## Abstract

The atmospheric concentrations of gaseous  $\text{HNO}_3$ ,  $\text{HCl}$  and  $\text{NH}_3$  and their relative salts have been measured during two field campaigns in the winter and in the summer of 2007 at Beijing (China), as part of CAREBEIJING (Campaigns of Air Quality Research in Beijing and Surrounding Region). In this study, annular denuder technique was used with integration times of 2 and 24 h to collect inorganic and soluble  $\text{PM}_{2.5}$  without interferences from gas-particle and particle-particle interactions. The results were discussed from the standpoint of temporal and diurnal variations and meteorological effects. Fine particulate  $\text{Cl}^-$ ,  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  exhibited distinct temporal variations, while fine particulate  $\text{NO}_3^-$  did not show much variation with respect to season. Daily mean concentrations of fine particulate  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  were higher during summer ( $12.30 \mu\text{g m}^{-3}$  and  $18.24 \mu\text{g m}^{-3}$ , respectively) than during winter ( $6.51 \mu\text{g m}^{-3}$  and  $7.50 \mu\text{g m}^{-3}$ , respectively). Instead, daily mean concentrations of fine particulate  $\text{Cl}^-$  were higher during winter ( $2.94 \mu\text{g m}^{-3}$ ) than during summer ( $0.79 \mu\text{g m}^{-3}$ ), while fine particulate  $\text{NO}_3^-$  showed similar variations both in winter ( $8.38 \mu\text{g m}^{-3}$ ) and in summer ( $9.62 \mu\text{g m}^{-3}$ ) periods. However, the presence of large amounts of fine particulate  $\text{NO}_3^-$  even in summer are due to higher local and regional concentrations of  $\text{NH}_3$  in the atmosphere available to neutralize  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$ , which is consistent with the observation that the measured particulate species were neutralized. Indeed, the composition of fine particulate matter indicated the domination of  $(\text{NH}_4)_2\text{SO}_4$  during winter and summer periods. In addition, the high relative humidity conditions in summer period seemed to dissolve a significant fraction of  $\text{HNO}_3$  and  $\text{NH}_3$  enhancing fine particulate  $\text{NO}_3^-$  and  $\text{NH}_4^+$  in the atmosphere. All measured particulate species showed diurnal similar patterns during the winter and summer periods with higher peaks in the early morning, especially in summer, when humid and stable atmospheric conditions occurred. These diurnal variations were affected nearly by wind direction suggesting regional and local source influences. Indeed, the fine particulate species were also correlated with  $\text{NO}_x$  and  $\text{PM}_{2.5}$ , supporting the hypothesis that the traffic may be also

an important source of secondary particles.

## 1 Introduction

Atmospheric particulate matter plays an important role in atmospheric visibility reduction, human health effects, acid deposition and climate (Heintzenberg, 1989; Dockery et al., 1993; Charlson and Heintzenberg, 1995; Vedal, 1997; IPCC, 2007). Fine particles, otherwise called  $PM_{2.5}$  with an aerodynamic diameter less than  $2.5 \mu\text{m}$ , contribute mainly to the above phenomena. The major inorganic particles identified in  $PM_{2.5}$  are sulphate ( $\text{SO}_4^{2-}$ ), nitrate ( $\text{NO}_3^-$ ), chloride ( $\text{Cl}^-$ ) and ammonium ( $\text{NH}_4^+$ ), which typically comprise 25–75% of atmospheric  $PM_{2.5}$  mass (Gray et al., 1986; Heintzenberg, 1989).

These species are secondary in nature and are formed in the atmosphere by physical processes (nucleation, condensation and evaporation), and/or chemical reactions of precursor gases (photochemical gas phase, oxidation aqueous-phase oxidation and particulate-phase processes), such as sulphuric acid ( $\text{H}_2\text{SO}_4$ ), nitric acid ( $\text{HNO}_3$ ), hydrochloric acid (HCl) and ammonia ( $\text{NH}_3$ ).  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$  are atmospheric oxidation products of gaseous sulphur dioxide ( $\text{SO}_2$ ) and nitrogen oxides ( $\text{NO}_x$ ), respectively, while  $\text{NH}_3$  is directly emitted into the atmosphere mainly by agricultural source.

Particulate  $\text{SO}_4^{2-}$  is a product of gas to particle phase reactions involving atmospheric oxidation of  $\text{SO}_2$  by both heterogeneous and homogeneous processes. In the gas, the oxidation of  $\text{SO}_2$  by the hydroxyl radical (OH) produces  $\text{H}_2\text{SO}_4$  which condenses to form  $\text{SO}_4^{2-}$ . The majority of aqueous phase reactions with  $\text{SO}_2$  occurs in cloud-water, and once dissolved,  $\text{SO}_2$  can oxidize into  $\text{SO}_4^{2-}$  via several pathways, reacting with dissolved ozone, hydrogen and organic peroxides, hydroxyl radicals, and various oxides of nitrogen. Particulate sulphate typically exists in one of three forms: sulphuric acid, ammonium sulphate ( $(\text{NH}_4)_2\text{SO}_4$ ) or ammonium bisulphate ( $\text{NH}_4\text{HSO}_4$ ). The formation of each is linked to the amount of ammonia available. If enough ammonia is present, the particulate sulphate will be found as  $(\text{NH}_4)_2\text{SO}_4$ .

