**Abstract.** Air quality forecasting plays a critical role in mitigating air pollution. However, current physics-based air pollution predictions encounter challenges in accuracy and spatiotemporal resolution due to limitations in the understanding of atmospheric physical mechanisms, observational constraints, and computational capacity. The world's first geostationary satellite UV–Vis spectrometer, i.e., the Geostationary Environment Monitoring Spectrometer (GEMS), offers hourly measurements of atmospheric trace gas pollutants at high spatial resolution over East Asia. In this study, we successfully incorporate geostationary satellite observations into a neural network model (GeoNet) to forecast full-coverage surface nitrogen dioxide (NO<sub>2</sub>) concentrations over eastern China at 4 h intervals for the next 24 h. GeoNet leverages spatiotemporal series of satellite NO<sub>2</sub> observations to capture the intricate relationships among air quality, meteorology, and emissions in both temporal and spatial domains. Evaluation against ground-based measurements demonstrates that GeoNet accurately predicts diurnal variations and spatial distribution details of next-day NO<sub>2</sub> pollution, yielding a coefficient of determination of 0.68 and a root mean square of error of 12.31 μg m<sup>-3</sup>, significantly surpassing traditional air quality model forecasts. The model's interpretability reveals that geostationary satellite observations notably improve NO<sub>2</sub> forecast capability more than other input features, especially over polluted regions. Our findings demonstrate the significant potential of geostationary satellite observations in artificial-intelligence-based air quality forecasting, with implications for early warning of air pollution events and human health exposure.

## 1 Introduction

Since the industrial revolution, numerous countries worldwide have encountered severe air pollution issues such as photochemical ozone smog and haze pollution (Hong et al., 2019), which significantly affect human health, crop yields, and the global environment (Manisalidis et al., 2020; Sathe et al., 2021; Guarin et al., 2024). Recent studies have shown that both long-term and short-term exposure to air pollutants such as nitrogen dioxide (NO<sub>2</sub>) can significantly affect human health, especially the respiratory system (Meng et al., 2021). Accurate and high-spatial-resolution predictions of air pollutant concentrations can provide critical information for sensitive persons to mitigate health risks. Meanwhile, air quality health risk (AQHI) forecasts and corresponding public response recommendations need to be communicated to the public promptly through public facilities (Tang et al., 2024; Fino et al., 2021). In recent decades, the advancement of atmospheric monitoring and modeling has enabled significant progress in air quality forecasting based on our understanding of atmospheric physics and chemistry (Peuch et al., 2022). Air pollution forecasting not only facilitates responses to environmental health risks but also improves the accuracy of climate and weather simulations (Makar et al., 2015). However, due to our still-limited understanding of atmospheric mechanisms and observational and emission constraints, existing air quality forecasts based on physical or statistical models still face challenges in terms of temporal, spatial, and accuracy aspects (Campbell et al., 2022; Zhong et al., 2021).

Artificial intelligence (AI) technology has made breakthroughs in the field of Earth science (Zhong et al., 2021; Boukabara et al., 2020), particularly excelling in addressing complex problems that are challenging for traditional physical paradigms to simulate (Irrgang et al., 2021), such as weather and climate forecasting (Andersson et al., 2021). Concerning meteorological data, some large-scale deep learning models have surpassed the predictive capabilities of existing numerical weather models to some extent. Examples include Climax (Nguyen et al., 2023), Pangu-Weather (Bi et al., 2023), and GraphCast (Lam et al., 2023). Despite significant progress and impressive performance achieved by forecasting meteorological variables with AI methods, there are still limitations in predicting atmospheric pollutant compositions. Compared to meteorological parameters, the prediction of air pollutant concentrations is affected by synoptic meteorology, chemistry, and anthropogenic emission activity, usually with more complex driven mechanisms and associated uncertainties. Current AI-based air quality forecasts often involve time series predictions at a limited number of observation stations rather than full-coverage predictions over the entire spatial domain (Du et al., 2021). This is primarily due to the lack of effective air quality observations with high temporal and spatial resolution simultaneously.

While past polar-orbiting satellite observations such as the Ozone Monitoring Instrument (OMI) and the TROPOspheric Monitoring Instrument (TROPOMI), have provided extensive coverage of atmospheric pollutant distributions such as nitrogen dioxide (NO<sub>2</sub>), sulfate dioxide (SO<sub>2</sub>), ozone (O<sub>3</sub>), and aerosols, they are limited to once-daily overpasses and are usually affected by clouds (van Geffen et al., 2022; Chan et al., 2023). This frequency usually exceeds the chemical lifetimes of many reactive-gas pollutants like NO<sub>2</sub>, making it challenging to offer effective observational constraints for short-term air quality forecasting with machine learning (Shah et al., 2020). However, these observations at a fixed daily overpass time could hardly support the prediction of atmospheric trace gas concentrations at other times of the day under different meteorological conditions. In February 2020, the world's first geostationary satellite payload for air pollution monitoring, the Geostationary Environment Monitoring Spectrometer (GEMS), began to provide high-coverage and high-precision air quality observations at an hourly rate for the East Asian region (Kim et al., 2020). The dynamic processes of air pollutants including emission, transformation, and transport can be observed by the geostationary satellite during the daytime. This monitoring capability may advance data-driven air quality forecasting such as machine learning techniques by offering unprecedented observational constraints with high spatial and temporal coverage. Recent observing system simulation experiments (OSSEs) indicate that assimilating trace gas observations by geostationary satellites into chemical models can effectively improve surface ozone simulations (Shu et al., 2023), nitrogen oxides (NO<sub>x</sub>), and emission estimates (Hsu et al., 2024).

