**Abstract.** Deposition of reactive nitrogen causes detrimental environmental effects, including biodiversity loss, eutrophication, and soil acidification. Measuring and modelling the biosphere–atmosphere exchange of ammonia, the most abundant reduced nitrogen species, is complex due to its high reactivity and solubility, often leading to systematic discrepancies between model predictions and observations. This study aims to determine whether three state-of-the-art exchange schemes for  $\text{NH}_3$  can accurately model  $\text{NH}_3$  exchange in a dune ecosystem (Solleveld) and detect factors causing the uncertainties in these schemes. The selected schemes are DEPAC (DEPosition of Acidifying Compounds) by van Zanten et al. (2010) and the schemes by Massad et al. (2010) and Zhang et al. (2010). Validation against 1 year of gradient flux measurements revealed that the Zhang scheme represented the  $\text{NH}_3$  deposition at Solleveld best, whereas the DEPAC scheme overestimated the total deposition, while the Massad scheme underestimated the total deposition. Yet none of these schemes captured the emission events at Solleveld, pointing to considerable uncertainty in the compensation point parameterization and possibly in the modelling of  $\text{NH}_3$  desorption processes from wet surface layers. The sensitivity analysis further reinforced these results, showing how uncertainty in essential model parameters in the external resistance ( $R_w$ ) and compensation point parameterization propagated into diverging model outcomes. These outcomes underscore the need to improve our mechanistic understanding of surface equilibria represented by compensation points, including the adsorption–desorption mechanism at the external water layer, and specific recommendations are provided for future modelling approaches and measurement setups to support this goal.

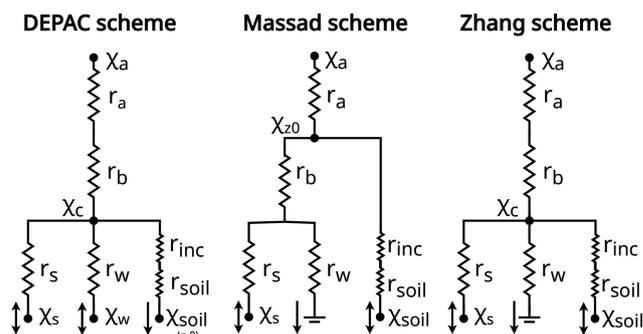

## 1 Introduction

Nitrogen deposition is known to have detrimental effects on the environment, such as biodiversity loss, greenhouse gas emissions, soil acidification, eutrophication, and particulate matter formation (Galloway et al., 2003). Nitrogen deposition consists of both oxidized and reduced nitrogen components. Measuring dry NH<sub>3</sub> deposition is challenging as NH<sub>3</sub> is very reactive and has a high solubility (Erisman and Wyers, 1993). Moreover, NH<sub>3</sub> is a weak absorber of light in both infrared and ultraviolet, which complicates remote-sensing measurements (Shephard and Cady-Pereira, 2015).

The development of NH<sub>3</sub> exchange schemes is mainly based on flux measurements with the gradient technique (Flechar et al., 2013) and more recently using the eddy covariance technique at a single height (Famulari et al., 2005; Swart et al., 2023; Wang et al., 2021). This has allowed for the parameterization of the exchange processes for different ecosystem types and also enabled the parameterization of multi-layer models and bi-directional exchange schemes (Nemitz et al., 2001). The exchange of NH<sub>3</sub> is a complex and dynamic process and is determined by a multitude of processes such as micrometeorology, soil properties, agricultural management practices, and vegetation growth, which are still only partly understood (Flechar et al., 2013).

Surface exchange schemes for NH<sub>3</sub> have three different pathways: (i) stomatal uptake into the leaf apoplasts, (ii) external deposition through solution of NH<sub>3</sub> in raindrops in water layers on vegetation surfaces, and (iii) surface deposition onto the soil surface. While the apoplasts, the external water layer, and the soil (hereafter called *exchange pathways*) can act as a sink for NH<sub>3</sub>, they can also be a source under certain conditions, making the surface exchange of NH<sub>3</sub> bi-directional (Farquhar et al., 1980). Most surface exchange schemes utilize the resistance analogy to calculate and describe factors that influence the rate of atmospheric deposition toward the biosphere (Wesely and Hicks, 1977). To account for the bi-directional nature of NH<sub>3</sub>, compensation points are introduced that act as an effective NH<sub>3</sub> concentration within the canopy. The NH<sub>3</sub> exchange schemes are illustrated in Fig. 1 and further discussed in Sect. 2.2. An inter-comparison of several NH<sub>3</sub> exchange schemes by Flechar et al. (2011) has shown that under identical meteorological and vegetative circumstances, the dry deposition velocities of different models vary by a factor of 2–3, pointing to a large uncertainty.

There is a need to improve the NH<sub>3</sub> surface exchange schemes to advance our understanding of the transport and deposition of reduced nitrogen. Therefore, this study aims to determine and quantify the uncertainties in three state-of-the-art NH<sub>3</sub> exchange schemes, which to our knowledge, has only scarcely been done (e.g. Hoogerbrugge et al., 2024; Bytnerowicz et al., 2015). Besides, comparative studies between bi-directional exchange schemes can help to improve models

**Figure 1.** Schematic of the DEPAC, Massad, and Zhang schemes. Note that at Solleveld, the DEPAC and Massad schemes do not model NH<sub>3</sub> exchange with the soil pathway.  $\chi_{z_0}$  is the NH<sub>3</sub> concentration at height  $z_0$  and is only calculated in the Massad scheme.

but are rare (e.g. Flechar et al., 2011; Neiryck and Ceulemans, 2008; Schrader et al., 2016; Wen et al., 2014).

Three operational exchange schemes are selected: the DEPAC (DEPosition of Acidifying Compounds) scheme (van Zanten et al., 2010), the Massad scheme by Massad et al. (2010), and the Zhang scheme by Zhang et al. (2010). We use a 1-year hourly flux measurement dataset from the dune area Solleveld (Vendel et al., 2023) to test and analyse the differences between the three models. Importantly, we evaluate these schemes without altering or optimizing their parameters, ensuring that the comparison reflects the formulations as implemented in the operational models. After presenting the results, the potential shortcomings of current NH<sub>3</sub> exchange schemes are discussed, and several recommendations for future NH<sub>3</sub> exchange schemes and measurement campaigns are provided that can contribute to lowering the model uncertainty and improving the understanding of the biosphere–atmosphere exchange of NH<sub>3</sub>.

## 2 Materials and methods

### 2.1 Experimental site and setup

The measurements took place in the dune ecosystem of Solleveld (52°2′ N, 4°11′ E), in the Netherlands (Vendel et al., 2023). The habitat type is grey dunes, and the measurement site consisted of sand sedge (*Carex arenaria*), moss, and lichens. To the east and south of the site are ponds surrounded by reed, contributing to terrain inhomogeneity. This inhomogeneity could be resolved by filtering out data from these wind directions; however, this would significantly reduce the dataset and would remove periods with higher NH<sub>3</sub> concentrations, limiting the validation of the schemes under more polluted conditions. Therefore, we did not apply this filter. The measurements with the GRAdient Ammonia High Accuracy Monitor (GRAHAM; Wichink Kruit et al., 2007) took place between September 2014 and September 2015. The measurements were performed at three heights:

0.8, 1.7, and 3.8 m. The GRAHAM instrument is a continuous wet denuder system with a low random bias of 1.9 %, a low detection limit of 0.1 µg m<sup>-3</sup>, and a temporal resolution of 10 min averaged to hourly measurements. Besides the NH<sub>3</sub> flux measurements, the wind speed and direction were measured with the 3D sonic anemometer Gill WindMaster Pro with a temporal resolution of 20 Hz at 5.15 m, from which the friction velocity  $u_*$  and Monin–Obukhov length were inferred. Based on the NH<sub>3</sub> concentrations measured and (partly) on-site meteorological measurements, the NH<sub>3</sub> exchange flux was inferred. To ensure the quality of the NH<sub>3</sub> gradient measurements, we have applied the same filters to the dataset as Vendel et al. (2023).

Meteorological input variables such as temperature, relative humidity (RH), and radiation were measured at Valkenburg weather station by the KNMI (the Royal Netherlands Meteorological Institute), located approximately 20 km northeast of Solleveld, provided at an hourly resolution. The DEPAC and Massad schemes also required SO<sub>2</sub> concentration data to account for co-deposition, which is the enhanced deposition of NH<sub>3</sub> caused by SO<sub>2</sub> deposition lowering the pH of the external leaf water (van Hove et al., 1989; Erisman and Wyers, 1993). SO<sub>2</sub> concentrations were not measured at Solleveld; therefore, hourly SO<sub>2</sub> measurements from monitoring station De Zilk were used, which were measured with the Thermo model 43w SO<sub>2</sub> analyser. De Zilk is a coastal station 35 km northeast of Solleveld and shares similar environmental conditions with Solleveld, as it is situated near the sea. The NH<sub>3</sub> and SO<sub>2</sub> concentrations were for 95 % of the measurements between 0–8 µg m<sup>-3</sup> and 0–7.5 µg m<sup>-3</sup> respectively. In September 2014, the SO<sub>2</sub> concentrations briefly spiked, caused by volcanic eruptions in Iceland (KNMI, 2024).