Interactive Discussion

Gaseous  $\text{NH}_3$  can be either wet or dry deposited, or can neutralize  $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$  and  $\text{HCl}$  to form ammonium sulphate salts, and ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ) and ammonium chloride ( $\text{NH}_4\text{Cl}$ ) salts via particle gas formation and gas to particle conversion (Baek and Aneja, 2005; Aneja et al., 2009). Ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ) and ammonium chloride ( $\text{NH}_4\text{Cl}$ ) are formed via reversible phase equilibrium with precursor gases as  $\text{NH}_3$ ,  $\text{HNO}_3$  and  $\text{HCl}$ . This thermodynamic equilibrium between gas- and particle-phase depends on the ambient temperature, relative humidity and chemical composition of particles and gases (Stelson and Seinfeld, 1982a; Pio and Harrison, 1987). Formation of  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  is favoured under conditions of high relative humidity and low temperature, otherwise these ammonium salts are volatile. The affinity of sulphuric acid for ammonia is much larger than that of  $\text{HNO}_3$  and  $\text{HCl}$  for ammonia that available ammonia is first taken up by sulphuric acid to form ammonium sulphate salts. Any excess available ammonia may then react with nitric and hydrochloric acid to form ammonium nitrate and chloride. These volatile species affect Earth's radiative balance and also contribute to the long-range transport of acidic pollutants. As a matter of fact, ammonium salts, with atmospheric lifetimes of the order of 1–15 days, will tend to deposit at larger distances from emission sources, contributing to soil acidification, forest decline and eutrophication of waterways (Aneja et al., 2000, 2001).

Particulate nitrate is formed in the atmosphere through gas to particle conversion processes starting with  $\text{NO}_x$ , and proceeding via  $\text{HNO}_3$  formation. Since this acid is subject to partitioning between gas and particle phase, the influence of  $\text{NO}_x$  extends to formation of particulate nitrate. During the daytime, the most important source of nitric acid is the homogeneous gas phase reaction of  $\text{NO}_2$  with the  $\text{OH}$ . At night, the free nitrate radical ( $\text{NO}_3$ ) is the source of tropospheric  $\text{HNO}_3$ .  $\text{NO}_3$  either may combine with  $\text{NO}_2$  to form dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ), which reacts with water on particles, fog or cloud water droplets to produce  $\text{HNO}_3$ , or it may form the acid by H-atom abstraction from aldehydes or hydrocarbons (Stockwell et al., 1997). When atmospheric nitric acid is available, it has a tendency to react with basic species such as  $\text{NH}_3$  to form  $\text{NH}_4\text{NO}_3$ . This reaction is believed to be the main source of fine particulate nitrate

in urban air (Stockwell et al., 2000). A second frequent path for particulate nitrate formation involves nitric acid attach on the sodium chloride (NaCl) in sea salt particles to generate sodium nitrate (NaNO<sub>3</sub>) aerosol and to release hydrochloric acid to the atmosphere.

5 The major source of HCl in the atmosphere is probably coal combustion. Globally, release of HCl from marine aerosols by reaction with less volatile HNO<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub> or SO<sub>2</sub> is of considerable importance. Reaction of NO<sub>2</sub> with sodium chloride under photochemical conditions, emissions from volcanoes, and refuse incineration may constitute other sources of HCl in the atmosphere. Besides wet and dry deposition, a major sink  
10 for HCl will be neutralization by gaseous ammonia to form NH<sub>4</sub>Cl aerosol.

The rapid industrial development and urbanization, increased vehicular population and energy consumption in Beijing (39°55' N, 116°23' E), the capital city of China, have led to an increased concentrations of air pollutants, especially in particulate pollution (Yao et al., 2002, 2003; Zhang et al., 2004). Dust-soil, industry emission, coal burning, vehicle exhaust emission and waste incineration have been identified as the major  
15 sources of particulate pollution in Beijing. Traffic emissions are considered to be one of the most important sources of sub-micrometer particles in the urban area of Beijing (He et al., 2001; Zheng et al., 2005; Song et al., 2006). Zheng et al. (2005) and Song et al. (2006) indicated that, as a primary source, traffic emissions in Beijing contributed  
20 6–7 % to PM<sub>2.5</sub> concentrations while the respective contribution from road dust resuspension was estimated to be 7–9 %. However, gaseous pollutants are also emitted by vehicular sources, such as NO<sub>x</sub>, which are essential for the atmospheric photochemical processes and the gas-to-particle conversions. NO<sub>x</sub> is also related to the formation of secondary particulate matter such as secondary particulate ammonium, sulphate and nitrate. These particulate species contribute over 35 % of PM<sub>2.5</sub> in Beijing. Coal  
25 dominated energy structure is one of the major causes of air pollution in Beijing. Beijing's power plants take about one third of the total coal consumptions emitting 49 % and 27 % of the total SO<sub>2</sub> and NO<sub>x</sub> emissions, respectively (He et al., 2003), which contribute to formation of atmospheric inorganic fine particles (nitrates and sulphates),

Interactive Discussion

as said above.

PM<sub>2.5</sub> mass and chemical compositions in Beijing have been widely studied since the last decade (He et al., 2001; Yao et al., 2002, 2003; Sun et al., 2004; Chan et al., 2005, 2008; Wang et al., 2005; Duan et al., 2006; Guinot et al., 2006). The sources of particulate matter in Beijing include the local primary emissions, secondary formation and regional transport (Yao et al., 2003; Wang et al., 2005; Chen et al., 2007; Street et al., 2007). Duan et al. (2007) reported that SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> were the major water soluble ions in wintertime in Beijing, with the average concentrations of 30.8 ± 25.4, 10.8 ± 8.0 and 6.7 ± 5.4 μg m<sup>-3</sup>, respectively. In these studies the maximum concentrations appeared on 4 January 1999, 114, 31 and 27 μg m<sup>-3</sup> for above three ions, respectively. Yao et al. (2002) found that a large part of SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> in PM<sub>2.5</sub> might be formed through the direct emissions of their precursor gases, such as SO<sub>2</sub>, NO<sub>x</sub> and NH<sub>3</sub>. However, data on PM<sub>2.5</sub>, especially regarding the semi-volatile species in PM<sub>2.5</sub>, e.g., NO<sub>3</sub><sup>-</sup> and Cl<sup>-</sup> are very limited. In a polluted urban environment, the volatile ammonium salts (NH<sub>4</sub>NO<sub>3</sub> and NH<sub>4</sub>Cl) account for 10–30 % of the fine aerosol mass, and the total inorganic salts account for 25–30 % of the fine aerosol mass.