Here, based on the unprecedented temporal and spatial resolution and coverage of the GEMS satellite (Kim et al., 2020), we incorporated geostationary satellite remote sensing of tropospheric NO<sub>2</sub> column densities (refer to Sect. 4 for details) into a neural network model (GeoNet) to forecast full-coverage surface NO<sub>2</sub> concentration over the next day from the current time  $t$  (i.e.,  $t + 24$  h). Compared with previous air quality forecasting based on the simulation of atmospheric physics and chemistry, possibly combined with data assimilation approaches, GeoNet relies solely on geostationary satellite measurements and ancillary meteorology data. GeoNet effectively addresses the complex, nonlinear relationships between future short-term air quality and current satellite observations, as well as temporally adjacent meteorological variables (Zhang et al., 2022). The method employs satellite and meteorological variables within the spatial vicinity of individual air quality monitoring sites as input features, with site observations serving as labels for model training. The resulting model achieves accurate and comprehensive air quality predictions across the entire domain over eastern China, which is a significant achievement given that past machine learning technologies have relied on only a few stations or polar-orbiting satellite observations.

## 2 Materials and methods

### 2.1 Geostationary satellite observations of atmospheric NO<sub>2</sub>

GEMS is the first UV–Vis spectrometer at a geostationary satellite orbit, measuring atmospheric pollutants such as NO<sub>2</sub>, SO<sub>2</sub>, O<sub>3</sub>, and HCHO over East Asia at a spatial resolution of 3.5 km × 7.5 km at nadir and a temporal resolution of 1 h during the daytime (Kim et al., 2020). Based on the unique spectral absorption of trace gases, the atmospheric NO<sub>2</sub> column can be retrieved in visible wavelengths from the spectra of back-scattered sunlight. The details of the GEMS NO<sub>2</sub> retrieval can be found in the Algorithm Theoretical Basis Document (available at <https://nesc.nier.go.kr/ko/html/satellite/doc/doc.do>, last access: 1 June 2023). In this study, we used the tropospheric NO<sub>2</sub> column from the GEMS NO<sub>2</sub> version 2.0 product, as well as the cloud fraction for each satellite ground pixel. Overall, GEMS NO<sub>2</sub> measurements have a good correlation with ground-based remote sensing instruments, with correlation coefficients ( $R$ ) between 0.69 and 0.81 and root mean square of errors (RMSE) between 3.2 and  $4.9 \times 10^{15}$  molec. cm<sup>-2</sup> (Kim et al., 2023). Our previous validation results indicated that GEMS NO<sub>2</sub> retrievals generally agreed well with ground-based MAX-DOAS measurements from six sites in China, with correlation coefficients ranging between 0.69 and 0.92 (Li et al., 2023).

### 2.2 Ancillary datasets

Other input information including meteorological datasets is necessary to better constrain the prediction of future NO<sub>2</sub> pollution. Here, both the ERA5 meteorology reanalysis (Hersbach et al., 2020) and the CAMS forecast (Peuch et al., 2022) were used to provide meteorological parameters such as zonal and meridional wind ( $U$  wind and  $V$  wind), temperature (Temp), relative humidity (RH), and precipitation (Precip). In addition, the fraction of cloud cover available from the satellite NO<sub>2</sub> datasets was also considered. To fill the missing gaps in the satellite NO<sub>2</sub> measurements, we use both the NO<sub>2</sub> concentrations from the WRF-Chem model (Zhang et al., 2022) and the CAMS forecast of atmospheric composition. Note that the reanalysis datasets were typically updated with a delay of 1 week from real time, while the forecast datasets can provide future 7 d meteorology from the current time. Therefore, the latency of input datasets would affect the operational prediction of the GeoNet model. Surface NO<sub>2</sub> measurements were used as the ground-truth label in the model training phase, available from over 1000 national air quality sites via the China National Environmental Monitoring Centre (CNEMC) (Kong et al., 2021).

The preprocessing steps of model input datasets, including outlier detection, missing value handling, resampling, and normalization, are described in Sect. S1 in the Supplement.

### 2.3 The GeoNet model

Figure 1 illustrates the structure and methodology of the artificial intelligence air quality forecasting model established in this study. Given the distinctive nature of spatiotemporal sequence data for air quality, predictions must consider not only temporal relationships but also spatial correlations. The deep learning model employed in this research utilizes convolutional long short-term memory (ConvLSTM) as its kernel, a variant of the LSTM model designed for the time series forecasting (Lin et al., 2020). It incorporates a convolutional network structure to capture spatial features of three-dimensional inputs. Both input-to-state and state-to-state transitions involve convolutional structures. ConvLSTM determines the future state of a unit within a grid based on inputs from its local neighbors and past states, allowing it to effectively model the spatiotemporal dynamics of air quality. The ConvLSTM kernel structure employed in training is illustrated in Fig. 5a. Here,  $X_t$  represents the input at time  $t$ ,  $H_t$  and  $H_{t-1}$  denote the outputs at times  $t$  and  $t-1$ , and  $C_t$  and  $C_{t-1}$  represent the states at times  $t$  and  $t-1$ . The computational process is as follows:

$$i_t = \sigma(X_t * w_{xi} + H_{t-1} * w_{hi} + b_i) \quad (1)$$

$$f_t = \sigma(X_t * w_{xf} + H_{t-1} * w_{hf} + b_f) \quad (2)$$

$$o_t = \sigma(X_t * w_{xo} + H_{t-1} * w_{ho} + b_o) \quad (3)$$

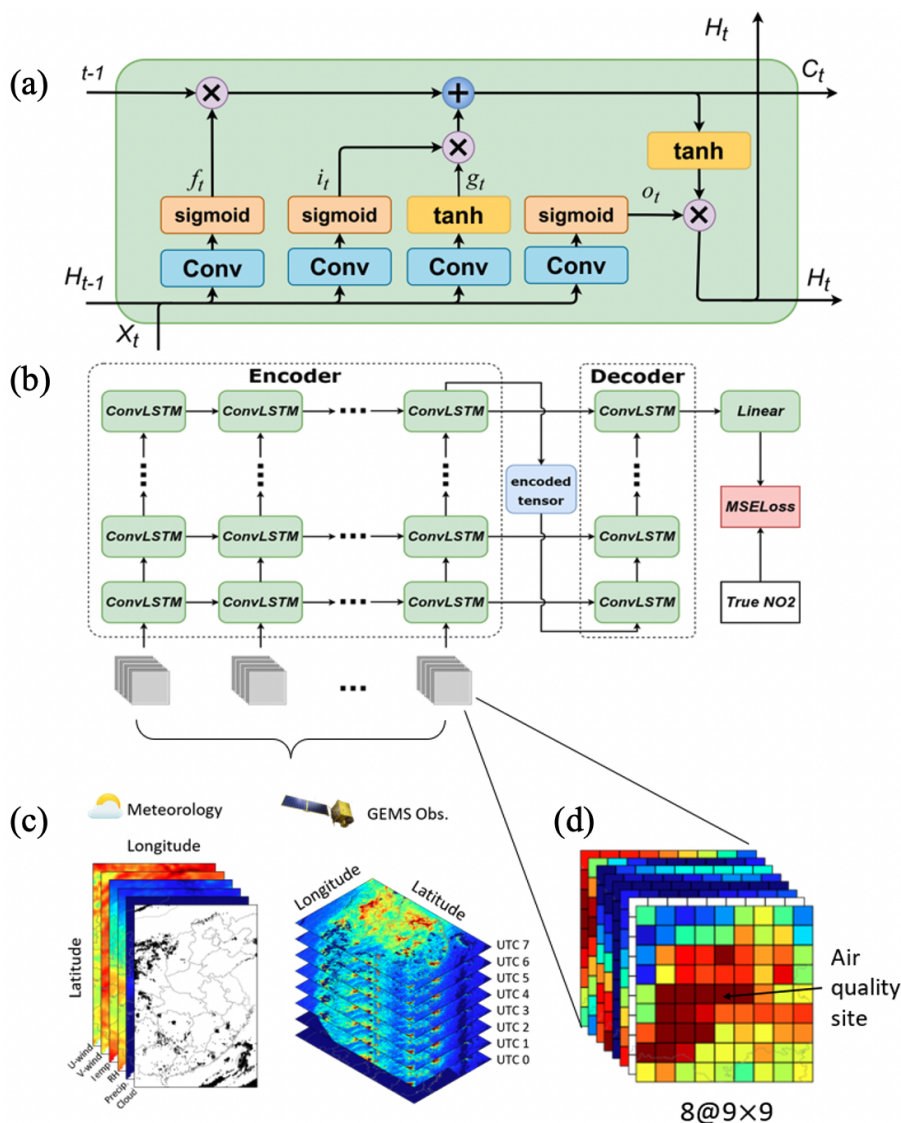

$$g_t = \tanh(X_t * w_{xg} + H_{t-1} * w_{hg} + b_g) \quad (4)$$

$$C_t = f_t \times C_{t-1} + i_t \times g_t \quad (5)$$

$$H_t = o_t \times \tanh(C_t), \quad (6)$$

where the asterisk (\*) represents the convolution operator,  $w$  is the convolution kernel,  $b$  is the offset,  $\tanh$  is the hyperbolic tangent function, and  $\sigma$  is the activation function of sigmoid.

The model primarily consists of three components: an encoder, a decoder, and fully connected layers. Tropospheric NO<sub>2</sub> observations from the GEMS satellite for different consecutive hours within a day, along with corresponding meteorological forecast field data, serve as input features for model training. The encoder processes the spatiotemporal sequences of input features for the preceding 8 h ( $t-7$  h,  $t-6$  h, ...,  $t$ ), which are then decoded by the decoder. The final output, representing NO<sub>2</sub> concentrations at 4 h intervals for the next 24 h ( $t+4$  h,  $t+8$  h,  $t+12$  h, ...,  $t+24$  h), is produced through fully connected layers. The loss function of mean square error (MSE) is calculated by comparing the model output with the actual values from station observations, and the model undergoes iterative training. In the training task for a single station sample, the model utilizes continuous and distinct hourly dynamic images of all variables within the spatiotemporal vicinity of the station as input (see Fig. 1c–d). This effectively considers the intricate correlations in time and space between air quality, satellite observations, and meteorological input features. We trained the GeoNet model with input features during the whole year of 2021. The train-

ing datasets were randomly selected from 75 % of the whole samples, while the remaining 25 % were used as validation sets.

#### 2.4 The model configuration and optimization

The model configurations and hyperparameters such as the optimizer, loss function, L1 or L2 regularization, dropout, training steps, and epochs can make a difference in the model performance, including the prediction accuracy and generalizability. The performance metrics, such as the coefficient of determination ( $R^2$ ), root mean square error (RMSE), mean absolute error (MAE), and mean absolute percentage error

(MAPE), were used to diagnose the model (see definition in Sect. S2). Thus, several scenarios of model hyperparameters have been tested during the model training phase. The model accuracy in validation datasets and the learning rate curve were used to diagnose the model hyperparameters. The model parameters mainly include the number of layers and the dimensions of the hidden layers; both control the model's capacity. If the model capacity is relatively small, underfitting may occur; overfitting may exist if it is too large. Therefore, selecting an appropriate model capacity is crucial for improving model performance. During the pre-training process, the model is trained by combining different numbers of layers and dimensions of the hidden layers. The mean square

error (MSE) loss is recorded for each training iteration, and a heatmap is generated as shown in Fig. S2. From the heatmap, it can be observed that when the number of layers is 2, and the dimension of the hidden layer is 256, the model achieves the minimum MSE Loss. Figure S3 shows the sensitivity test results of model loss varying with different batch size settings, indicating that a batch size of 64 is optimal. Based on the model's MSE loss under different hyperparameter configurations, the best-fitting model can be selected.