## 2.2 Dry deposition modelling of NH<sub>3</sub>

To calculate the dry deposition fluxes at Solleveld, the parameterizations of the DEPAC, Massad, and Zhang schemes have been coded in Python based on the parameterization presented in van Zanten et al. (2010), Massad et al. (2010), and Zhang et al. (2010). The modelled fluxes have an hourly temporal resolution. No parameterization for the land use class dunelands specifically was available in the three schemes. Therefore, “grass” was selected in the DEPAC scheme, “un-managed” and “semi-natural vegetation” in the Massad scheme, and “short grass and forbs” in the Zhang scheme. For a complete description of the schemes, we refer to van Zanten et al. (2010), Massad et al. (2010), and Zhang et al. (2010). The parameterizations are summarized in Table 1 and illustrated in Fig. 1.

The aerodynamic ( $R_a$ ) and quasi-laminar boundary layer resistances ( $R_b$ ) are parameterized consistently across all schemes following Wesely and Hicks (1977) and Hicks et al. (1987) respectively. Here we used the stability correction functions from Holtslag and de Bruin (1988) for stable con-

ditions ( $z/L > 0$ ) and the function from Paulson (1970) and Dyer (1974) for unstable conditions ( $z/L < 0$ ). The stomatal resistance  $R_s$  describes the exchange of gases with the atmosphere through the stomata with apoplastic fluids and is modelled with Jarvis-like functions. The DEPAC scheme follows the  $R_s$  parameterization by Emberson et al. (2000). Similarly, the Massad scheme also adopts this parameterization as Massad et al. (2010) do not provide a specific  $R_s$  parameterization. The Zhang scheme uses a slightly different parameterization for  $R_s$  and includes a function for stomatal blocking caused by water droplets blocking the stomata. The external resistance  $R_w$  (in the literature also denoted by  $R_{\text{cut}}$  or  $R_{\text{ext}}$ ) describes the exchange of gases with the (wet) layer on the cuticula (Erisman and Wyers, 1993; Sutton et al., 1995b; van Hove et al., 1989). While implemented differently across the three schemes, they all incorporate dependencies on RH, the leaf area index (LAI), a minimal external resistance  $R_{w,\text{min}}$  (or  $\alpha$ ), and an RH-response strength parameter, known as the  $\beta$  value. Finally, the soil resistance  $R_{\text{soil}}$  (also called  $R_g$ ) models the exchange of NH<sub>3</sub> with the soil, and the in-canopy resistance  $R_{\text{inc}}$  is the additional resistance exerted on a gas while being transported from the canopy towards the soil (David et al., 2009; Nemitz et al., 2000). Given the selected land use classes, only the Zhang scheme calculates the  $R_{\text{soil}}$  and  $R_{\text{inc}}$  at Solleveld.

To model the bi-directional exchange of NH<sub>3</sub> with the stomata, the wet dew layer, or the soil, compartment-specific compensation points  $\chi_i$  are calculated. The equation for  $\chi_i$  is the same across all schemes, incorporating principles from the Henry equilibrium, the NH<sub>3</sub>–NH<sub>4</sub><sup>+</sup> dissociation equilibrium, and the ideal gas law (e.g. Sutton et al., 1994):

$$\chi_i = \frac{2.75 \times 10^{15}}{T + 273.15} \exp\left(\frac{-1.04 \times 10^4}{T + 273.15}\right) \cdot \Gamma_i, \quad (1)$$

where  $\Gamma_i$  is the emission potential of the exchange pathway  $i$ , which is the [NH<sub>4</sub><sup>+</sup>]:[H<sup>+</sup>] ratio in either the apoplasts, the external dew layer, or the soil. The canopy compensation point  $\chi_c$  can be interpreted as the effective NH<sub>3</sub> concentration in an ecosystem and is used to calculate the total flux. The formulae of  $\chi_c$  in the three exchange schemes are lengthy but generally adhere to the following format (Sutton et al., 1995b):

$$\chi_c = \frac{\sum_i \chi_i / R_i}{\sum_i 1 / R_i}. \quad (2)$$

Finally, the exchange flux  $F$  is calculated as follows:

$$F = -\frac{\chi_a - \chi_c}{R_a + R_b}. \quad (3)$$

By convention, deposition and emission fluxes have a negative and positive sign respectively. Studies have demonstrated that integrating compensation points into exchange schemes generally improves the agreement with measurements compared to unidirectional deposition models

**Table 1.** Main parameterization of the DEPAC, Massad, and Zhang exchange schemes for the NH<sub>3</sub> exchange utilized in this study.

Variable name	DEPAC (grasslands)	Massad (non-fertilized, semi-natural)	Zhang (short grass and forbs)
$F_{\text{tot}}^a$ ( $\mu\text{g m}^{-2} \text{s}^{-1}$ )	$-\frac{\chi_a - \chi_c}{R_a + R_b}$	$-\frac{\chi_a - \chi(z_0)}{R_a}$	$-\frac{\chi_a - \chi_c}{R_a + R_b}$
$F_s$ ( $\mu\text{g m}^{-2} \text{s}^{-1}$ )	$-\frac{\chi_c - \chi_s}{R_s}$	$-\frac{\chi_c - \chi_s}{R_s}$	$-\frac{\chi_c - \chi_s}{R_s}$

$\Gamma_s^h$ (–)	$1701.4 \cdot \bar{\chi}_a(\text{long-term}) \cdot \exp(-0.071T)$	$246 + 0.0041 \cdot (\text{N}_{\text{in}})^{3.56}$	300
$\Gamma_w$ (–)	$F(\alpha_{\text{SN}}) \cdot [1.84 \times 10^3 \cdot \chi_{a,4\text{m}} \cdot \exp(-0.11T) \cdot -850]$	–	–
$F(\alpha_{\text{SN}})^f$ (–)	$F(\alpha_{\text{SN}} < 0.83) = 1.10 - 1.32\alpha_{\text{SN}}$ $F(\alpha_{\text{SN}} \geq 0.83) = 0$	–	–
$\Gamma_{\text{soil}}^e$ (–)	–	–	395

<sup>a</sup> The equations for  $\chi_c$  and  $\chi(z_0)$  are extensive and can be found in van Zanten et al. (2010), Massad et al. (2010), and Zhang et al. (2010). <sup>b</sup> Note that the soil resistances and compensation points are not calculated in the DEPAC and Massad schemes. <sup>c</sup> Acidity ratio used in Massad scheme. No  $\text{HNO}_3^-$  and  $\text{HCl}$  concentration data were available for Sollefeld; therefore, the alternative function proposed by Schrader et al. (2016) of  $3.5 \cdot \frac{\text{SO}_2}{\text{NH}_3}$  is used. <sup>d</sup> Formula for the calculation of the compensation point in the unit  $\mu\text{g m}^{-3}$  specifically where  $a = 2.75 \times 10^{15}$  and  $b = -1.04 \times 10^4$ . <sup>e</sup> Note that originally the  $\Gamma_{\text{soil}}$  in the Zhang scheme is 2000, but a lower value of 395 has been implemented, which is an average of the  $\Gamma_{\text{soil}}$  value reported by Massad et al. (2010) and Wentworth et al. (2014). <sup>f</sup> The co-deposition function is described in Wichink Kruit et al. (2017), where  $\alpha_{\text{SN}} = \frac{[\text{SO}_2]}{[\text{NH}_3]}$ . <sup>g</sup> The Zhang scheme uses different parameterizations for dry and wet conditions. The threshold value for wet conditions is when  $\text{RH} \geq 95$ , based on the threshold value used in the GEM-MACH model (Chen and GEM-MACH Development Team, 2019). <sup>h</sup> The  $\bar{\chi}_a(\text{long-term})$  is the average long-term  $\text{NH}_3$  concentration. In this study, we calculate a monthly average  $\text{NH}_3$  concentration. The  $\text{N}_{\text{in}}$  at Sollefeld was extracted from the annual deposition map published by RIVM (2024) and was 20.7 and 18.2 kg  $\text{N ha}^{-1}$  in 2014 and 2015 respectively. <sup>i</sup> PAR is the photosynthetically active radiation, and VPD is the vapour pressure deficit.

(Neiryneck and Ceulemans, 2008; Wen et al., 2014; Wichink Kruit et al., 2012). Yet the empirical functions in surface exchange schemes are adapted to a scarce set of flux measurements.