Different field measurements of simultaneous concentrations of NH<sub>3</sub>, HCl, and HNO<sub>3</sub> observed that the concentration products of [HCl] [NH<sub>3</sub>] and [HNO<sub>3</sub>] [NH<sub>3</sub>] were in agreement with theoretical values predicted by thermodynamic equilibrium laws for NH<sub>4</sub>Cl and NH<sub>4</sub>NO<sub>3</sub> formations, respectively, (Harrison and Pio, 1983; Chang et al., 1986). In other cases experimental products were different from theoretical predictions mainly at relative humidity below 60 % and above 90 % (Cadle et al., 1982; Allen et al., 1989; Harrison and MacKenzie, 1990; Pio et al., 1992; Harrison and Msibi, 1994; Mehlmann and Warneck, 1995), some of them lower and others higher than theoretical values. They also found that gas-particle equilibrium conditions were not attained instantaneously in the atmosphere at temperatures lower than 15 °C, requiring several minutes for the achievement of the system equilibrium. They attributed the departures of experimental data to unknown kinetic constraints on attainment of the system equilibrium. These kinetic constraints on the evaporation of ammonium containing aerosols

Interactive Discussion

have been restricted to chemical reaction and mass-transfer-limited particle evaporation.

Measurements of semi-volatile fine particulate species, such as inorganic ammonium salts ( $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ ), are complicated by the existence of the thermodynamic equilibrium between precursor gases ( $\text{HCl}$ ,  $\text{HNO}_3$  and  $\text{NH}_3$ ) and relative particulate ammonium salts. The concentrations of these fine particulate species will be significantly underestimated in urban environments because of the loss of the semi-volatile material from particles collected on the filters during and after sampling, resulting from gas-particle and particle-particle interactions (Sickles et al., 1999a). The underestimation of the semi-volatile inorganic ammonium salts will tend to over emphasize the importance of non-volatile fine particulate species such as sulfate. For this reason, there is a need for representative and reliable methods for measuring atmospheric concentrations of the semi-volatile inorganic ammonium salts without disturbing atmospheric equilibrium conditions during sampling. Denuders for absorbing gases prior to particle collection and back-up filters for absorbing  $\text{HNO}_3$ ,  $\text{HCl}$  and  $\text{NH}_3$  evaporated from collected particles have been widely accepted as effective tools to avoid sampling artifacts (gas-particle and particle-particle interactions). In this study, annular denuder and filter pack technique was used to accurately measure inorganic and soluble  $\text{PM}_{2.5}$  without disturbing the partition equilibrium existing in the atmosphere. Following this, as part of the international collaborative research CAREBEIJING (Campaigns of Air Quality Research in Beijing and Surrounding Region), the main objectives of the present work were to measure experimentally and accurately the formation of inorganic ammonium salts and their chemical associations, to provide quantitative information on the their concentrations, to investigate their temporal and diurnal variations, and to examine the contributions of local and regional sources to their observed concentrations in the atmosphere of Beijing.

## 2 Experimental

Atmospheric measurements were performed at the Peking University (39°59'23" N, 116°18'19" E), located in the northwestern urban area of Beijing and outside of the fourth ring road. The sampling site was located on the roof of a fifth-floor academic building, 15 m a.g.l. There are two major roads at the east and south of the sampling site, which are 200 and 600 m away from the sampling site, respectively. Measurements were carried out on a 24-h basis, starting at midnight from 23 January to 14 February 2007 and from 2 to 31 August 2007. The air samples on a 2-h basis (intensive measurements) were carried out on 9–10 February during the winter period and on 17–21 August during the summer period. Problems occurred on 9 February between 10:00 and 12:00 in the morning and on 19 August between 22:00 and 00:00, thus data from these events were not considered.

Ambient concentrations of gases and particles were measured using the annular denuder system (Possanzini et al., 1983; Allegrini et al., 1987; Febo et al., 1989; Perrino et al., 1990, 2001; Perrino and Gherardi, 1999; Beine et al., 2001, Ianniello et al., 2002, 2007). The denuder line configuration used in this study included two sodium fluoride (1 % NaF in 9 : 1 ethanol/water solution) coated denuders for the simultaneous collection of HCl and HNO<sub>3</sub>, followed by two sodium carbonate plus glycerol (1 % Na<sub>2</sub>CO<sub>3</sub> + 1 % glycerol in 1 : 1 ethanol/water solution) coated denuders for the collection of HONO and SO<sub>2</sub>. A fifth denuder was coated with phosphorous acid (1 % H<sub>3</sub>PO<sub>4</sub> in 9 : 1 ethanol/water solution) for the collection of NH<sub>3</sub> (Perrino and Gherardi, 1999; Perrino et al., 2001; Ianniello et al., 2010). Downstream of the denuder train a cyclone collected coarse particles (>2.5 μm aerodynamic diameter cut size at flow rate of 15 l/min), while fine particles (<2.5 μm at flow rate of 15 l min<sup>-1</sup>) were collected on a filter pack set in series. The filter pack included a Teflon filter (Gelman Teflon, 47-mm, 1-μm pore size) for the collection of fine particles, a Nylon filter (Nylosorb Gelman, 47 mm, 1-μm pore size) and one phosphorous acid coated paper filter (Whatman 41). These last two back-up filters separately collected NO<sub>3</sub><sup>-</sup> as HNO<sub>3</sub>, Cl<sup>-</sup> as HCl, and

