH}]$  then increases to  $1 \times 10^{-14} \text{ M}$  at

$1 \times 10^{-3} \mu\text{g PM} / \mu\text{g H}_2\text{O}$  as the aqueous production rate ( $P_{\text{OH,aq}}$ ) increases rapidly and aqueous reactions dominate  $\cdot\text{OH}$  production. When moving to more concentrated conditions,  $[\cdot\text{OH}]$  plateaus because we assume the aqueous  $\text{H}_2\text{O}_2$  concentration reaches a maximum of  $100 \mu\text{M}$  due to equilibrium with the gas phase (Sect. S3). Thereafter,  $P_{\text{OH,aq}}$  increases linearly, but more slowly, with the PM mass / water mass ratio; since  $k'_{\text{OH}}$  also increases linearly with the concentration factor,  $[\cdot\text{OH}]$  remains nearly constant at  $9 \times 10^{-15} \text{ M}$  for PM / water ratios of roughly  $10^{-3}$  to  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ . For both WIN and SUM, our measured  $\cdot\text{OH}$  concentrations in the most concentrated extracts are approximately an order of magnitude higher than in Kaur et al. (2019), and this difference is maintained throughout the predicted  $[\cdot\text{OH}]$  to ambient particle water conditions.

### 3.4.2 Oxidizing triplet concentrations in ALW

To predict  ${}^3\text{C}^*$  concentrations in aerosol liquid water, we used the data in Table S11 to extrapolate  ${}^3\text{C}^*$  production rates ( $P_{3\text{C}^*}$ ) and sinks ( $k'_{3\text{C}^*}$ ) to concentrated conditions and calculated  ${}^3\text{C}^*$  concentrations for syringol (SYR) and (phenylthio)acetic acid (PTA) with Eq. (10). As shown in Fig. 5a and b, measured  $[{}^3\text{C}^*]$  values in SUM and WIN are higher than the results in Kaur et al. (2019) at the same particle mass / water mass ratio. This is likely due to higher ratios of OC / PM in our samples. In all three sets of samples,  $[{}^3\text{C}^*]$  rises rapidly with the PM mass / water mass ratio at low DOC and then reaches or approaches a plateau under aqueous aerosol conditions, as the dominant triplet sink transitions from dissolved  $\text{O}_2$  to DOC. We believe the production rate of  ${}^3\text{C}^*$  linearly increases with particle mass / water mass ratio ( $P_{3\text{C}^*}$  in Fig. 5c and d), but the sinks for triplets change, as proposed by Kaur et al. (2019). Under dilute conditions,  $\text{O}_2$  is a dominant and constant sink ( $k'_{3\text{C}^*,\text{O}_2}$ ), causing  $[{}^3\text{C}^*]$  to increase with an increasing concentration factor. But for our more concentrated extracts (and continuing at higher PM mass / water mass ratios), organic compounds become the major sink for  ${}^3\text{C}^*$  (Fig. 5c and d). Thus the ratio of the production rate and sink rate constant becomes constant at higher DOC, causing  $[{}^3\text{C}^*]$  to plateau. For SYR, we predict WIN and SUM both reach a maximum value of  $8 \times 10^{-13} \text{ M}$  at  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ . This value is 22 times higher than the concentration under the most dilute conditions in WIN and around 8 times higher than the dilute result in SUM. While SUM starts with a higher  $[{}^3\text{C}^*]_{\text{SYR}}$  under dilute conditions, it experiences greater curvature than WIN, apparently because its organic compounds react with and/or physically quench oxidizing triplets more rapidly (i.e.,  $k'_{3\text{C}^*,\text{DOC}}$  is larger for SUM than WIN). For both samples, the ALW prediction for  $[{}^3\text{C}^*]_{\text{SYR}}$  is near the geometric mean of the two bounding fits of Kaur et al. (2019). For the lower  ${}^3\text{C}^*$  concentrations determined by PTA, SUM and WIN start with essentially the same  $[{}^3\text{C}^*]_{\text{PTA}}$  value,  $3 \times 10^{-14}$  and  $2 \times 10^{-14} \text{ M}$ , respectively, at