The three exchange schemes selected in this study differ in which exchange pathway is bi-directional. The DEPAC scheme has a stomatal compensation point  $\chi_s$  and an external compensation point  $\chi_w$ : the stomatal emission potential  $\Gamma_s$  parameterization is derived from a meta-analysis of  $\Gamma_s$  values for multiple land use classes (see Wichink Kruit et al., 2010). It is a function of temperature and the long-term average  $\text{NH}_3$  concentration (e.g. 1 month or 1 year), which serves as a memory component assuming that the apoplastic  $\Gamma_s$  is a function of the historic  $\text{NH}_3$  accumulation. The

DEPAC scheme is the only operational model with a  $\chi_w$  parameterization, which is a function of temperature and the instantaneous  $\text{NH}_3$  concentration and is based on 3 years of measurements at Haarweg (Wichink Kruit et al., 2010). The scheme also implicitly has a soil compensation point  $\chi_{\text{soil}}$ , but this is currently set to zero. Besides, soil exchange is disabled for the grasslands land use class in the DEPAC scheme. The Massad scheme has a  $\chi_s$  and  $\chi_{\text{soil}}$ , but the  $\chi_{\text{soil}}$  is set to 0 at Sollefeld as the scheme assumes no soil exchange takes place when vegetation is present. The  $\Gamma_s$  equation in the Massad scheme is derived from a meta-analysis of reported  $\Gamma_s$  values and is a function of annual nitrogen input  $\text{N}_{\text{in}}$  (Massad et al., 2010). The Massad scheme also has a parameterization specifically for management events (e.g. fer-

tilizer application or grazing) but is not utilized as Solleveld is an unmanaged site. The Zhang scheme has a  $\chi_s$  and  $\chi_{\text{soil}}$ , and in contrast to the DEPAC and Massad schemes, it also assumes soil exchange when vegetation is present. The scheme has a lookup table with  $\Gamma$  values for an extensive set of land use classes based on a meta-analysis of reported  $\Gamma_s$  and  $\Gamma_{\text{soil}}$  values (Zhang et al., 2010). For several land use classes, they provide  $\Gamma$  values for ecosystems with either a low or high nitrogen content. In this study, the low content value was used. The  $\Gamma_{\text{soil}}$  value for the land use category of short grass and forbs in the Zhang scheme is set at 2000, leading to unrealistic model output, which results in extremely high emission fluxes (see Figs. 6 and A2). Wentworth et al. (2014) also observe this issue, explaining that the high  $\Gamma_{\text{soil}}$  value was derived from measurements at fertilized sites, which are not representative of unfertilized soils. Therefore, the  $\Gamma_{\text{soil}}$  value of 2000 is lowered to 395, which is an averaged value derived from the  $\Gamma_{\text{soil}}$  value reported by Massad et al. (2010) and Wentworth et al. (2014). The effects of this modification are further discussed in Sect. 4.4.

Moreover, all schemes used the yearly LAI curves employed in the DEPAC scheme. Vendel et al. (2023) found stronger performance for the DEPAC scheme with a minimum and maximum LAI of 0.5 and 1.0 respectively. These values were also applied in this study. Vendel et al. (2023) have also experimented with enabling the soil pathway in the DEPAC scheme, but this was not implemented in this study.

### 2.3 Uncertainty analysis and sensitivity analysis

In addition to validating the NH<sub>3</sub> exchange schemes, a comprehensive error analysis was conducted to estimate the uncertainties in input variables and model parameters. A Monte Carlo uncertainty analysis was used to propagate these uncertainties and quantify the total uncertainty in the model output. Additionally, a sensitivity analysis was performed by only perturbing one input variable or model parameter to identify the most sensitive inputs. The uncertainty of each input variable or model variable was estimated using literature-based estimations or expert judgement. A 95 % confidence interval was determined for each input. Table A1 provides a complete list of the variables selected for the uncertainty/sensitivity analysis, together with the derived standard deviations, the lower and upper bounds per variable used for the sensitivity analysis, and the type of probability distribution (e.g. normal, uniform, discrete). Additionally, the methods and assumptions for deriving these probability density functions are briefly explained.

Three uncertainty categories were propagated in the Monte Carlo analysis. The first is measurement biases, both random and systematic, which arise from the measurement device itself. From this, the extent to which these biases may propagate into modelling errors could be assessed, consequently determining whether more accurate measurement equipment is necessary. Second, two systematic environmen-

tal biases were analysed: these are differences between temperature and RH within and outside the canopy, where these variables are typically measured. This can aid in detecting potential systematic errors that need to be considered. Research by Personne et al. (2009) has shown that systematic temperature differences could lead to diverging modelling outcomes, because NH<sub>3</sub> exchange schemes are sensitive to this temperature offset, as temperature is a key parameter for stomatal conductance and compensation point parameterization. Likewise, RH is a key variable for calculating the external resistance  $R_w$  but could strongly differ inside and outside of the canopy (von Arx et al., 2012; Westreenen et al., 2020). Third, model biases such as empirically derived model parameters like  $\alpha$  and  $\beta$  in  $R_w$  were propagated to identify parameters that may require revision. It should be acknowledged that estimating the uncertainty for these parameters is challenging and involves some degree of subjectivity, and results can vary strongly depending on the chosen uncertainty range.

In total, 5000 trials were run per model; i.e. the three exchange schemes calculated the fluxes at Solleveld 5000 times with different settings. A 95 % confidence interval for modelled fluxes was derived, calculated from the 2.5th and 97.5th percentile. To ensure the number of trials was sufficient, it was verified that the mean flux of the 5000 trials converged to stable values. Vendel et al. (2023) have conducted an assessment of the uncertainty associated with the GRAHAM instrument and flux calculations. They report an error margin of  $\pm 24$  % ( $2\sigma$ ) for accumulated fluxes, which was used in this study.

## 3 Results

### 3.1 Quantitative comparison of exchange schemes with measurements

The comparison of the measured and modelled fluxes is given in Table 2. The mean measured NH<sub>3</sub> flux at Solleveld is  $-7.0 \text{ ng m}^{-2} \text{ s}^{-1}$ . The mean flux modelled by the Zhang scheme at  $-6.8 \text{ ng m}^{-2} \text{ s}^{-1}$  comes close to the mean measured flux. In contrast, the DEPAC scheme overestimates the mean flux at  $-14.6 \text{ ng m}^{-2} \text{ s}^{-1}$ , which is more than twice the measured mean flux, and the Massad scheme strongly underestimates the mean flux at  $-3.0 \text{ ng m}^{-2} \text{ s}^{-1}$ . When comparing the hourly measured and the modelled NH<sub>3</sub> fluxes at Solleveld, the Zhang scheme has the highest Pearson correlation at 0.63, indicating a moderately strong linear relationship. This is followed by the DEPAC scheme at 0.56, whereas the Massad scheme has a low correlation of 0.18. Table 2 also displays the performance of the exchange scheme when strong deposition, moderate deposition, or emission is observed. Both during moderate and strong deposition events, the Zhang scheme has the lowest RMSE. However, the DEPAC scheme had the highest correlation of 0.50 during moderate deposition, slightly better than the Zhang scheme.

**Table 2.** Descriptive statistics of the measured and the modelled fluxes per exchange scheme. Additionally, the statistics are shown when strong deposition ( $F_{\text{tot}} \leq -20$ ), moderate deposition ( $-20 > F_{\text{tot}} > F_{\text{tot}} < 0$ ), and emission ( $F_{\text{tot}} \geq 0$ ) are observed.

Table 2 shows that emission events are poorly captured by all three schemes. In total, 33 % of the fluxes were emission fluxes with the DEPAC scheme capturing emissions in only 14 % of the instances, compared to 20 % for the Massad scheme and 31 % for the Zhang scheme. NH<sub>3</sub> emissions were observed at all hours of the day, with a peak between 10:00 and 18:00 LT, but emissions also took place during the night. Figure 2 shows hexbin plots comparing the hourly measured fluxes with the modelled fluxes. The weak performance of all three models during emission events is clearly visible, showing no correlation with the measurements and often predicting deposition instead of emission. This indicates that the current parameterization of compensation points in all three exchange schemes cannot model the emission events correctly at Solleveld.

Figure 3 shows the average diurnal pattern of the measured and modelled NH<sub>3</sub> flux per scheme at Solleveld. The measured NH<sub>3</sub> flux exhibits a clear diurnal pattern where the deposition is enhanced during the evening and the night and lower during the day. In terms of timing, the DEPAC scheme closely matches the measured flux; however, it overestimates deposition due to a negative offset at all times. The observed deposition “dip” at noon (i.e. when the deposition is at its lowest) is shifted to 15:00 LT in the DEPAC scheme. On the contrary, the Massad scheme exhibits a rather flat diurnal pattern and consistently underestimates NH<sub>3</sub> deposition at Solleveld throughout the day. The Zhang scheme approximates the order of magnitude of the measured fluxes well, although it does not accurately model the temporal variation of the fluxes.