Interactive Discussion

$\text{NH}_4^+$  as  $\text{NH}_3$ , which evolved from the front Teflon filter as a result of ammonium salt dissociations ( $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ ) (Possanzini et al., 1992; Masia et al., 1994; Perrino and Gherardi, 1999; Perrino et al., 2001; Ianniello et al., 2010). The evaporation of volatile ammonium salts from the fine particles collected on the front Teflon filter is due to fluctuations in temperature and relative humidity and/or pressure drop across this filter, which perturb the gas-particle equilibrium (Appel et al., 1984; Pathak et al., 2004, 2009; Pathak and Chan, 2005). The dissociation products recovered on the back-up filters are indicated with term of evolved particulate species, estimating their concentrations from the nitrate, chloride and ammonium amounts measured on the back-up filters, as follows:

$$[\text{NO}_3^-]_{\text{evolved}} = [\text{NO}_3^-]_{\text{N}} \quad (1)$$

$$[\text{Cl}^-]_{\text{evolved}} = [\text{Cl}^-]_{\text{N}} \quad (2)$$

$$[\text{NH}_4^+]_{\text{evolved}} = [\text{NH}_4^+]_{\text{N}} + [\text{NH}_4^+]_{\text{PA}} \quad (3)$$

where subscripts N and PA stand for the Nylon filter and phosphorous acid coated paper filter, respectively. The concentration of  $\text{NH}_4^+$  is the sum of its amounts measured both on the Nylon filter, which absorbs a small fraction of evolved  $\text{NH}_3$  (Masia et al., 1994), and on the coated paper filter. The remaining fine particulate species recovered on the Teflon filter are indicated with term of unevolved particulate species. Thus, adding the amounts of  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  found on the Teflon filter (unevolved fine particles) to the respective amounts found on back-up filters (evolved fine particles), the total concentrations of the fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were determined without disturbing the partition equilibrium existing in the atmosphere between gaseous  $\text{NH}_3$  and the particulate components ( $\text{NH}_4\text{Cl}$  and  $\text{NH}_4\text{NO}_3$ ), as follows:

$$[\text{NO}_3^-]_{\text{fine}} = [\text{NO}_3^-]_{\text{unevolved}} + [\text{NO}_3^-]_{\text{evolved}} \quad (4)$$

$$[\text{Cl}^-]_{\text{fine}} = [\text{Cl}^-]_{\text{unevolved}} + [\text{Cl}^-]_{\text{evolved}} \quad (5)$$

$$[\text{NH}_4^+]_{\text{fine}} = [\text{NH}_4^+]_{\text{unevolved}} + [\text{NH}_4^+]_{\text{evolved}} \quad (6)$$

The fine particulate  $\text{SO}_4^{2-}$  is not volatile and, therefore, its concentration was taken as that on the Teflon filter only.

Thus, the particulate chloride, nitrate, sulphate, sodium, ammonium, potassium, magnesium and calcium in the coarse and fine fractions were measured. After sampling, the denuders and filters were extracted and samples were analyzed within 24-h at the PKU laboratories by using Ion Chromatography (IC) (Dionex DX 120 connected with autosampler DX AS50 for anions and DX ICS90 connected with autosampler DX AS40 for cations).

The sampling flow rate was  $15 \text{ l min}^{-1}$ . The sampling volume was about  $23.10 \text{ m}^3$  for a 24-h sampling period. In these operative conditions the collection efficiency for all species was higher than 99%. The detection limits on 24-h measurement period were  $0.020 \mu\text{g m}^{-3}$  for  $\text{NH}_4^+$ ,  $0.0093 \mu\text{g m}^{-3}$  for  $\text{Na}^+$ ,  $0.0051 \mu\text{g m}^{-3}$  for  $\text{K}^+$ ,  $0.0082 \mu\text{g m}^{-3}$  for  $\text{Mg}^{2+}$ ,  $0.015 \mu\text{g m}^{-3}$  for  $\text{Ca}^{2+}$ ,  $0.0013 \mu\text{g m}^{-3}$  for  $\text{SO}_4^{2-}$ ,  $0.0014 \mu\text{g m}^{-3}$  for  $\text{NO}_3^-$  and  $0.0073 \mu\text{g m}^{-3}$  for  $\text{Cl}^-$ .

Information about the mixing properties of the lower boundary layer were obtained by means of a Stability Monitor (OPSIS SM200) during the summer period. These measurements were described in detail in Ianniello et al. (2010). The Stability Monitor instrument collects atmospheric particles and determines their short life radioactivity due to Radon decay products, providing 1-h interval radioactivity data. From the study of the temporal trend of natural radioactivity and of its time derivative one can gather important information about the mixing properties of the lower atmosphere and about its ability to dilute atmospheric pollutants.

## 3 Results and discussion

### 3.1 Temporal variation

Summary statistics for fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NH}_4^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$ , and gaseous  $\text{HNO}_3$  and  $\text{HCl}$  determined by means of the annular denuder technique during the winter and summer periods at Beijing are listed in Table 1.

The temporal patterns of these measured fine particulate and gas-phase species during the two sampling periods are reported in Fig. 1. The temporal variations are evaluated applying the paired  $t$ -test to determine the significance at the 0.05 level ( $p \leq 0.05$ ) of differences among the mean of components by examining the amount of variation between the samples. Fine particulate  $\text{Cl}^-$ ,  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  exhibited distinct and significant ( $p < 0.001$ ,  $p = 0.004$ ,  $p = 0.002$ , respectively) temporal variations (Yao et al., 2002; Duan et al., 2003), while fine particulate  $\text{NO}_3^-$  did not show much variation with respect to season (Duan et al., 2006; Lin et al., 2006).

Specifically, the mean concentrations of fine particulate  $\text{NO}_3^-$  were  $8.38 \pm 3.00 \mu\text{g m}^{-3}$  and  $9.62 \pm 2.37 \mu\text{g m}^{-3}$  during winter and summer periods, respectively, and reached the maximum peak of  $44.96 \mu\text{g m}^{-3}$  on 6 August 2007. Similar variation of  $\text{NO}_3^-$  concentrations has been reported by other studies (Erduran and Tuncel, 2001; Gupta et al., 2003). Particulate  $\text{NO}_3^-$  is mostly formed through gas to particle conversion and, therefore, through the oxidation of precursor gases, such as  $\text{NO}_x$ , to nitrate. In winter, local  $\text{NO}_2$  emissions, which are mainly from the vehicular emissions in big cities (Hao et al., 2005; Chak and Yao, 2008; Meng et al., 2008), were an important source of fine particulate  $\text{NO}_3^-$  because  $\text{NO}_3^-$  and  $\text{NO}_2$  correlated significantly ( $R^2 = 0.58$ ,  $p < 0.001$ , at the 99.9% confidence level). Thus,  $\text{NO}_2$  was converted to  $\text{NO}_3^-$  principally through photochemical processes in Beijing during the winter season (Wang et al., 2006, Kai et al., 2007; Hu et al., 2008; Pathack et al., 2009, 2011). However, the nitrate formation might be also ascribed to heterogeneous processes such as the condensation or absorption of  $\text{NO}_2$  in moist aerosols in addition to  $\text{N}_2\text{O}_5$  oxidation and  $\text{HNO}_3$  condensation (Wang