The Adam optimization algorithm controls the learning rate, which can design independent adaptive learning rates for different parameters. The three initialization parameters  $\epsilon$ ,  $\rho_1$ , and  $\rho_2$  of the Adam algorithm are set to be 0.0001, 0.9, and 0.99, respectively. For the epoch, its size is controlled by the early stop method. The early stop method monitors the change in the model's loss function in the validation set during the training process and stops the model training immediately when the validation loss of the model starts to become larger. Due to the fluctuation in the loss function, a threshold  $\rho$  is set for the early stopping method in practice, and when the validation loss of the model becomes large for  $\rho$  consecutive epochs, the model is rolled back to the lowest validation loss, and the training is stopped. The threshold  $\rho$  is set to 10 in this paper. Figure S4 shows a typical learning curve of the MSE loss in training and validation datasets for different learning steps in training an optimal model. Such diagnostics can be used to avoid the model overfitting.

## 2.5 The importance of the model input feature

Permutation feature importance is a technique used to assess the significance of each input feature in a machine learning model (Altmann et al., 2010). The core idea is to evaluate the impact of each feature on model performance by randomly shuffling its values and observing the resulting change in the model's accuracy. In this study, for each input feature of the GeoNet, we iteratively shuffle its value independently while keeping other features unchanged and then observe the model prediction with the modified input. The difference in the model prediction performance between using the original and shuffling input quantifies the feature's importance. Here, we measure the relative importance of each input feature using the metric of  $1 - R^2$ , due to its good standardized and indicative ability (Zhang et al., 2022). Generally, a larger performance drop indicates greater importance, as the model heavily relies on that feature for predictions. Conversely, smaller drops or increases suggest that the feature may be less crucial or redundant. By permuting the input feature array based on the different spatial and temporal domains, we can gain a deeper understanding of how feature importance varies spatially and temporally. For example, the relative importance of one meteorology variable may vary with different diurnal, weekly, and monthly cycles, revealing the variability in its impact on the predicted NO<sub>2</sub> levels.