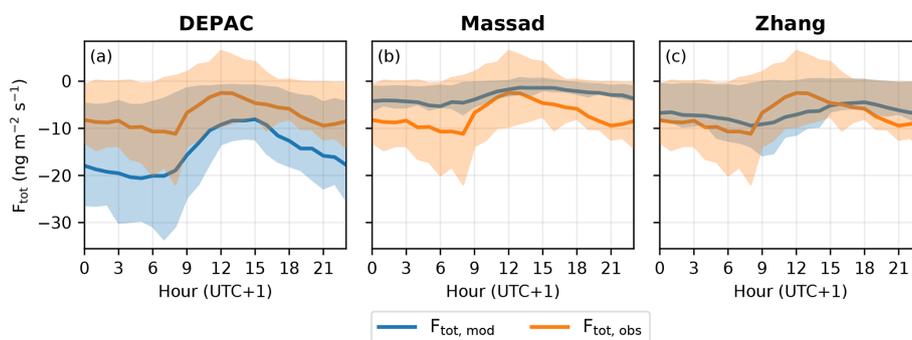

Figure 4 displays the comparison between monthly averaged observed and modelled NH<sub>3</sub> fluxes. The strongest deposition took place in March, attributed to the elevated NH<sub>3</sub> concentrations stemming from agricultural fertilization practices in the region. Additionally, a minor deposition peak can be observed in November. The DEPAC scheme demonstrates a moderately good comparison with the measurements in spring, while the deposition flux is overestimated in the second half of the year, especially in November. In contrast, the Massad scheme underestimates deposition almost every month, showing very little correlation with the measured yearly trend. Finally, the Zhang scheme demonstrates the strongest performance every month, accurately modelling NH<sub>3</sub> deposition during both strong and weak deposition months. The accumulated measured and modelled fluxes during the Solleveld campaign are illustrated in Fig. A1.

### 3.2 Model comparison

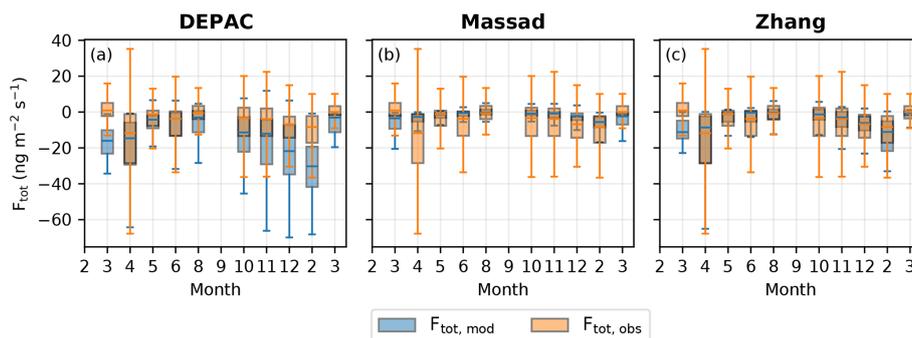

To understand the differences between the three exchange schemes, the separate pathways of the three schemes are illustrated in Fig. 5. A general observation from Fig. 5a–c is that all exchange schemes are predominantly governed by deposition towards the external leaf surface, highlighting the importance of  $R_w$  parameterization for NH<sub>3</sub>. The dominance

**Figure 2.** Hexbin plot with the measured and modelled fluxes for the DEPAC, Massad, and Zhang schemes.

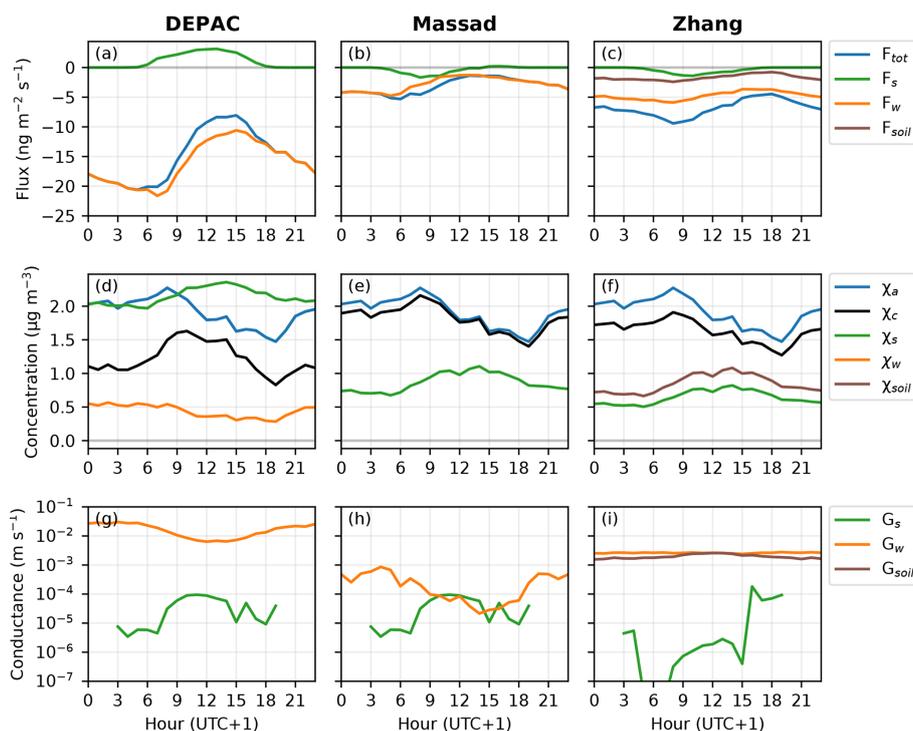

**Figure 3.** Measured and modelled average diurnal pattern of the NH<sub>3</sub> flux at Sollelveld in  $\text{ng m}^{-2} \text{s}^{-1}$ , per model. The shading around the lines depicts the 25%–75% percentile range.

**Figure 4.** Measured and modelled monthly averaged NH<sub>3</sub> flux at Sollelveld in  $\text{ng m}^{-2} \text{s}^{-1}$ , per model. The outer whiskers show the quartile +  $1.5 \times$  the interquartile range. Note that outliers are not displayed.

of the external leaf pathway is also shown in Fig. A3, showing the total accumulated flux per exchange pathway for all three exchange schemes. Conversely, the stomatal exchange is minimal across all three schemes. In the Zhang scheme, a small but not insignificant fraction of the deposition is towards the soil. Figure 5g–i show the conductances, which are the reciprocals of the resistances and are more convenient to show, as resistances can vary strongly throughout the day.

In the DEPAC scheme, the external flux is higher than the other two schemes, caused by the higher external conductance  $G_w$  (Fig. 5g), resulting in the highest deposition flux among all three schemes. The high  $G_w$  modelled in the DEPAC scheme aligns with the findings by Schrader et al. (2016). Both the DEPAC and Massad schemes show that  $G_w$  is highest during the evening and night and lower during the day.

**Figure 5.** Diurnally averaged fluxes (a–c), compensation points (d–f), and conductances (g–i) per exchange pathway of the DEPAC, Massad, and Zhang schemes.

In contrast,  $G_w$  in the Massad scheme is several orders of magnitude lower than in the DEPAC scheme. This difference is due to (i) a higher base resistance ( $\alpha$  or  $R_{w,\min}$ ) of  $31.5 \text{ s m}^{-1}$  compared to  $2 \text{ s m}^{-1}$  in the DEPAC scheme, (ii) a lower RH scaling parameter  $\beta$  of 8.3 compared to 12 in the DEPAC scheme, and (iii) the inclusion of the  $\beta_T$  parameter, which increases  $R_w$  with rising temperature.

The Zhang scheme, however, does not exhibit a strong diurnal cycle of  $G_w$ , indicating that it is less dependent on RH compared to the other two schemes. Similarly, the soil conductance  $G_{\text{soil}}$  in the Zhang scheme does not show a diurnal cycle and has a similar magnitude to  $G_w$  (Fig. 5i). Despite this, the soil flux is significantly lower than the external flux (Fig. 5c), caused by the incorporation of a soil compensation point, which counteracts soil deposition.

Finally, while both the DEPAC and Massad schemes use the same parameterization for  $R_s$ , the DEPAC scheme calculates stomatal emission rather than deposition, unlike the Massad scheme. This contrast is caused by the high stomatal compensation point  $\chi_s$  in the DEPAC scheme (Fig. 5d). Both functions for  $\Gamma_s$  in the DEPAC and Massad scheme are derived with a least squares fit from measurements at multiple land use types (grasslands, semi-natural, and forests), but the exact reason for the significant difference between  $\Gamma_s$  in the DEPAC and Massad schemes remains unclear.

### 3.3 Uncertainty and sensitivity analysis

The results of the uncertainty analysis, presented in Table 3 and Fig. A1, indicate significant uncertainties in the modelled flux of the three exchange schemes. The total uncertainty of the DEPAC scheme ranges from a 107 % deposition increase to a –142 % decrease (i.e. net emission would take place), showing a large range of possible outcomes. The Massad scheme shows an even greater spread, with uncertainties ranging from a 471 % increased deposition to a –132 % decrease. In contrast, the Zhang scheme showed a more moderate uncertainty ranging from an 81 % deposition increase to a –69 % decrease. When comparing the absolute uncertainty of the mean modelled flux at Sollelveld, the DEPAC scheme showed the largest spread of  $[-30.3; 6.1 \text{ ng m}^{-2} \text{ s}^{-1}]$ , followed by the Massad scheme with an interval of  $[-17.4; 1.0 \text{ ng m}^{-2} \text{ s}^{-1}]$  and the Zhang scheme with an uncertainty range of  $[-12.3; -2.1 \text{ ng m}^{-2} \text{ s}^{-1}]$ .