Interactive Discussion

et al., 2006). The heterogeneous formation generally relates to relative humidity (RH) and the particulate loading. In summer, the correlation between fine particulate  $\text{NO}_3^-$  and  $\text{NO}_2$  did not occur, while significant correlation between fine particulate  $\text{NO}_3^-$  and RH was the highest ( $R^2 = 0.43$ ,  $p < 0.001$  and  $R^2 = 0.20$ ,  $p = 0.04$  in summer and in winter, respectively).  $\text{PM}_{2.5}$  was not collected during the winter period but there is a good and significant linear correlation ( $R^2 = 0.62$ ,  $p < 0.001$ ) between particulate  $\text{NO}_3^-$  and  $\text{PM}_{2.5}$  in summer period showing the possible heterogeneous formation of particulate nitrate at Beijing. However, the presence of large amounts of fine particulate  $\text{NO}_3^-$  even in summer is surprising since  $\text{NH}_4\text{NO}_3$  is volatile and tends to dissociate and remain in gas phase under high temperatures. The mean concentration of  $\text{NH}_3$  was  $31.84 \pm 16.70 \mu\text{g m}^{-3}$  in summer period at Beijing, which was 6 times higher than in winter period of  $5.22 \pm 3.75 \mu\text{g m}^{-3}$  (Ianniello et al., 2010). In addition, the temperatures ranged between 1 and 14 °C and 22 and 35 °C in winter and summer periods, respectively. Thus, the high concentrations of fine particulate  $\text{NO}_3^-$  in summer period might be due to higher concentrations of  $\text{NH}_3$  in the atmosphere available to neutralize  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$ , which is consistent with the observation that the measured particulate species seemed to be neutralized (see below). In addition, the high relative humidity conditions (daily mean 35–90 %) in summer period might dissolve a significant fraction of  $\text{HNO}_3$  and  $\text{NH}_3$  in humid particles, therefore enhancing fine particulate  $\text{NO}_3^-$  and  $\text{NH}_4^+$  in the atmosphere (Hesterberg et al., 1996; Krupa, 2003; Trebs et al., 2004, 2005; Guinot et al., 2007; Sciare et al., 2007; Hu et al., 2008; Pathack et al., 2009, 2011; Ianniello et al., 2010; Sun et al., 2010).

As shown in Fig. 1 and in Table 1, the mean concentrations of fine particulate  $\text{Cl}^-$  were higher during the winter period ( $2.94 \pm 0.79 \mu\text{g m}^{-3}$ ) than during the summer period ( $0.79 \pm 0.10 \mu\text{g m}^{-3}$ ) and reached the maximum peak of  $10.69 \mu\text{g m}^{-3}$  on 4 February 2007. The major sources of particulate  $\text{Cl}^-$  in Beijing might be associated to coal burning activities, which could explain the higher  $\text{Cl}^-$  concentrations in winter because of the enhanced burning activities in this season (Yao et al., 2002; Wang et al., 2005), and the formation of  $\text{NH}_4\text{Cl}$ .

Mean concentrations of fine particulate  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  were higher during summer ( $12.30 \pm 2.48 \mu\text{g m}^{-3}$  and  $18.24 \pm 2.01 \mu\text{g m}^{-3}$ , respectively) than during winter ( $6.51 \pm 2.51 \mu\text{g m}^{-3}$  and  $7.50 \pm 2.34 \mu\text{g m}^{-3}$ , respectively). Similarly to  $\text{NH}_3$  (Ianniello et al., 2010), particulate  $\text{NH}_4^+$  concentrations showed higher values during warm months (Sickles, 1999b; Walker et al., 2000, 2004; Whittall and Paerl, 2001; Robarge et al., 2002; Street et al., 2007; Ianniello et al., 2010), as shown in Table 1 and in Fig. 1. The temporal variations of fine particulate  $\text{NH}_4^+$  basically coincided with those of fine particulate  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$  and  $\text{Cl}^-$ , indicating that  $\text{NH}_4^+$  largely originated from the neutralization between ammonia and acidic species (Wang et al., 2006). The very similar patterns of sulfate, nitrate, chloride and ammonium suggest that they were likely internally mixed and came from similar gas-to-particle processes (Huang et al., 2010).

The highest concentrations of particulate  $\text{SO}_4^{2-}$  during the summer period at Beijing were attributed to the higher temperatures and solar radiation, which enhance the photochemical activities and the atmospheric oxidation (higher concentrations of ozone, hydrogen peroxide and hydroxyl radical) and, thus, the oxidation rate of  $\text{SO}_2$  to particulate sulphate (Puxbaum et al., 1993; Robarge et al., 2002; Bari et al., 2003; Gupta et al., 2003; Plessow et al., 2005; Wang et al., 2005; Duan et al., 2006; Street et al., 2007). Sulphate showed also a strong correlation with fine particulate  $\text{K}^+$ , the most abundant cation after  $\text{NH}_4^+$ , during the winter ( $R^2 = 0.95$ ,  $p < 0.001$ ) and summer periods ( $R^2 = 0.80$ ,  $p = 0.001$ ), indicating the presence of potassium sulphate ( $\text{K}_2\text{SO}_4$ ). Agricultural biomass burning and its impacts on the regional brown hazes in northern China, especially in Beijing, were reported by previous studies (Duan et al., 2004; Li et al., 2010). They showed that the agricultural biomass burning consisted mostly of fine potassium salts ( $\text{K}_2\text{SO}_4$ ,  $\text{KNO}_3$  and  $\text{KCl}$ ), and they were internally mixed.