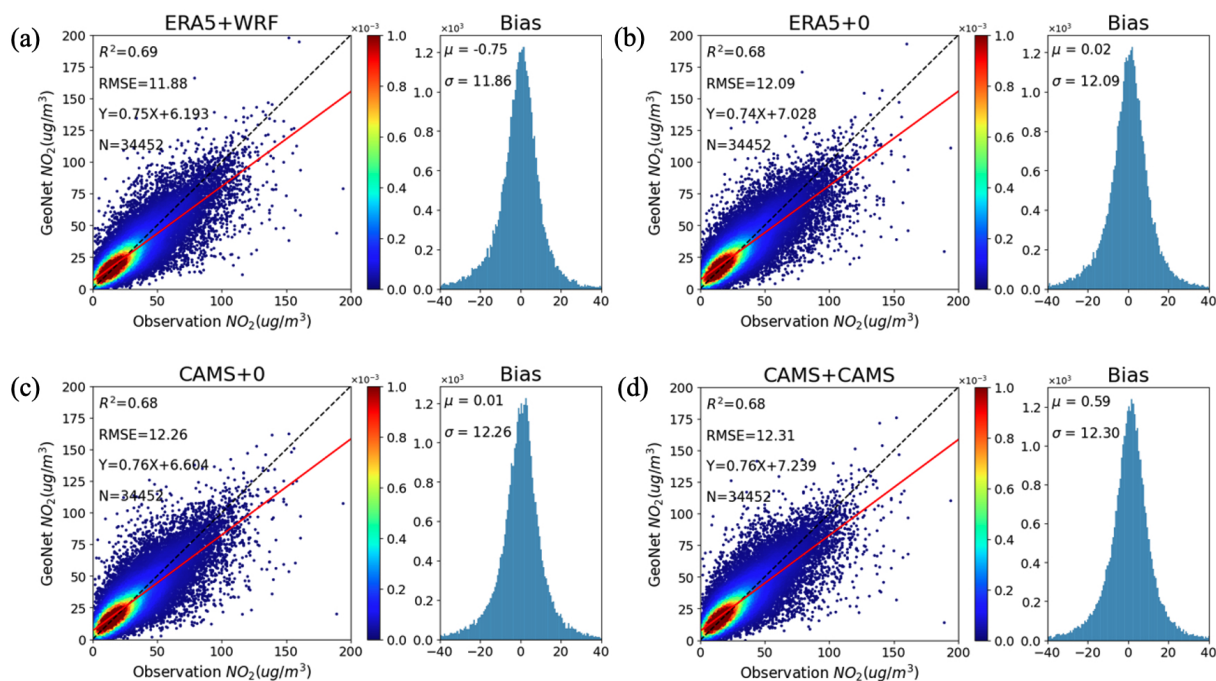

## 3 Results and discussion

### 3.1 Model performance

Based on the GeoNet model and necessary input data (refer to Sect. 2), we have achieved preliminary predictions of near-surface NO<sub>2</sub> concentration with full spatial coverage and a spatial resolution of 0.1° over eastern China at 4 h intervals over the next 24 h. In this study, we first tested the impact of using reanalysis and forecast meteorology datasets and filling in missing values in satellite observation data on the model predictions. The reanalysis datasets usually have higher precision than the forecast. Previous studies revealed that the accuracy of the information on meteorology and chemical composition significantly affects the performance of machine learning models in estimating air pollutant concentrations (Zuo et al., 2023; Wang et al., 2024). Due to the shielding effect of clouds, a considerable proportion of missing values may even exist in satellite NO<sub>2</sub> observations. Recent big-data research on air quality has usually required the gap-filling of missing satellite data before inputting them into the machine learning model by either spatial interpolation or regression techniques (Kim et al., 2021). We tested three methods for handling missing data, such as setting them to a fill value of zero or replacing them with real-time CAMS-simulated NO<sub>2</sub> or WRF-Chem-simulated NO<sub>2</sub> results (not real-time, but with higher precision).

The comparison results for the validation datasets indicate that the scenario using CAMS meteorology datasets and replacing missing satellite NO<sub>2</sub> data with fill values (Fig. 2c) corresponds to a modest NO<sub>2</sub> prediction performance with  $R^2 = 0.68$  and  $\text{RMSE} = 12.26 \mu\text{g m}^{-3}$ . In contrast, the configuration scenario using ERA5 reanalysis meteorology and imputing with WRF-Chem simulations (Fig. 2a) corresponds to the best prediction performance of  $R^2 = 0.69$  and  $\text{RMSE} = 11.88 \mu\text{g m}^{-3}$ . This may indicate that the importance of the imputation of missing satellite data may be diminished by cloud mask inputs, especially since the model can extract informative features from spatial and temporal neighboring inputs. To compromise between the performance of real time and accuracy, we selected the configuration scenario using CAMS meteorology and imputing with CAMS NO<sub>2</sub> (Fig. 2d) for subsequent discussion and operational forecasting, with an  $R^2 = 0.68$  and  $\text{RMSE} = 12.31 \mu\text{g m}^{-3}$ . In summary, using higher-precision meteorology and filling missing NO<sub>2</sub> data enhances the model's prediction accuracy with the validation dataset, but to a rather limited extent. This suggests that, unlike previous machine learning techniques, GeoNet can effectively adapt to three-dimensional inputs of varying accuracy and type, fully explore the spatiotemporal correlation of data features, and demonstrate strong model generalization capabilities.

Figures S5–S8 provide an overview of the major metrics (e.g.,  $R^2$ , RMSE, MAE, and MAPE) of GeoNet prediction performance varying with prediction hours from  $t + 4$  h to

**Figure 2.** The GeoNet prediction performance of the surface  $\text{NO}_2$  concentration compared to the validation samples, based on different input datasets of meteorology and atmospheric composition: (a) use ERA5 meteorology and fill satellite measurement gaps with WRF-Chem-simulated  $\text{NO}_2$ ; (b) use ERA5 meteorology and a  $\text{NO}_2$  fill value of zero for over gaps; (c) use CAMS meteorology and a  $\text{NO}_2$  fill value of zero for gaps; (d) use CAMS meteorology and CAMS  $\text{NO}_2$ . The left plot shows the scatter comparisons between GeoNet predictions and site observations, while the right plot shows the bias distribution between the two.

$t + 24$  h in different months. The results indicate that the model exhibits a higher correlation with  $\text{NO}_2$  forecasting during the spring and winter seasons compared to the summer, while the RMSE errors show the opposite trend. This could be attributed to much higher  $\text{NO}_2$  pollution levels in winter months. Additionally, GeoNet's  $\text{NO}_2$  prediction errors gradually increase during the next 24 h, particularly after  $t + 20$  h. This is primarily due to the short lifetime of atmospheric  $\text{NO}_2$ , leading to a diminishing constraint from historical observational data on future  $\text{NO}_2$  predictions. Similar phenomena are also observed in machine learning or model-assisted weather forecasts (Andersson et al., 2021).