The outcome of the uncertainty analysis can be further interpreted when viewed alongside the results of the sensitivity analysis, as shown in Table 3. The values of the variables and parameters in this sensitivity analysis are both increased and decreased, whereas the upper and lower parameter values are based on the  $2\sigma$  confidence bounds (see Table A1). The sensitivity of each parameter is expressed as the percentage increase or decrease of the mean flux at Sollelveld, caused by the perturbation. As stated in the methods section, three types of biases have been considered: measurement biases,

**Table 3.** Results of the uncertainty analysis (top row) and the sensitivity analysis of the three exchange schemes, showing the percentage increase/decrease of the mean modelled flux at Sollefeld during the measurement period. Positive values indicate an increase in the deposition and negative values a decrease in the deposition. Percentage changes lower than  $-100\%$  imply net emission. Sensitivities  $> 10\%$  are in bold. The lower and upper values represent the  $2\sigma$  confidence intervals shown in Table A1.

systematic environmental biases, and model biases. The measurement bias of the RH instrument has the most pronounced impact on the modelled fluxes in the DEPAC and Massad schemes, which can be explained by the strong dependency of these two schemes on the  $R_w$ . For similar reasons, the sensitivity of the LAI measurement error is more pronounced in these schemes. The measurement bias for RH and LAI was not as pronounced in the Zhang scheme, which can be explained by the slightly lesser dominance of the external pathway (see Fig. A3). Conversely, the Zhang scheme is more affected by the measurement error of  $u^*$  given its importance in both  $R_w$  and  $R_{\text{soil}}$  parameterization. The influence of the measurement bias of temperature and radiation was not significant. The effect of systematic environmental biases on in-canopy and above-canopy temperature and RH has also been analysed. Only the Massad scheme showed strong changes in the output caused by the systematic temperature differences, as  $R_w$  is also a function of temperature due to the  $\beta_T$  parameter. The insensitivity of the DEPAC scheme to systematic temperature difference was surprising, given the strong relationship between temperature and the compensation points. However, model output has shown that  $\chi_s$  increased significantly, consequently increasing the stomatal emission flux. However, this effect was completely counteracted by the  $\chi_w$ , which decreased, as  $\Gamma_w$  is inversely proportional to temperature, therefore increasing the external flux.

Generally, the most sensitive parameters in all three schemes can be related to model biases with sensitivities often surpassing a  $\pm 50\%$  change in the modelled flux: In the DEPAC scheme, uncertainties in  $\Gamma_w$ ,  $\alpha$ , and  $\beta$  significantly impacted the model's output. In the Massad scheme, the most sensitive parameters are  $\beta$ ,  $\alpha$ , and  $\beta_T$ . In both the DEPAC and the Massad schemes, these sensitive parameters can, in some cases, cause the direction of the flux to shift from net deposition to net emission. In the Zhang scheme, the parameters with the highest sensitivities were  $\beta$  and  $\Gamma_{\text{soil}}$ . From this analysis, it can be concluded that (i) in all three exchange schemes, the most sensitive variables are primarily related to the exchange of NH<sub>3</sub> via the external leaf path and the compensation point parameterization and (ii) that the DEPAC and Massad schemes are more sensitive to parameter perturbations than the Zhang scheme, as indicated by the stronger impact the perturbations have on the modelled fluxes.

## 4 Discussion

The comparison of the three exchange schemes revealed that the Zhang scheme has a better performance than the DEPAC and Massad schemes when validated against the Sollefeld measurement. Additionally, the exchange at the external leaf surface is a key process across all three schemes, which has also been observed in previous studies (e.g. Hansen et al., 2013; Jones et al., 2007; Neiryck and Ceulemans, 2008; Wyers and Erisman, 1998). This also implies that the pa-

rameterization of external leaf surface exchange of NH<sub>3</sub> is primarily responsible for the stark differences between the schemes, in accordance with results by Flechard et al. (2011). In contrast, differences in the parameterization of stomatal and soil exchange only resulted in subtle differences between the schemes. A critical issue that arises from the results is the inability of all three schemes to accurately model emission fluxes (see Fig. 2), pointing to significant shortcomings in the parameterization of compensation points. The sensitivity analysis confirms these findings, showing that the greatest uncertainties lie in the parameterization of  $R_w$  and compensation points, significantly affecting model outcomes. The results of this study align with the findings of Schrader et al. (2016), as the external flux in the DEPAC scheme was stronger than in the Massad scheme, and both studies recognize the sensitivity of NH<sub>3</sub> exchange schemes to environmental parameters such as temperature and relative humidity. While Schrader et al. (2016) only focused on the non-stomatal parameterization of the DEPAC and Massad schemes during nighttime conditions at four sites (including the Sollefeld dataset), this study extended the analysis by incorporating both stomatal and the non-stomatal parameterization and validated the schemes during nighttime and daytime conditions. Moreover, it offers a more comprehensive evaluation of schemes as the Zhang scheme is included, and it uses post-processed Sollefeld data, whereas Schrader et al. (2016) used preliminary data from Sollefeld.

In this section, we first discuss several hypotheses as to why observed emissions were not modelled by the three schemes. The following section elaborates on how desorption processes from the external water layers are currently not modelled by any of the three exchange schemes and how dynamic modelling approaches can resolve this issue. Finally, the influence of the uncertainty of RH and temperature measurements on the model output is discussed, and the limitations of this research are given.

### 4.1 Determining the emission source

The results of the scheme intercomparison indicate that emissions are not modelled properly across all three schemes (see Fig. 2). Given the fact that soil exchange could not be ruled out at Sollefeld, it was not possible to isolate the fluxes properly in order to derive the source of the emission. However, several hypotheses can be made regarding the source of the emission. The origin could be the desorption of NH<sub>3</sub> from the leaf surfaces, although these emissions usually take place in the morning and would not fully explain the emissions that take place in the afternoon (see Fig. 3). These emissions could also originate from the stomata, as  $\chi_s$  would increase during the day, caused by the temperature increase. This phenomenon of stomatal emission would be in line with previous analyses on non-fertilized fields (e.g. Horváth et al., 2005; Wichink Kruit et al., 2007). The soil and litter layer could also be a potential source of NH<sub>3</sub> that should not be

overlooked. At Sollefeld, the LAI is very low, which makes it less likely for the overlying vegetation to recapture NH<sub>3</sub> (David et al., 2009; Hansen et al., 2013; Sutton et al., 2009). However, given that Sollefeld is a non-fertilized ecosystem, it could be expected that  $\Gamma_{\text{soil}}$  is not large, thus reducing the likelihood of the soil layer acting as a strong NH<sub>3</sub> source. Yet research on soil and litter NH<sub>3</sub> exchange is limited, particularly in non-fertilized ecosystems such as Sollefeld. Therefore,  $\Gamma_{\text{soil}}$  (and  $\Gamma_{\text{litter}}$ ) measurements similar to the work by Wentworth et al. (2014) would be valuable. Additionally, flux measurements over bare soil would be useful, which could be utilized for improving our understanding regarding the significance of soil NH<sub>3</sub> exchange, as well as for validating and revising  $R_{\text{soil}}$  parameterization.

Auxiliary measurements that would help identify the emission sources at Sollefeld, as well as in other ecosystems, include direct  $\Gamma$  measurements of the apoplasts, leaf surface water, soil, and litter to derive the compensation points per pathway. Ideally, these measurements would also be done over longer periods of time to understand seasonal and ecosystem-related influences on the  $\Gamma$  values. Moreover, H<sub>2</sub>O or CO<sub>2</sub> fluxes could be measured parallel to NH<sub>3</sub> flux measurements to serve as an indication for the stomatal conductance  $G_s$  (Schrader et al., 2020; Schulte et al., 2024). Such a setup will simplify isolating and determining the flux of each exchange pathway by subtracting the stomatal flux from the total flux, aiding in determining the magnitude of the external flux and soil flux, which are currently subject to the greatest uncertainty. This would also enable a derivation of a parameterization for  $R_w$  based on daytime measurements. The current parameterization of  $R_w$  has been based on nighttime flux data, possibly resulting in a systematic bias for nocturnal conditions, such as lower temperatures, higher RHs, and lower turbulence. Theoretically, soil fluxes could also have been estimated from the Sollefeld dataset; however, after filtering for conditions when stomatal and external exchange are assumed to be limited (i.e. RH < 71 and no solar radiation), only a small subset of data ( $n = 88$ ) was left which was too little to infer reliable claims about soil NH<sub>3</sub> exchange.