It is worth to point out that  $[\text{NH}_3]$  in units of  $\mu\text{mol m}^{-3}$  was always in same time scale above that of  $[\text{HNO}_3] + [\text{HCl}]$  in gas phase. Indeed, the ratio of  $[\text{NH}_3]$  to  $[\text{HNO}_3] + [\text{HCl}]$  was  $27.90 \pm 12.70$  in the winter period and  $54.06 \pm 20.60$  in the summer period, respectively. It implied that the atmosphere was ammonia-rich in gas phase during the winter

Interactive Discussion

and summer periods in Beijing. Thus, the evaluation of the chemical composition of fine particulate species collected on annular denuder/filter pack system can be used to calculate the  $\text{NH}_4^+$  neutralization factor, defined as the molar ratio of  $\text{NH}_4^+$  to the theoretical one, assuming complete conversion to  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ . Thus, the ionic composition of  $\text{PM}_{2.5}$  has been evaluated with regard to the balance between the major anions ( $\text{NO}_3^-$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ) and ammonium (Fig. 2) in the winter and summer periods.

During the winter period the strong correlation between  $\mu\text{mol m}^{-3}$  concentrations of fine particulate  $\text{NH}_4^+$  and  $\mu\text{mol m}^{-3}$  concentrations of fine particulate  $\text{SO}_4^{2-}$  ( $R^2 = 0.85$ ,  $p = 0.001$ ) collected on the Teflon filters and a slope of this regression line of 3.82, higher than 2, suggested the complete neutralization of  $\text{H}_2\text{SO}_4$  by  $\text{NH}_3$  and a predominance of particulate  $(\text{NH}_4)_2\text{SO}_4$  during the winter period (Possanzini et al., 1999; Walker et al., 2004). Thus, the excess of  $\text{NH}_4^+$  was inferred to be associated with fine particulate  $\text{Cl}^-$  and  $\text{NO}_3^-$ . In addition, the ionic composition of  $\text{PM}_{2.5}$  has been also evaluated with regard to the balance between the major anions ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ) and ammonium. Indeed, the  $\mu\text{mol m}^{-3}$  concentrations of fine particulate ammonium compared to the sum of the  $\mu\text{mol m}^{-3}$  concentrations of fine particulate nitrate, chloride and sulphate collected on Teflon filters (Fig. 2) improved the correlation between ammonium and measured anions ( $R^2 = 0.98$ ,  $p < 0.001$ ). The correlation showed an ion charge balance with a slope of 1.00, confirming that sufficient  $\text{NH}_3$  was present to completely neutralize all acidic components ( $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$  and  $\text{HCl}$ ) to form  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ . The scattering of some data could be attributed to the minor influences of other atmospheric processes, such as the formation of non volatile nitrate and chloride salts (e.g.,  $\text{NaNO}_3$ ,  $\text{KNO}_3$ ,  $\text{NaCl}$ ,  $\text{KCl}$ ). In addition, our denuder data showed that on average 33.05 %, 23.65 % and 34.71 % of the fine particulate nitrate, chloride and ammonium, respectively, evaporated from the Teflon filters during the winter period at Beijing (Fig. 3). Indeed, a comparison between  $\mu\text{mol m}^{-3}$  amount of  $\text{NH}_4^+$  with sum of  $\mu\text{mol m}^{-3}$  amounts of anions ( $\text{NO}_3^- + \text{Cl}^-$ ) determined on the back-up filters showed a

good and significant correlation between these ions ( $R^2 = 0.90$ ,  $p < 0.001$ ). The slope of this regression line was 1.65, indicating an excellent ion balance and, thus, the presence on Nylon filters of  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  as constituent of the total fine particles. In addition, using the approach of Ansari and Pandis (1998) and of Blanchard et al. (2000) it is possible to calculate the excess  $\text{NH}_3$ , which represents the quantity of  $\text{NH}_3$  that would remain after complete neutralization of available aerosol and acid gases, is defined as:

$$\text{Excess ammonia} = [\text{NH}_3] + [\text{NH}_4^+] - 2[\text{SO}_4^{2-}] - [\text{NO}_3^-] - [\text{HNO}_3] - [\text{HCl}] - [\text{Cl}^-] \quad (7)$$

where all concentrations are in units of  $\mu\text{mol m}^{-3}$ . Our results showed that excess  $\text{NH}_3$  existed with a mean value of  $0.30 \mu\text{mol m}^{-3}$  ( $5.10 \mu\text{g m}^{-3}$ ) during the winter period, indicating that the atmosphere contained sufficient ammonia to form ammonium nitrate and chloride. Furthermore, there might be also the presence of other nitrate and chloride containing species, which are less volatile than  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ . Hence, a part of the fine particulate nitrate and chloride might be bound as a relatively non-volatile salts of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$  or  $\text{Na}^+$ . Therefore, we have calculated the free nitrate and chloride concentrations (Hildemann et al., 1984; Gaidajis, 2002), defined as the fractions of nitrate and chloride in excess which are not bound with the alkali or alkaline earth metals, expressed in  $\mu\text{mol m}^{-3}$ , from data collected on the Teflon filters during the winter period:

$$\text{Free nitrate} = [\text{NO}_3^-] - \{2[\text{Ca}^{2+}] + 2[\text{Mg}^{2+}] + [\text{K}^+] + [\text{Na}^+] - [\text{Cl}^-]\} \quad (8)$$

$$\text{Free chloride} = [\text{Cl}^-] - \{2[\text{Ca}^{2+}] + 2[\text{Mg}^{2+}] + [\text{K}^+] + [\text{Na}^+]\} \quad (9)$$