**Figure 4.** (a) Dependence of hydroxyl radical concentration on the particle mass / water mass ratio in winter (blue) and summer (red) extracts. Solid circles are measured values, while lines are extrapolations to the ambient aqueous aerosol conditions, including contributions from aqueous  $^{\bullet}\text{OH}$  formation and  $^{\bullet}\text{OH}$  mass transport from the gas phase. Previous measurements and extrapolation with Davis winter particle extracts are shown in green (Kaur et al., 2019). (b, c) Dependence of the hydroxyl radical production rate, including the rate of transport from the gas phase ( $P_{\text{OH,gas}}$ , orange), aqueous reaction ( $P_{\text{OH,aq}}$ , purple), and the total rate ( $P_{\text{OH,tot}} = P_{\text{OH,aq}} + P_{\text{OH,gas}}$ , pink), and the rate constant of  $^{\bullet}\text{OH}$  loss by natural sinks ( $k'_{\text{OH}}$ , blue) on the particle mass / water mass ratio for (b) WIN and (c) SUM.

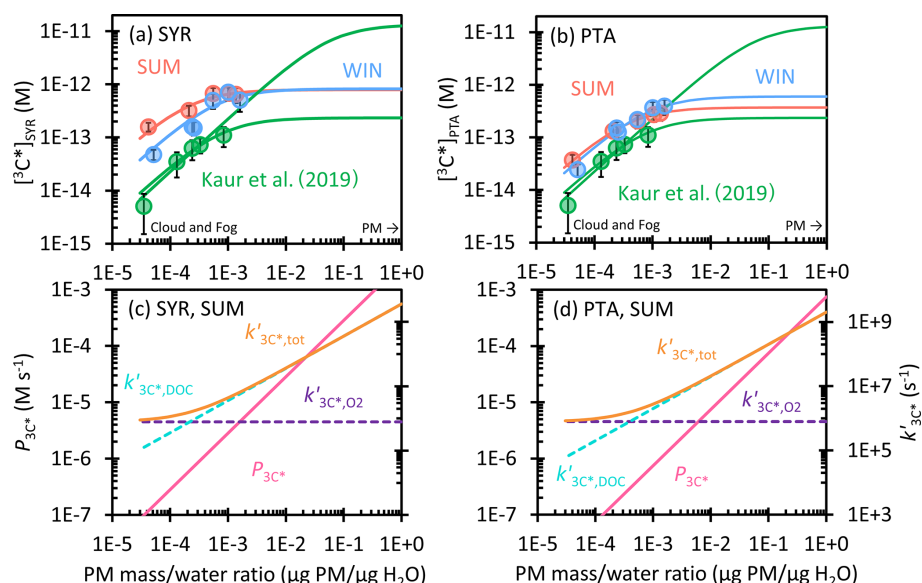

$3 \times 10^{-5} \mu\text{g PM} / \mu\text{g H}_2\text{O}$ . SUM exhibits more curvature, as seen for  $[^3\text{C}^*]_{\text{SYR}}$ , leading to a lower predicted  $[^3\text{C}^*]_{\text{PTA}}$  at  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ :  $4 \times 10^{-13} \text{ M}$  for SUM vs.  $6 \times 10^{-13} \text{ M}$  for WIN. For SUM and WIN,  $[^3\text{C}^*]_{\text{PTA}}$  increases by factors of 14 and 29, respectively, from the most dilute condition to the ALW condition, which is similar to  $[^3\text{C}^*]_{\text{SYR}}$ .