#### 4.2 $R_w$ and external exchange

Given the importance of  $R_w$ , we further examine the key parameters involved in its calculation. Both the DEPAC and Massad schemes use the  $\alpha \cdot e^{\beta(100-\text{RH})}$  structure to determine  $R_w$ , whereas the Zhang scheme follows a slightly different framework. The parameters  $\alpha$  and  $\beta$  play a crucial role in these parameterizations, yet their physical interpretation remains poorly understood. The  $\alpha$  parameter indicates the minimal  $R_w$  resistance, and the  $\beta$  parameter can be described as the RH-response coefficient (Wichink Kruit, 2010). The  $R_w$  equations (also presented in Table 1) are as follows:

$$R_w(\text{DEPAC}) = \frac{3.5}{\text{SAI}} \cdot \alpha \cdot \exp\left(\frac{100 - \text{RH}}{\beta}\right), \quad (4)$$

where SAI is the surface area index,  $\alpha = 2.0 \text{ s m}^{-1}$  and  $\beta = 12$ .

$$R_w(\text{Massad}) = \alpha \cdot \text{AR} - 1 \cdot \exp[\beta \cdot (100 - \text{RH}) + 0.15T] \cdot \text{LAI}^{-0.5}, \quad (5)$$

where  $\alpha = 31.5 \text{ s m}^{-1}$ ,  $\beta = 0.12$ , and AR is the acid : NH<sub>3</sub> ratio. Note that  $\beta$  in the Massad scheme operates as a multiplier, whereas in DEPAC, it is a denominator.

$$R_w(\text{Zhang, dry}) = \min\left(100, \frac{1000}{\exp(0.03\text{RH})\text{LAI}^{0.25}u_*}\right) \quad (6)$$

$$R_w(\text{Zhang, wet}) = \min\left(20, \frac{100}{\text{LAI}^{0.5} \cdot u_*}\right), \quad (7)$$

where the minimum resistances of  $100 \text{ s m}^{-1}$  and  $20 \text{ s m}^{-1}$ , for dry and wet conditions respectively, can be interpreted as an effective  $R_{w,\text{min}}$ , or  $\alpha$  value.

The strong sensitivity of these two parameters can be seen both in the model intercomparison and the sensitivity analysis: the DEPAC scheme has the lowest  $\alpha$  value of  $2.0 \text{ s m}^{-1}$ , whereas the Massad scheme has the highest  $\alpha$  of  $31.5 \text{ s m}^{-1}$ , which results in a much stronger external flux in the DEPAC scheme (see Fig. 5g and h). Similarly, the sensitivity analysis revealed that propagation of the uncertainties of  $\alpha$  and  $\beta$  led to strongly varying model outcomes (see Table 3).

To reduce the uncertainty of modelling NH<sub>3</sub> exchange via the external leaf surface, it is essential to understand the underlying physical properties of the  $\alpha$  and  $\beta$  parameters. Massad et al. (2010) discuss that  $\alpha$  is impacted by the SO<sub>2</sub> : NH<sub>3</sub> ratio, while the  $\beta$  parameter is affected by leaf hygroscopicity and aerosol deposition. They also supply  $\alpha$  and  $\beta$  values derived from multiple measurement campaigns, revealing significant differences in these parameters both among different ecosystem types and within each type. The Massad scheme provides ecosystem-specific  $\beta$  values, albeit with great uncertainties where the standard deviations of  $\beta$  are almost equal to the  $\beta$  value itself. Options for improved  $R_w$  parameterization include a more diverse set of  $\alpha$  and  $\beta$  values for different ecosystem types and pollution conditions or the formulation of parameterization to derive location-specific  $\alpha$  and  $\beta$  values. The availability of significantly more NH<sub>3</sub> flux measurements allows for revisiting the  $\alpha$  and  $\beta$  parameters.

Big steps forward can be made by including  $\chi_w$  parameterization in the Massad and Zhang schemes to account for the adsorption–desorption dynamics at the external leaf surface. Although  $\chi_w$  parameterization is already included in the DEPAC scheme, it is not able to explicitly model NH<sub>3</sub> re-emission from the external leaf surface as  $\chi_w$  is a function of  $\chi_a$ . Wentworth et al. (2016) found that 94 % of the NH<sub>3</sub> emitted during the morning could be attributed to NH<sub>3</sub> accumulated in the water layer overnight, indicating that NH<sub>3</sub> re-emission is a phenomenon that should not be overlooked. Moreover, it is hard to properly interpret the specific “roles” of the  $R_w$  and  $\chi_w$  parameters in the DEPAC scheme, and it may be possible to rely on compensation points alone to model the external flux. This requires further research.

The formula of  $\Gamma_w$  in the DEPAC scheme is empirically inferred from 3 years of flux measurements at the Haarweg grasslands site (Wichink Kruit et al., 2010). This parameterization is used across all land use classes, which could introduce a systematic bias when used for other land use classes: interspecies differences in the chemical composition of the water layer (e.g. caused by guttation) and differences in wettability caused by the wax content of the cuticula could result in variations in NH<sub>3</sub> absorption among different plant species (Flechard et al., 1999). The effect of interspecies differences on NH<sub>3</sub> external leaf layer exchange is understudied, but despite the knowledge gap, analyses can already be performed on existing flux datasets to validate whether the  $\chi_w$  parameterization is accurate across different ecosystem types. Note that this was challenging for the Solleveld dataset, as the external compensation point could not be inferred from the measurements due to the inability to rule out soil NH<sub>3</sub> exchange. Moreover, the  $\chi_w$  values were inferred from micrometeorological measurements, which could contain considerable noise. Direct surface water measurements of  $\Gamma_w$  are scarce (Burkhardt et al., 2009; Sutton et al., 1995a; Wentworth et al., 2016), and for the development and calibration of more accurate parameterization of  $\chi_w$ , measurements of  $\Gamma_w$  with a high temporal resolution would be valuable. Additionally, this dataset would be useful to infer whether micrometeorological inference is an accurate method for estimating  $\Gamma_w$  values.

Given the challenges of modelling NH<sub>3</sub> exchange with the external leaf surface, we suggest moving beyond the static  $R_w$  parameterization by adopting a more mechanistic and dynamic modelling approach. Here, the inclusion of a memory effect could, for example, aid in modelling the NH<sub>3</sub> re-emission that is often observed in the morning, as nighttime NH<sub>3</sub> reservoirs in water layers are depleted, as discussed earlier in this section. Dynamic models for NH<sub>3</sub> exchange have already been developed (Flechard et al., 1999; Sutton et al., 1998), which considers preceding fluxes, an adsorption charge, and leaf surface chemistry, which moderates NH<sub>3</sub> solution due to saturation effects. Neiryneck and Ceulemans (2008) found that the accuracy of the dynamic model from Sutton et al. (1998) had a better performance than a unidirectional model for  $R_w$  and was also able to model emission events. The latter is promising, as NH<sub>3</sub> desorption from the external leaf layer is not modelled by any of the three exchange schemes in this study. The downside of the dynamic approach is that it requires additional input data such as surface water pH, which is generally unavailable; however, initial efforts can be made to estimate surface water pH. As mentioned previously, direct surface water measurements of  $\Gamma_w$  would be valuable for this purpose.

#### 4.3 Relative humidity and temperature biases

In the DEPAC and Massad schemes, RH is a crucial parameter for estimating  $R_w$ . The sensitivity analysis for RH

showed a significant impact on the mean modelled flux in both schemes, with changes of approximately  $\pm 15\%$  and  $\pm 30\%$  respectively (see Table 3). Therefore, precise RH equipment is essential for providing accurate input when modelling the NH<sub>3</sub> fluxes and for properly analysing NH<sub>3</sub> flux data when developing new parameterization. Although the influence of systematic differences in RH was analysed in the sensitivity analysis, the effect on the modelled NH<sub>3</sub> flux was small.

The influence of the random error of the temperature measurement equipment of  $\pm 0.1^\circ\text{C}$  has also been analysed but remained small across all three exchange schemes. In contrast, the influence of systematic temperature changes inside and outside of the canopy was significant in the Massad scheme, which can be attributed to the inclusion of the  $\beta_T$  parameter in  $R_w$ . Studies on typical temperature and RH profiles in dune ecosystems were not found, and the systematic uncertainties therefore had to be estimated. Hence, it is recommended to perform NH<sub>3</sub> flux measurements together with RH or temperature profile measurements for different vegetation types, to determine the influence of neglecting these systematic differences in NH<sub>3</sub> flux modelling.

Personne et al. (2009) elaborated further on these systematic temperature differences and coupled a deposition scheme to an energy budget model that explicitly models in-canopy temperatures. Their results indicate that systematic temperature variations should be explicitly considered in parameterization, particularly due to the exponential relationship between compensation points and temperature, as well as the relationship between stomatal conductance and temperature. However, while the sensitivity analysis shows that the Massad scheme is significantly affected by the systematic temperature difference, the net effect on the modelled flux is limited in the Zhang scheme and nearly zero in the DEPAC scheme. It must be noted that the uncertainty range used to test the sensitivity to systematic temperature difference of  $\pm 1^\circ\text{C}$  was fairly conservative. Personne et al. (2009) report on temperature differences exceeding more than  $4^\circ\text{C}$ ; propagating such temperature differences would likely lead to stronger variations in modelled fluxes.

#### 4.4 Methodological constraints

Several limitations should be taken into account. First, the results and implications in this study are drawn from measurements at a dune ecosystem, and therefore it remains an open question whether these results apply to other ecosystems as well. It is recommended to extend this study across different ecosystem types, similar to analyses by Flechard et al. (2011) and Schrader et al. (2016).