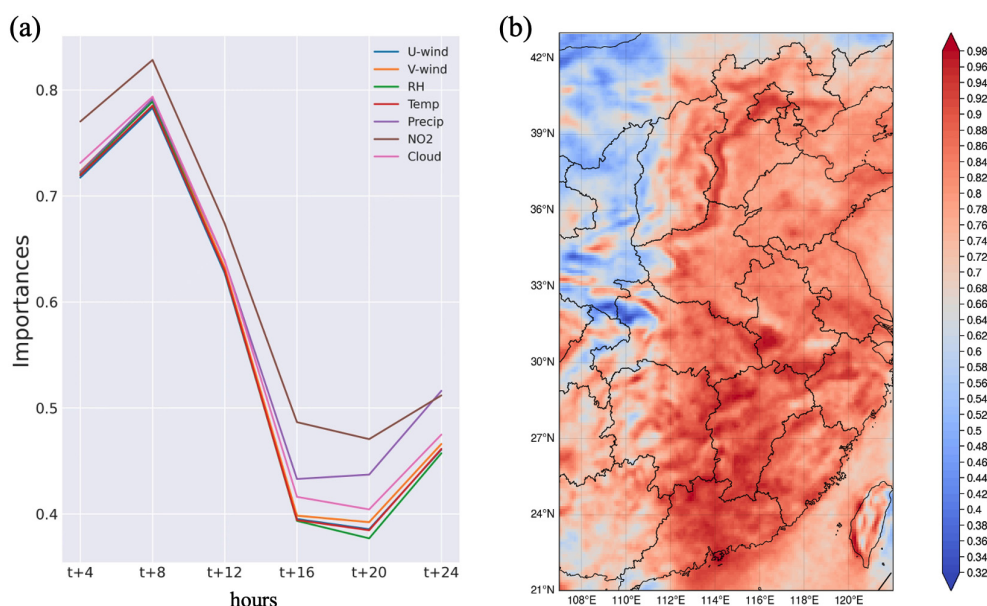

To assess the GeoNet model's performance for short-term pollution events, we compared it with near-surface  $\text{NO}_2$  from CAMS forecasts and in situ observations from CNEMC ground stations. Figure S9 illustrates the daily time series of  $t + 4$  h  $\text{NO}_2$  from GeoNet, CAMS, and CNEMC for three typical sites in Beijing, Shanghai, and Guangzhou in 2021. As shown from the plot,  $\text{NO}_2$  predictions by both GeoNet and CAMS generally agreed with the variation trends of CNEMC measurements. However, CAMS forecasts systematically overestimate the surface  $\text{NO}_2$  concentration by 100 %, possibly resulting from the biases in the  $\text{NO}_x$  emission inventory (Douros et al., 2023). Compared to CAMS, the GeoNet prediction closely aligns with the ground-truth observations at CNEMC sites over eastern China, with an overall  $R^2 > 0.5$

and mean bias  $< 5 \mu\text{g m}^{-3}$  for polluted regions (see Figs. S10 and S11, respectively).

### 3.2 Main factors in $\text{NO}_2$ forecasting and their implications

Previous physics-based numeric models of air quality prediction, e.g., the CAMS global forecast model and the regional WRF-CMAQ model (Liu et al., 2023; Kumar et al., 2021; Kuhn et al., 2024), can simulate the physical and chemical atmospheric processes (such as advection, diffusion, deposition, and chemical reactions) by solving the atmospheric equations. Recent data assimilation techniques further take real-time monitoring data from satellite and ground-based platforms as model constraints to better predict air quality variables (Inness et al., 2022). Compared with physics-based models, “black box” models such as the deep learning technique usually lack interpretability and explainability (Zhang and Zhu, 2018). This hinders the understanding and implications for predicting air quality variables such as  $\text{NO}_2$ . Here, we measure the relative importance of each input feature on the  $\text{NO}_2$  forecast accuracy by iteratively permuting the input array and observing its influences on the model prediction.

Figure 3a presents the relative importance ( $1 - R^2$ ) of different input features varying with prediction hour steps from  $t + 4$  h to  $t + 24$  h. The geostationary satellite  $\text{NO}_2$  measure-

**Figure 3.** (a) The overall relative importance of different input features such as wind, surface pressure, satellite NO<sub>2</sub>, and cloud mask in GeoNet NO<sub>2</sub> forecasting, varying with different hour steps from  $t + 4$  h to  $t + 24$  h. (b) The spatial distribution of the relative importance of satellite NO<sub>2</sub> measurements in the GeoNet NO<sub>2</sub> forecast in 2021.

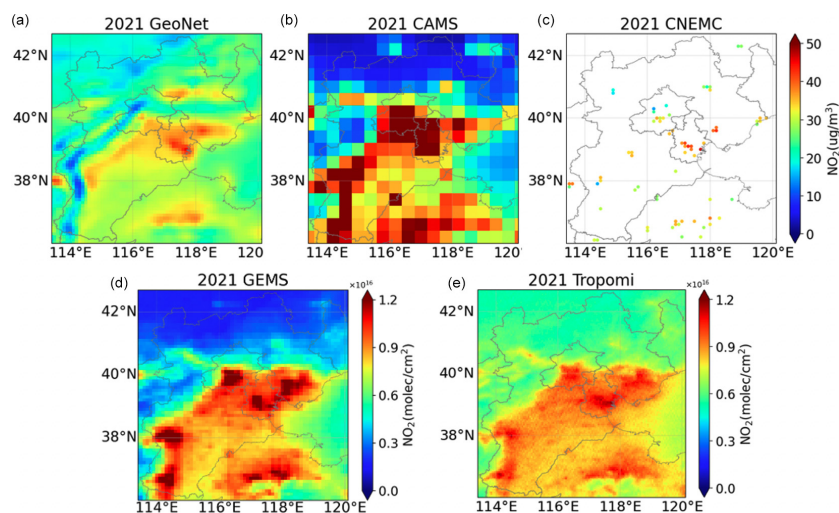

ments play the biggest role in predicting surface NO<sub>2</sub> levels of the next day, although it degrades after  $t + 8$  h. Other meteorological input features also show a major impact on NO<sub>2</sub> prediction performance. The significance of the different input variables remained generally consistent across seasons, with minor variations (as shown in Fig. S12). By permutating the input array for each ground pixel, Fig. 3b derived the spatial distribution of the relative importance of geostationary satellite NO<sub>2</sub> in the predicting performance. Overall, satellite NO<sub>2</sub> has a higher impact in densely populated areas experiencing severe air pollution, such as the Pearl River Delta, Yangtze River Delta, and Jianghuai Plain, than in western China. Such results highlight the underappreciated role of satellite NO<sub>2</sub> measurements with high spatial and temporal coverage in air pollution forecasts.