### 3.4.3 Singlet molecular oxygen in ALW

Lastly, we consider the extrapolation of  $^1\text{O}_2^*$  concentrations from our dilute experimental solutions to ALW conditions. To do this, we consider the production of  $^1\text{O}_2^*$  by  $^3\text{C}^*$  as well as  $\text{H}_2\text{O}$  and DOM as sinks for singlet oxygen. In terms of  $^1\text{O}_2^*$  sources, we first assume the  $\text{O}_2$  concentration is con-

stant at all conditions, i.e., not considering a solute effect on  $\text{O}_2$  solubility. Next, we assume the plateauing of  $[^3\text{C}^*]$  at high concentration factors results in a plateauing of the  $^1\text{O}_2^*$  production rate, as evidenced in the curvature of  $[^1\text{O}_2^*]$  in SUM (Fig. 2d). To account for this effect, we fit  $[^1\text{O}_2^*]$  versus DOC using an equation analogous to Eq. (11) and calculate the  $^1\text{O}_2^*$  production rate ( $P_{1\text{O}_2^*}$ ) with the fitted parameters (Eq. S11). This process does not work for WIN, however, since it shows no curvature of  $[^1\text{O}_2^*]$ . So to predict the  $^3\text{C}^*$  effect for this sample, we adjusted the regression parameters so that the fitted line passed through just the first four data points (Fig. S6). In terms of modeling DOM as a sink for  $^1\text{O}_2^*$ , this effect does not appear in our lab extracts (due to their relatively low DOC content), but we expect it would happen under more concentrated conditions. To incorporate this effect, we estimated the second-order rate constant for loss of  $^1\text{O}_2^*$  by DOC ( $k_{1\text{O}_2^*+\text{DOC}}$ ) using the same approach as in Kaur et al. (2019) but determined a lower value ( $1 \times 10^5 \text{ L} (\text{mol C})^{-1} \text{ s}^{-1}$ ) based on our  $^1\text{O}_2^*$  concentration data versus DOC. We then calculate the first-order sink for  $^1\text{O}_2^*$  due to DOC as the product of this second-order rate constant and the DOC concentration.

The resulting predictions for  $^1\text{O}_2^*$  concentrations, along with the production rate and sink rate constants for the summer sample, are in Fig. 6. Figure 6a shows that our predictions of  $^1\text{O}_2^*$  under ALW conditions are roughly 10 to 100 times lower than those in Kaur et al. (2019); this is because we include the effect of plateauing  $^3\text{C}^*$  concentration on the  $^1\text{O}_2^*$  production rate, which decreases  $^1\text{O}_2^*$  concentrations under ALW conditions. In Fig. 6a,  $[^1\text{O}_2^*]$  for SUM starts at  $4 \times 10^{-13} \text{ M}$  in dilute drops, peaks at  $1 \times 10^{-11} \text{ M}$  at  $1.0 \times 10^{-2} \mu\text{g PM} / \mu\text{g H}_2\text{O}$  (where  $P_{1\text{O}_2^*}$  first plateaus; Fig. 6b), and then starts to decrease. This decrease is because the production rate for  $^1\text{O}_2^*$  ( $P_{1\text{O}_2^*}$ ) is constant while the  $^1\text{O}_2^*$  sink from DOC ( $k'_{1\text{O}_2^*+\text{DOC}}$ ) increases with particle mass concentration and becomes the dominant  $^1\text{O}_2^*$  sink; the result is a singlet oxygen concentration of  $1 \times 10^{-12} \text{ M}$  at  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ . This concentration is only 1.4 times higher than  $[^3\text{C}^*]_{\text{SYR}}$  under the same conditions (Fig. S8). For WIN,  $[^1\text{O}_2^*]$  starts at  $1 \times 10^{-13} \text{ M}$  in dilute drops, reaches a maximum of  $3 \times 10^{-11} \text{ M}$  at  $4.0 \times 10^{-2} \mu\text{g PM} / \mu\text{g H}_2\text{O}$ , and then decreases to  $5 \times 10^{-12} \text{ M}$  at  $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$  (Fig. S7). Under ALW conditions, WIN has a maximum  $[^1\text{O}_2^*]$  that is 3 times higher than SUM because measured  $[^1\text{O}_2^*]$  in WIN presents much less curvature than SUM; i.e., the organics in WIN appear to be less reactive with  $^1\text{O}_2^*$ -producing triplet states compared to those in the SUM sample. Therefore, the plateau of  $P_{1\text{O}_2^*}$  in WIN shows up only under more concentrated conditions compared to SUM (Fig. S7).