Second, this study did not discuss the influence and contribution of soil exchange, as it was challenging to isolate the soil flux from the stomatal and external flux. This limitation prevented a deeper mechanistic analysis at Solleveld, where each exchange pathway could be quantitatively eval-

uated. This also implies that although the exchange schemes signal that the external flux is the most dominant flux at Solleveld, consistent with previous research (Hansen et al., 2013; Jones et al., 2007; Neiryndck and Ceulemans, 2008; Wyers and Erisman, 1998), this does not necessarily mean it was the most dominant flux in reality. Incorporating auxiliary measurements of CO<sub>2</sub> or H<sub>2</sub>O fluxes along with  $\Gamma_s$ ,  $\Gamma_w$ ,  $\Gamma_{\text{soil}}$  and  $\Gamma_{\text{litter}}$ , as discussed in Sect. 4.1, would address these issues. Additionally, directly inserting in situ  $\Gamma$  values into the model descriptions – rather than calculating the  $\Gamma$  using the model equations – would allow for a more targeted validation of the resistance parameterization. By using measured  $\Gamma$  values, errors related to the compensation point parameterization can be ruled out, making it easier to assess the accuracy of the resistance terms – assuming that the measured  $\Gamma$  values themselves are accurate. Consequently, this would enable the validation of  $R_w$  parameterization and evaluate whether a soil pathway should be incorporated in exchange schemes for dune ecosystems, as done in the Zhang scheme. Especially in ecosystems with low LAIs such as Solleveld, the contribution of soil exchange should be understood better. Moreover, this would aid in identifying the emission sources, which are currently not accounted for by any of the three schemes.

Third, several state-of-the-art models such as SURFATM-NH<sub>3</sub> (Personne et al., 2009), CMAQ-EPIC (Pleim et al., 2019) and the dynamic model by Sutton et al. (1998) were not included in this study, as they required additional input parameters, which were unavailable or difficult to estimate. This touches upon the trade-off between a model's usability and accuracy, as more complex models might be more accurate but require extra input data, which are often not readily available. Fourth, specific parameterization for dunelands does not exist, and grasslands or semi-natural vegetation parameterization has been used across all schemes instead. Yet systematic differences between these land use classes and dunelands can lie in the LAI, the apoplastic NH<sub>4</sub><sup>+</sup> : H<sup>+</sup> ratio, the wettability of plant surfaces, and the potential presence of soil NH<sub>3</sub> exchange. This also calls for expanding available land use classes in all three schemes (e.g. dunelands, heathlands, and moorlands) and conducting additional measurements to develop new parameterization. Fifth, due to the temporal resolution of the GRAHAM instrument of approximately 30 min (Wichink Kruit et al., 2010), and further aggregation to hourly averages in this study, sudden temporal features such as emission or deposition pulses can be smoothed out. This limitation can hinder the ability to accurately study diurnal dynamics and detect short-lived events such as emission pulses. Sixth, some meteorological input data such as temperature, RH, and radiation have not been measured at Solleveld but at a meteorological station at Valkenburg, which is approximately 20 km to the northeast, which can introduce inaccuracies in the model output due to local differences between the two locations. Seventh, although the uncertainty ranges for each input variable or model parameter defined for the uncertainty and sensitiv-

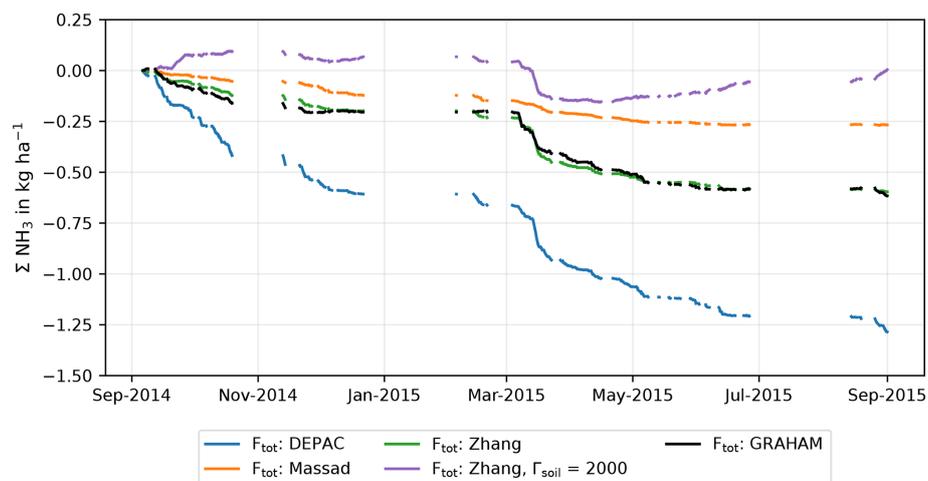

ity analysis were assessed with great care, decisions such as defining these ranges and the distribution type (i.e. normal, uniform, etc.) inevitably involved a degree of subjectivity, which could impact the outcome of the analyses. Moreover, the uncertainty analysis only accounts for the uncertainty in processes or variables that are explicitly included in the schemes, meaning the analysis will not capture the uncertainty of these excluded processes.

Eighth, as stated in the methods section, the  $\Gamma_{\text{soil}}$  value in the Zhang scheme has been lowered from 2000 to 395. We acknowledge this is a modification to the Zhang scheme, which strongly alters the modelled output of the scheme; however, it is justifiable given the mismatch between the original parameterization and the empirical findings by Wentworth et al. (2014) for unfertilized ecosystems. With the original  $\Gamma_{\text{soil}}$  value of 2000, the Zhang scheme (purple line) would strongly underestimate the deposition at Solleveld and even predicts a slight net emission (see Fig. 6). In addition, the effect of the  $\Gamma_{\text{soil}}$  adaptation on the average diurnal cycle is displayed in Fig. A2.

Finally, the parameters in the surface exchange schemes stem from flux measurements and are empirically translated into parameterization. That means that generalization to different environmental circumstances or pollution climates can give different outcomes, as demonstrated by the differing results per exchange scheme in this study. Thus, more flux measurements across a range of environmental conditions are necessary.

## 5 Conclusion

This study aimed to determine the accuracy of three state-of-the-art NH<sub>3</sub> exchange schemes in a dune ecosystem and to identify the key factors that contribute to model uncertainties. The results of this study indicate that the performance of the exchange schemes differed significantly at the Solleveld dune site: both on hourly and monthly timescales. The Zhang scheme accurately models the NH<sub>3</sub> exchange, whereas the DEPAC and Massad schemes respectively overestimate and underestimate the total deposition. However, the Zhang scheme does not capture the average daily cycle well: the DEPAC scheme captures this most realistically. The results also reveal that the exchange with the external leaf layer is the most important exchange pathway in all exchange schemes, which is in coherence with previous studies (e.g. Erisman and Wyers, 1993; Burkhardt et al., 2009). A serious flaw identified among all three models is that the frequent emission events at Solleveld are poorly modelled, implying that the compensation point parameterization is ineffective. The sensitivity analysis of individual model parameters demonstrates that the biggest portion of the uncertainty can be attributed to the model uncertainty in the  $R_w$  parameterization and the compensation point modelling. The findings of these analyses provide additional quantification of the

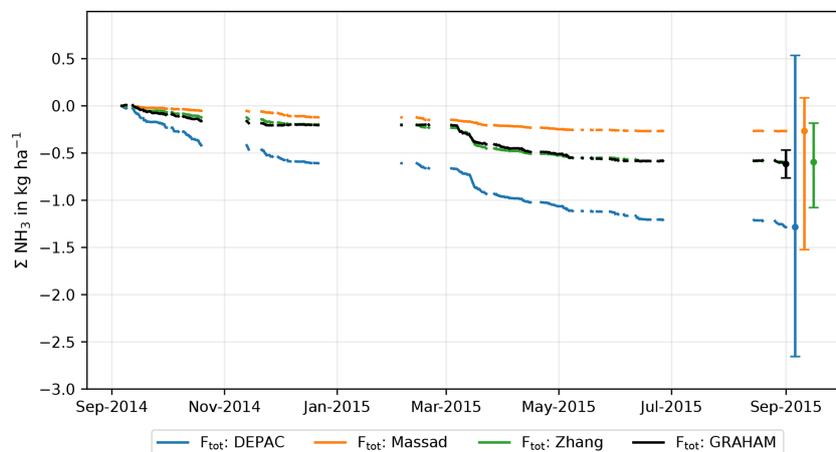

**Figure 6.** Accumulated deposition at Sollefeld during the measurement period, including the accumulated flux of the unmodified Zhang scheme with a  $\Gamma_{\text{soil}}$  value of 2000.

model uncertainties and corroborate the findings of Schrader et al. (2016), who also highlighted the difficulties in modelling  $R_w$ . Additionally, the sensitivity analysis has shown that the random bias in RH measurements can lead to strong fluctuations in the modelled fluxes in the DEPAC and Massad schemes. The effect of propagating systematic temperature differences inside and outside the canopy only led to strong effects on the modelled flux in the Massad scheme. Similarly, the net effect of a potentially higher RH in the canopy was minimal in all three schemes.