### 3.3 NO<sub>2</sub> pollution episodes and health exposure forecast

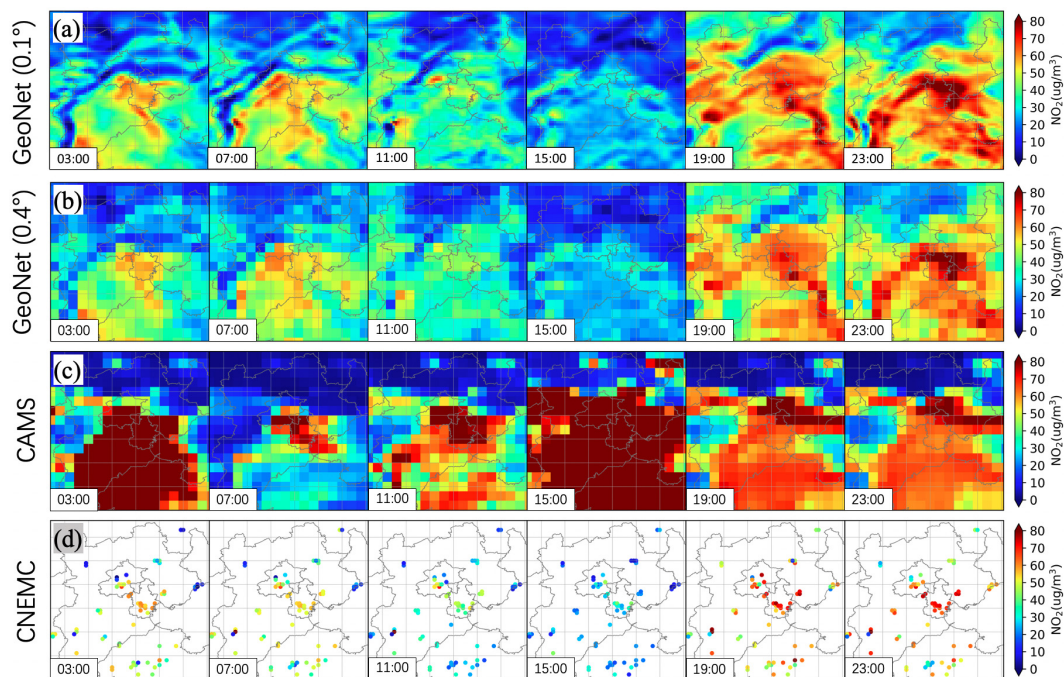

Beyond its prediction accuracy, GeoNet exhibits a pronounced advantage in spatial coverage and resolution, allowing finer-scale details in the pollutant distribution to be captured. Illustrated in Fig. 4, GeoNet demonstrates remarkable performance in predicting spatial nuances of NO<sub>2</sub> pollution, particularly when contrasted with ground-based and satellite observations. During a typical winter NO<sub>2</sub> pollution event (as shown in Fig. 5), GeoNet accurately simulates a significant decrease in concentrations at 11:00 and 15:00 local solar time, probably led by intense photochemical activity in the daytime, coincident with ground-based observations. It also outperforms CAMS in predicting NO<sub>2</sub> vari-

ations throughout the day. The GeoNet model also retains the distributional differences in NO<sub>2</sub> concentrations between urban and rural areas, consistent with emission source characteristics and satellite observations. The suboptimal performance of CAMS predictions can be attributed to insufficient observational constraints and the use of outdated emission inventories (Dourous et al., 2023). In the European region, the assimilation of TROPOMI observations into CAMS forecasts significantly improves the simulation accuracy of near-surface NO<sub>2</sub> concentrations and tropospheric column densities (Inness et al., 2019). Neural network methods, similar to GeoNet, could be used to correct and downscale forecast results by existing models (Baghanam et al., 2024). This approach holds promise for achieving operational air quality forecasts that balance efficiency and accuracy.

In this study, we used a simplified linearized risk model for the short-term NO<sub>2</sub> exposure (Meng et al., 2021; Zhang et al., 2022) to calculate the distribution of all-cause mortality risks based on GeoNet NO<sub>2</sub> predictions (see Fig. 6). Short-term NO<sub>2</sub> exposure leads to remarkable regional differences in all-cause mortality, which are mainly concentrated in highly polluted and densely populated urban areas. For both urban and suburban locations in Beijing (see Fig. 6c–d), GeoNet-based NO<sub>2</sub> pollution exposure predictions are more consistent with actual in situ observations than the CAMS forecasts. Current air quality health index forecasting based on limited station data has significant gaps, making it difficult to meet the refined needs for different populations in urban, suburban, and rural areas. Integrating GeoNet forecasts based on hourly geostationary satellite observations can sup-

**Figure 4.** The comparisons of annual surface  $\text{NO}_2$  concentrations from GeoNet, CAMS, and CNEMC, respectively (a–c), as well as the tropospheric  $\text{NO}_2$  column observations from GEMS and TROPOMI over eastern China in 2021 (d–e).