Zero or negative values of free nitrate and chloride imply that  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  are not present. The free nitrate and chloride concentration were found to be present with a mean value of  $0.13 \mu\text{mol m}^{-3}$  ( $8.06 \mu\text{g m}^{-3}$ ) and  $0.01 \mu\text{mol m}^{-3}$  ( $0.35 \mu\text{g m}^{-3}$ ), respectively, indicating the presence of  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  during winter period. Besides,  $\text{NO}_3^-$  showed significant correlations with cations  $\text{K}^+$  ( $R^2 = 0.91$ ,  $p < 0.001$ ) and  $\text{Na}^+$

Interactive Discussion

( $R^2 = 0.40$ ,  $p = 0.002$ ), indicating possible formation of non-volatile  $\text{KNO}_3$  and  $\text{NaNO}_3$  salts along with  $\text{NH}_4\text{NO}_3$ .  $\text{Cl}^-$  had also good correlations with cations  $\text{K}^+$  ( $R^2 = 0.75$ ,  $p < 0.001$ ), suggesting the possible formation of  $\text{KCl}$  along with  $\text{NH}_4\text{Cl}$ . The presence of  $\text{K}^+$  suggests biomass burning emissions, including most likely house-hold combustion of agricultural residues and firewood in Beijing, and road and soil dust emissions (Duan et al., 2004; Wang et al., 2005, 2007, 2008). However, the observed  $\text{K}^+$  concentrations were low (mean values of  $1.07 \mu\text{g m}^{-3}$ ) and might not play a significant role in the formation of these particles in Beijing during winter period (Wang et al., 2005; Behera and Sharma, 2010).

During the summer period the correlation between particulate  $\text{NH}_4^+$  with  $\text{SO}_4^{2-}$  collected on Teflon filters was also very strong ( $R^2 = 0.85$ ,  $p < 0.001$ ). The mean value of  $\text{NH}_4^+/\text{SO}_4^{2-}$  molar ratio was 2.10, indicating the complete neutralization of  $\text{H}_2\text{SO}_4$  by  $\text{NH}_3$  and a predominance of  $(\text{NH}_4)_2\text{SO}_4$  aerosol during the summer season. In addition, the molar concentrations of fine particulate ammonium compared to the sum of the molar concentrations of fine particulate nitrate, chloride and sulphate collected on Teflon filters (Fig. 2) showed a very strong correlation ( $R^2 = 0.90$ ,  $p < 0.001$ ) and an ion charge balance (Possanzini et al., 1999; Walker et al., 2004). The slope of this regression line was higher than unity (1.53), confirming that abundant  $\text{NH}_3$  was present to neutralize the acidic components ( $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$  and  $\text{HCl}$ ) to form  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ . Indeed, our results show also that excess  $\text{NH}_3$  exists with a mean value of  $1.60 \mu\text{mol m}^{-3}$  ( $27.20 \mu\text{g m}^{-3}$ ) during the sampling period, indicating that ammonium salts formation occurred. In addition, our denuder data showed that on average 83.33 %, 74.64 % and 53.07 % of the fine particulate nitrate, chloride and ammonium, respectively, evaporated from the Teflon filters during the summer period at Beijing (Fig. 4). Indeed, a comparison between  $\mu\text{mol m}^{-3}$  amount of  $\text{NH}_4^+$  with sum of  $\mu\text{mol m}^{-3}$  amounts of anions ( $\text{NO}_3^- + \text{Cl}^-$ ) determined on the back-up filters showed a good and significant correlation between these ions ( $R^2 = 0.70$ ,  $p = 0.001$ ) indicating the presence of  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  as constituent of the total fine particles.

Interactive Discussion

Furthermore, free nitrate and chloride concentrations were also present with mean values of  $0.10 \mu\text{mol m}^{-3}$  ( $6.20 \mu\text{g m}^{-3}$ ) and  $0.06 \mu\text{mol m}^{-3}$  ( $2.13 \mu\text{g m}^{-3}$ ), respectively. Besides,  $\text{NO}_3^-$  showed significant correlation with cationic species such as  $\text{K}^+$  ( $R^2 = 0.24$ ,  $p < 0.001$ ), indicating possible presence of non-volatile  $\text{KNO}_3$  salt along with  $\text{NH}_4\text{NO}_3$ .

However, the observed  $\text{K}^+$  concentrations were also low (mean values of  $1.74 \mu\text{g m}^{-3}$ ) and might not play a significant role in the formation of these particles in Beijing during summer period.

These results indicate that  $\text{NH}_4\text{NO}_3$ ,  $\text{NH}_4\text{Cl}$ ,  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{K}_2\text{SO}_4$  and  $\text{KNO}_3$  were formed preferentially in Beijing during winter and summer seasons.

Following similar studies on equilibria of inorganic trace gases with related ionic aerosol compounds, we have tested if thermodynamic equilibrium was attained for the pure  $\text{NH}_3/\text{HNO}_3/\text{NH}_4\text{NO}_3$  ( $\text{HNO}_{3(\text{g})} + \text{NH}_{3(\text{g})} \leftrightarrow \text{NH}_4\text{NO}_{3(\text{s or aq})}$ ) and  $\text{NH}_3/\text{HCl}/\text{NH}_4\text{Cl}$  ( $\text{HCl}_{(\text{g})} + \text{NH}_{3(\text{g})} \leftrightarrow \text{NH}_4\text{Cl}_{(\text{s or aq})}$ ) systems under the meteorological conditions in Beijing during the winter and summer periods. The theoretical equilibrium dissociation constants for solid  $\text{NH}_4\text{NO}_3$  ( $K_n$ ) and for solid  $\text{NH}_4\text{Cl}$  ( $K_c$ ) were calculated and compared to the measured concentration products of  $\text{NH}_3$  and  $\text{HNO}_3$  ( $K_{mn} = [\text{HNO}_3][\text{NH}_3]$ ) and of  $\text{NH}_3$  and  $\text{HCl}$  ( $K_{mc} = [\text{HCl}][\text{NH}_3]$ ). The measured concentration product  $K_{mn}$  in units of  $\text{ppb}^2$  was determined using the measured data for 24-h sampling time while the theoretical equilibrium constant  $K_n$  in units of  $\text{ppb}^2$  was calculated according to the method in Stelson and Seinfeld (1982a), when the ambient relative humidity (RH) is less than relative humidity of deliquescence (RHD) at any absolute temperature ( $T$ ) recorded in Kelvin (Hammer and Wu, 1972):

$$\ln K_n = 84.6 - 24220/T - 6.1 \ln(T/298) \quad (10)$$

$$\ln(\text{RHD}) = 723.7/T + 1.7037 \quad (11)$$

The deliquescence relative humidity (DRH) (62% RH for pure  $\text{NH}_4\text{NO}_3$ , 298 K) varies with air temperature and can be modified by particle size and composition under real ambient conditions (Seinfeld and Pandis, 1998). If the ambient RH is less than the RHD, then the equilibrium state of  $\text{NH}_4\text{NO}_3$  is modeled as a solid. At relative humidity