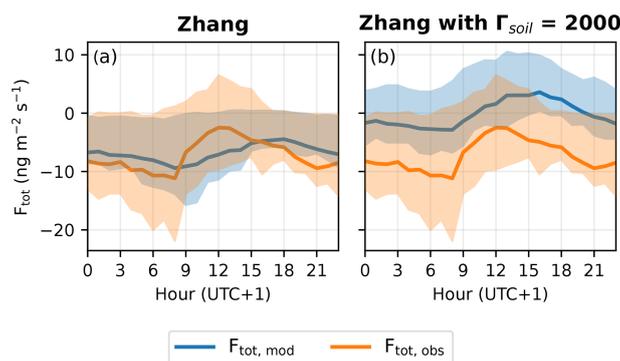

To address these uncertainties, we recommend conducting additional external leaf water measurements to quantify  $\Gamma_w$  to better understand the adsorption–desorption processes taking place at the wet leaf surfaces and to calibrate and improve the parameterization of  $\Gamma_w$ . Furthermore, auxiliary measurements of H<sub>2</sub>O or CO<sub>2</sub> fluxes as a proxy for stomatal conductance can aid in isolating the stomatal, external, and soil fluxes from each other, making it easier to estimate the contribution per exchange pathway. Moreover, although the external leaf pathway is identified as a crucial pathway in NH<sub>3</sub> exchange, the soil pathway remains understudied. Additional measurements of  $\Gamma_{\text{soil}}$  and measurements over bare soil to validate  $R_{\text{soil}}$  parameterization would be viable for reducing the modelling uncertainty.

Future research should focus on improving our understanding of the mechanisms controlling NH<sub>3</sub> exchange with the external leaf layer, as this process is pivotal for accurate NH<sub>3</sub> exchange modelling. Environmental factors influencing the  $\alpha$  and  $\beta$  parameters here are key. Additionally, despite the relevance of NH<sub>3</sub> desorption from the external leaf surface, it is not explicitly included in either of the three exchange schemes in this study. Dynamic models simulating external leaf surface fluxes can be an effective alternative to the current  $R_w$  parameterization methods, and promising work in dynamic modelling of leaf surface NH<sub>3</sub> exchange (Sutton et al., 1998; Flechard et al., 1999; Burkhardt et al., 2009) should be further pursued.

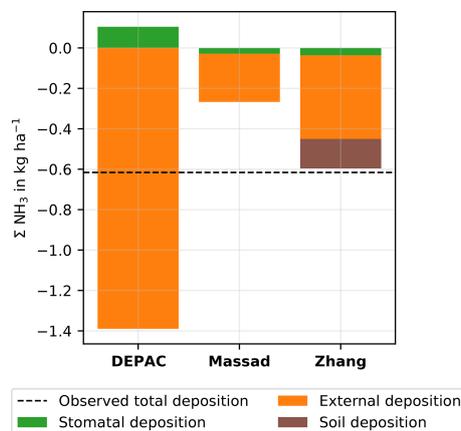

## Appendix A: Additional figures and tables

**Figure A1.** Accumulated deposition at Solleveld during the measurement period. The error bars on the right represent the uncertainty range (95 % CI) of the schemes, calculated by the Monte Carlo uncertainty analysis.

**Figure A2.** Modelled and observed average diurnal cycle of the Zhang scheme at Solleveld, comparing the adjusted parameterization used in this study (a) to the original parameterization with a  $\Gamma_{soil}$  of 2000 (b).

**Figure A3.** Accumulated flux per exchange pathway at Solleveld per exchange scheme. Note that the DEPAC scheme models net stomatal emission, hence the positive value. The striped line depicts the total deposition measured with the GRAHAM at Solleveld.

**Table A1.** Input variables and model parameters and the bias categories, the associated uncertainty ( $1\sigma$ ), the lower and upper bound values, and the chosen distribution functions. The lower and upper bounds represent the  $2\sigma$  values, forming the 95 % confidence interval.

Parameter <sup>a</sup>	Unit	Bias type	Uncertainty range ( $1\sigma$ )	Lower bound	Upper bound	Distribution type	Source

<sup>a</sup> The D, M, or Z in parentheses denotes the DEPAC, Massad, or Zhang scheme respectively. <sup>b</sup> For some variables, the lower bound would become negative, which is physically impossible (e.g. for  $G_{s,\text{max}}$  or the roughness length). In these cases, the lower value was capped at 10 % of the base value. <sup>c</sup> Kelliher et al. (1995) reported a  $G_{s,\text{max}}$  of 0.008 with a standard deviation  $\sigma$  of 0.004, from which a coefficient of variation ( $CV = \mu/\sigma$ ) of 0.5 is calculated. This CV is subsequently used to define the  $\sigma_{G_{s,\text{max}}}$  and the variability space for  $G_{s,\text{max}}$  in the three exchange schemes. <sup>d</sup> The uncertainty ranges of the  $\alpha$  and  $\beta$  parameters used in  $R_w$  are based on the data from van Hove et al. (1989) and Benner et al. (1992). These data are also displayed in Fig. 4 in Sutton et al. (1995b), from which the  $\alpha$  and  $\beta$  values of 2 sm<sup>-1</sup> and 12 sm<sup>-1</sup> respectively are derived. Note that these parameter values are also used in the DEPAC scheme. A curve has been fitted to this dataset in Python using SciPy's `curve_fit` function, which supplied a covariance matrix. Consequently, the standard deviations of the  $\alpha$  and  $\beta$  parameters were determined. From this, the  $CV_\alpha = 0.41$  and  $CV_\beta = 0.17$  were calculated. Using these CVs, the  $\sigma_\alpha$  and  $\sigma_\beta$  were calculated for  $\alpha$  and  $\beta$  per scheme. For  $\sigma_{\beta,\text{Massad}}$ , the standard deviation reported by Massad et al. (2010, p. 10379) is used instead. Note that slightly different parameters for  $\alpha$  and  $\beta$  were found with the `curve_fit` function in this study compared to the values reported by Sutton et al. (1995b), but uncertainty ranges have been scaled proportionally to the original  $\alpha$  and  $\beta$  values found by Sutton et al. (1995b). <sup>e</sup> The Zhang scheme does not explicitly have an  $\alpha$  value but has a cut-off value of 100 sm<sup>-1</sup> and 20 sm<sup>-1</sup> for dry and wet conditions respectively, which can be interpreted as an  $\alpha$  value. The  $CV_\alpha$  of 0.41 is used to derive the standard deviation applied to these cut-off values. <sup>f</sup> The constant  $R_{\text{soil}}$  parameter for dry and wet conditions is randomly replaced with  $R_{\text{soil}}$  values for dry and wet conditions used in the Zhang, DEPAC, and MATCH schemes (Klein et al., 2002; van Zanten et al., 2010). <sup>g</sup> From Table 3 in Massad et al. (2010), measured  $\Gamma_s$  values from different studies are listed together with the uncertainty range. From this, an average  $CV_{\Gamma_s} = 0.52$  is derived. This  $CV_{\Gamma_s}$  is also used to derive the  $\sigma$  of  $\Gamma_s$  in the DEPAC and Zhang schemes. The standard deviation of  $\Gamma_s$  in the DEPAC scheme is derived from the mean modelled  $\Gamma_s$  at Sollefeld (= 1461.5), leading to a standard deviation of 760. <sup>h</sup> The  $CV_{\Gamma_w}$  in the DEPAC scheme is assumed here to be of the same order of magnitude as  $CV_{\Gamma_s}$  and  $CV_{\Gamma_{\text{soil}}}$ , which are 0.52 and 0.50 respectively. Therefore,  $CV_{\Gamma_w}$  is estimated here as 0.5. Based on a mean  $\Gamma_w$  of 1576 at Sollefeld, a standard deviation of 788 has been derived. <sup>i</sup> A  $CV_{\Gamma_{\text{soil}}}$  of 0.5 has been derived from  $\Gamma_{\text{soil}}$  data from a non-fertilized grassland (Wentworth et al., 2014). From the  $\Gamma_{\text{soil}}$  (= 395) in the Zhang scheme, a standard deviation of 197.5 has been derived. <sup>j</sup> The leaf area index (LAI) has been altered according to Vendel et al. (2023) to a minimum LAI of 0.5 and a maximum LAI of 1.0. These values have been derived from MODIS LAI data. Fang et al. (2012) derive a relative uncertainty of 26.6 % for the MODIS LAI product. For consistency, this value has also been used for the  $SAI_{\text{Haarweg}}$  parameter used in the DEPAC scheme. <sup>k</sup> As in Vendel et al. (2023), roughness lengths are wind sector dependent, accounting for the heterogeneous footprint of Sollefeld, and are calculated with the  $u^*$  measurements from the sonic anemometer, according to Moene and van Dam (2016, p. 119). The standard deviation of the  $z_0$  per wind sector is used to describe the uncertainty in  $z_0$ .