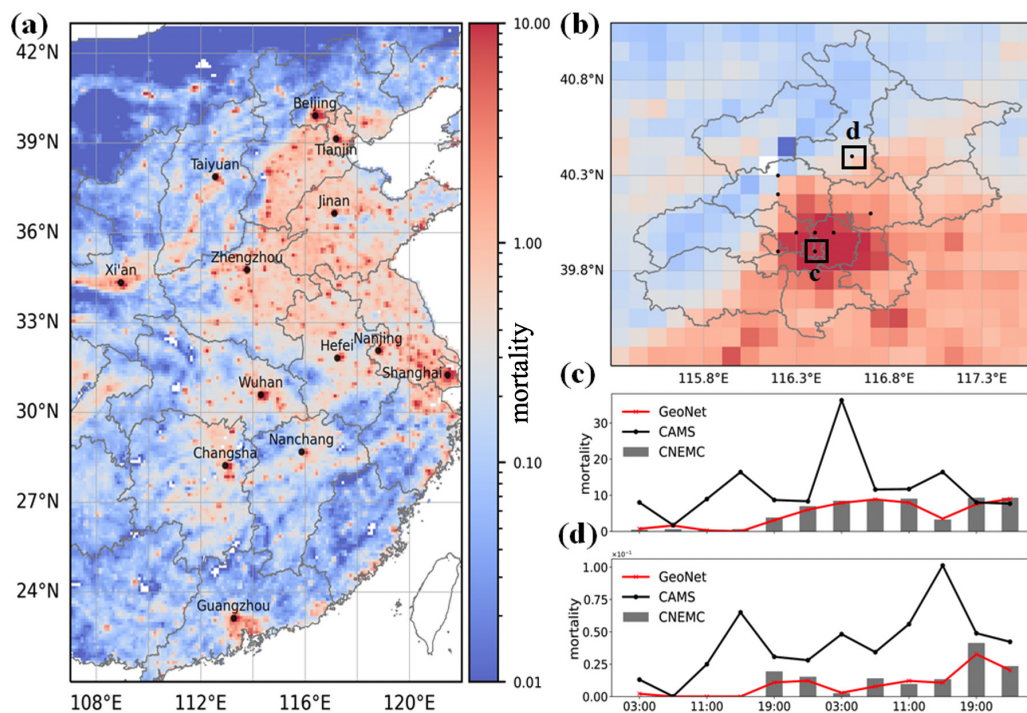

**Figure 5.** The spatial distribution comparisons of surface  $\text{NO}_2$  concentration between (a) GeoNet prediction at the original resolution of  $0.1^\circ$ , (b) GeoNet prediction resampled to the CAMS resolution of  $0.4^\circ$ , (c) CAMS prediction, and (d) ground-based CNEMC site measurements. port spatially comprehensive and fine-scale air quality health risk prediction. This, in turn, guides the management of the risks of air-pollution-exposure-related diseases in sensitive populations and communities.

#### 4 Conclusion

The GeoNet model utilizes the unprecedented hourly air quality observations from geostationary satellites and resolves nonlinear associations in spatiotemporal proximity across multiple data sources. It achieves seamless short-term regional air quality predictions, exhibiting significant performance advantages over existing machine learning air qual-

**Figure 6.** Mortality risk of short-term  $\text{NO}_2$  exposure based on the GeoNet prediction on 23 November 2021. (a) Mean mortality due to the predicted  $\text{NO}_2$  exposure in eastern China, (b) a zoom-in map over Beijing and its neighboring area. ity prediction models. To strike a balance between real-time and accuracy requirements, we evaluated the impact of using reanalysis- and forecast-based meteorology datasets, as well as imputing the missing values of satellite  $\text{NO}_2$ . The findings reveal that the GeoNet model demonstrates robust generalization across diverse datasets, with minimal fluctuations in prediction performance. Overall, the model achieves an RMSE of  $12.31 \mu\text{g m}^{-3}$  and an  $R^2$  of 0.68 when predicting  $\text{NO}_2$  concentrations every 4 h for the next 24 h. However, validation accuracy notably diminishes after  $t + 16$  h within the next 24 h, with stronger predictive correlations observed in seasons characterized by severe pollution, such as spring and winter, compared to summer. The variation in the model forecasting performance also shows that accurate prediction for longer time windows and heavy-pollution events is still a major difficulty. This may be due to the high level of uncertainty in emissions and meteorology. In the future, a combination of higher resolution and more accurate multi-source data constraints, as well as machine learning models coupled with physical atmospheric mechanisms, may be needed to improve the existing forecasts.

Compared to traditional chemical model forecasts and data assimilation predictions, the GeoNet model handles various data sources, including meteorological simulations and air quality observations, and more accurately captures spatial in-

tricacies of air pollution evolution. The GeoNet framework elucidated in this study forecasts short-term, near-surface  $\text{NO}_2$  concentrations and demonstrates transferable learning potentials for predicting other pollutants. This work also has important implications for the prediction of near-surface  $\text{O}_3$  and particulate matter. For example, the integration of using vertical  $\text{O}_3$  profiles from the GEMS satellite, in particular near-surface layer concentrations, and their joint observations of important  $\text{O}_3$  precursors, including  $\text{NO}_2$  and  $\text{HCHO}$ , is expected to significantly improve the uncertainty in existing estimates of near-surface air pollution. This study underscores the pivotal role of next-generation stationary satellite observations of air pollution constituents in air quality forecasting, with the potential to advance operational air quality forecasting and mitigate associated health risks by integrating machine learning technologies.

**Code and data availability.** The GEMS  $\text{NO}_2$  v2.0 data are available from the National Institute of Environmental Research (NIER) of South Korea (<https://nesc.nier.go.kr/en/html/index.do>, last access: 10 September 2023, NIER, 2023). We downloaded the  $\text{NO}_2$  measurements from the CNEMC real-time air quality platform (<https://air.cnemc.cn:18007/>, last access: 8 June 2023, CNEMC, 2023). ERA5 reanalysis meteorological data are obtained from the European Centre for Medium-Range

Weather Forecasts (<https://doi.org/10.24381/cds.adbb2d47>, Hersbach et al., 2023). CAMS forecasts of meteorological and atmospheric NO<sub>2</sub> datasets are retrieved from the CAMS Atmosphere Data Store (<https://ads.atmosphere.copernicus.eu/datasets/cams-global-atmospheric-composition-forecasts?tab=download>, Copernicus Atmosphere Monitoring Service, 2023). The source codes of the GeoNet model, surface NO<sub>2</sub> prediction, and necessary input data can be obtained from Chengxin Zhang (zcx2011@ustc.edu.cn) upon reasonable request.

**Supplement.** The supplement related to this article is available online at: <https://doi.org/10.5194/acp-25-759-2025-supplement>.

**Author contributions.** CZ implemented the GeoNet model and analyzed the data. CL supervised the study. CZ wrote the manuscript with input from all co-authors.

**Competing interests.** The contact author has declared that none of the authors has any competing interests.