**Figure 5.** (a, b) Dependence of triplet excited state concentration determined by (a) SYR and (b) PTA on the particle mass / water mass ratio in WIN (blue) and SUM (red). Solid circles are measured values in dilution experiments, while lines are extrapolations to ALW conditions. Previous measurements and extrapolations (best fit and high estimate) for Davis winter particle extracts are in green (Kaur et al., 2019). (c, d) The triplet production rate ( $P_{3C^*}$ , pink line) and first-order rate constants for  $^3C^*$  loss, including quenching by oxygen ( $k'_{3C^*,\text{O}_2}$ , dashed purple), dissolved organic carbon ( $k'_{3C^*,\text{DOC}}$ , dashed blue), and total ( $k'_{3C^*,\text{tot}} = k'_{3C^*,\text{O}_2} + k'_{3C^*,\text{DOC}}$ , orange) determined by (c) SYR and (d) PTA for SUM. Figure S5 shows  $P_{3C^*}$  and  $k'_{3C^*}$  for WIN.

#### 4 Conclusions and uncertainties

We measured concentrations of three photooxidants – hydroxyl radicals, oxidizing triplet excited states of organic matter, and singlet molecular oxygen – as a function of particle dilution in aqueous extracts of winter particles (influenced by residential wood combustion) and summer particles (strongly influenced by wildfires). The extracts contain high amounts of organic matter, with dissolved organic carbon concentrations ranging from 10 to 495  $\text{mg CL}^{-1}$ . DOC-normalized mass absorption coefficients at 300 nm are  $2.1 (\pm 0.2) \text{ m}^2 (\text{g C})^{-1}$  in winter and  $3.1 (\pm 0.1) \text{ m}^2 (\text{g C})^{-1}$  in summer, with absorption Ångström exponents of 7.2 for both, indicating significant amounts of brown carbon.

In the winter sample, the measured  $\cdot\text{OH}$  concentration appears to be independent of extract concentration, while in the summer sample  $\cdot\text{OH}$  increases with the concentration factor. In both WIN and SUM, measured  $^3C^*$  concentrations determined by our two probes initially increase rapidly with the concentration factor and then approach or reach a plateau under more concentrated conditions. Measured  $^1\text{O}_2^*$  concentrations in WIN are linear with DOC, while in SUM singlet oxygen levels show curvature (like  $^3C^*$ ) in more concentrated extracts. By extrapolating the oxidant kinetics in our dilute extracts to the much more concentrated conditions of ambient particle water ( $1 \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ), we obtain photooxidant concentrations of  $[\cdot\text{OH}] = (6\text{--}9) \times 10^{-15} \text{ M}$ ,  $[^3C^*] = (4\text{--}8) \times 10^{-13} \text{ M}$ , and

$[^1\text{O}_2^*] = (1\text{--}5) \times 10^{-12} \text{ M}$ . The  $\cdot\text{OH}$  particle water concentrations are not significantly different from those in fog/cloud waters, while  $[^3C^*]$  and  $[^1\text{O}_2^*]$  are 10–30 and 3–40 times higher, respectively, than fog/cloud values (at  $3 \times 10^{-5} \mu\text{g PM} / \mu\text{g H}_2\text{O}$ ). The ratio of concentrations of  $^1\text{O}_2^* : ^3C^* : \cdot\text{OH}$  in aerosol liquid water is  $10^3\text{--}10^2 : 10^2 : 1$ , which is lower than the  $10^5 : 10^4\text{--}10^2 : 1$  ALW ratio predicted by Kaur et al. (2019). This is because our predicted ALW concentration of  $\cdot\text{OH}$  is approximately 10 times higher than in this past work, while  $^3C^*$  is around 5 times higher than their best fit, and  $^1\text{O}_2^*$  is 30–150 times lower than their prediction (Fig. S8). Kaur et al. (2019) discussed the large uncertainties in predicting  $^1\text{O}_2^*$  and  $^3C^*$  for ALW conditions, in part because of the difficulty in experimentally observing the interactions between DOC and  $^3C^*$  or  $^1\text{O}_2^*$ . However, in this current work, we are able to clearly see triplet quenching by DOC, since organic carbon concentrations in our particle water extracts were up to 5 times higher than in the past work. When extrapolating to more concentrated conditions, we predict  $^3C^*$  concentrations are heavily suppressed due to quenching by DOC, resulting in triplet concentrations that are between the two estimates from Kaur et al. (2019). For the first time, we also see curvature in  $[^1\text{O}_2^*]$  versus DOC in our most concentrated summer extracts, which appears to result from suppression of triplets by organics. With this experimental finding, we are able to include this effect in the

**Figure 6.** (a) Dependence of singlet molecular oxygen concentration on the particle mass / water mass ratio in winter (blue) and summer (red) samples. Solid circles are measured values in dilution experiments, while lines are extrapolations to ALW conditions. Previous measurements and extrapolation with Davis winter particle extracts are in green (Kaur et al., 2019). (b) Dependence of singlet oxygen production rate ( $P_{1\text{O}_2^*}$ , pink line) and the rate constant for  $^1\text{O}_2^*$  loss, including deactivation by water ( $k'_{\text{H}_2\text{O}}$ , dashed purple), quenching by dissolved organic carbon ( $k'_{1\text{O}_2^*,\text{DOC}}$ , dashed blue), and the total sink ( $k'_{1\text{O}_2^*,\text{tot}} = k'_{\text{H}_2\text{O}} + k'_{1\text{O}_2^*,\text{DOC}}$ , orange) on the particle mass / water mass ratio for SUM. Figure S7 shows  $P_{1\text{O}_2^*}$  and  $k'_{1\text{O}_2^*}$  for the winter sample.

prediction of  $^1\text{O}_2^*$  concentrations under particle water conditions.

While our samples have higher DOC than the dilution sample in Kaur et al. (2019), our extrapolations from dilute extracts to ALW still span a huge range (approximately a factor of 600 in the PM mass / water mass ratio), bringing significant uncertainties. For example, it is unclear whether an appreciable portion of the organic compounds will precipitate under the much more concentrated conditions of ALW. In terms of experimental uncertainties, we could not observe how efficiently organic matter quenches  $^1\text{O}_2^*$  and thus were only able to estimate an upper bound of the rate constant, which is poorly constrained. In addition, highly concentrated particle extracts make it difficult to measure  $^3\text{C}^*$  by SYR because of strong inhibition by dissolved organic matter, with inhibition corrections of up to a factor of 7.5 in our samples. Additionally, the difficulty in inhibition factor measurements (and resulting high uncertainties) in concentrated extracts can bring large uncertainties. High DOC concentrations also result in significant light screening, which carries

additional uncertainty in the corresponding correction. While future work could use more concentrated particle extracts to reduce the extrapolation uncertainty, this approach would likely increase other uncertainties, including light screening and probe inhibition. Also, it is unlikely that the bulk solution approach that we have used can ever approach the concentration conditions in particle water. Because of this, other approaches, such as flow tubes or reaction chambers, will be required to more closely simulate oxidant generation and their subsequent reactions in ambient aerosols.

**Data availability.** All data are available upon request.

**Supplement.** The supplement related to this article is available online at: <https://doi.org/10.5194/acp-23-8805-2023-supplement>.

**Author contributions.** CA and LM developed the research goals and designed the experiments. KJB lent and set up the PM sampler, while LM and CG collected samples. LM and RL performed the photochemistry experiments, while WJ and CN analyzed OC and ions, respectively. LM analyzed the data and prepared the manuscript with contributions from all co-authors. CA reviewed, wrote portions of, and edited the manuscript. CA and QZ provided supervision and oversight during the experiments and writing.