Interactive Discussion

above that of deliquescence,  $\text{NH}_4\text{NO}_3$  is modeled in the aqueous state. During the winter the ambient RH was always lower than RHD (Fig. 3), thus,  $\text{NH}_4\text{NO}_3$  will exist in equilibrium with the solid phase. Instead, during the summer the ambient RH was not always lower than RHD (Fig. 4), thus,  $\text{NH}_4\text{NO}_3$  will be also in equilibrium with the aqueous phase and deliquescent particles. The relationship between  $K_{\text{mn}}$  and  $K_{\text{n}}$ , when RH was lower than RHD, is shown in Fig. 5 for winter and summer periods. The solid line indicates the theoretical equilibrium constant  $K_{\text{n}}$  for solid  $\text{NH}_4\text{NO}_3$  calculated as a function of temperature (Stelson and Seinfeld, 1982a). Concentration products  $K_{\text{mn}}$  are plotted on a logarithmic scale against a reciprocal average absolute temperature ( $1000/T$ ) and compared with the constant dissociations for both seasons.  $1000/T$  values varied from 3.6 to  $3.7\text{ K}^{-1}$  and from 3.3 to  $3.4\text{ K}^{-1}$  in the winter and summer, respectively, during the 24-h sampling periods in both seasons. In order for solid  $\text{NH}_4\text{NO}_3$  to be formed in the atmosphere, the concentration products of  $\text{HNO}_3$  and  $\text{NH}_3$  must exceed the theoretical equilibrium dissociation constant  $K_{\text{n}}$  (Stelson and Seinfeld, 1982a).

According to this, during the winter period the results of these thermodynamic calculations (Fig. 5 and Table 2) showed that the measured concentration products were higher than the theoretical predictions at low temperatures (Walker et al., 2006), with the exception of two days, 3 and 5 in February, where the  $K_{\text{mn}}$  are lower than  $K_{\text{n}}$ . Thus, almost on all days  $\text{NH}_4\text{NO}_3$  would be expected to be formed at Beijing site under winter conditions, in agreement with other results (Harrison and Pio, 1983; Allen et al., 1989; Harrison and Mackenzie, 1990; Pio et al., 1992; Possanzini et al., 1992; Mehlmann and Warneck, 1995; Danalatos and Glavas, 1999; Gupta et al., 2003). This could be due to the presence of excess  $\text{NH}_3$  even during the winter.

During the summer period, the results of thermodynamic calculations (Fig. 5) showed that almost on all days  $\text{NH}_4\text{NO}_3$  would not be expected to be formed at Beijing site under summer conditions. The measured concentration product values are below the thermodynamically predicted dissociation constants (Table 2), despite the fact that our measurements showed that the fine particulate ammonium nitrate was present at Bei-

Interactive Discussion

jing in the summer period (Fig. 1), as showed by other studies (Hildemann et al., 1984; Yao et al., 2002; Gupta et al., 2003; Trebs et al., 2005; Pathak et al., 2009; Guo et al., 2010). This disagreement can be understood by the fact that the theoretical predictions are achieved on the assumption that ammonium nitrate and chloride exist as pure solids or liquid particles. However, previous studies (Wu et al., 1987; Matsumoto and Tanaka, 1996; Zhang et al., 2000) confirmed that, for deliquescent particles, most of the fine particulate nitrate exists as an internal mixture with sulphate, so that  $\text{HNO}_3$  can easily be absorbed into the droplets. This coexistence of sulphate considerably reduces the thermodynamic dissociation constant  $K_n$  for  $\text{NH}_4\text{NO}_3$ . Thus, the fine particulate nitrate can be formed from  $\text{HNO}_3$  and  $\text{NH}_3$  through heterogeneous reactions on fully neutralized fine particulate sulphate, which is abundantly present in an urban area. Indeed, a strong and significant correlation between sulphate and nitrate was observed ( $R^2 = 0.80$ ,  $p < 0.001$ ), and a high concentrations of sulphate and nitrate were found at high levels of RH (35–83 %). Indeed, good and significant correlations between sulphate and RH ( $R^2 = 0.40$ ,  $p = 0.002$ ), and nitrate and RH ( $R^2 = 0.43$ ,  $p < 0.001$ ) were observed. These results can be interpreted as nitrate being produced on preexisting sulfate aerosols, which could provide sufficient surface area and aerosol water content for the heterogeneous reactions. In this case, at high RH, the amounts of the gaseous precursors, such as  $\text{NH}_3$  and  $\text{HNO}_3$ , have relatively less influence on the formation of the fine particulate nitrate (Zhang et al., 2010; Markovic et al., 2011). Accordingly, to include the coexistence of  $\text{SO}_4^{2-}$ , the  $\text{NH}_4\text{NO}_3$  ionic strength fraction  $Y = [\text{NH}_4\text{NO}_3]/([\text{NH}_4\text{NO}_3] + 3[(\text{NH}_3)_2\text{SO}_4])$  was calculated according to Stelson and Seinfeld (1982c) resulting in a mean value of  $Y = 0.20$  at Beijing site during the summer period, as seen in previous studies where fine particulate  $\text{NH}_4^+$ ,  $\text{NO}_3^-$  and  $\text{Cl}^-$  were observed under high temperatures (33–36 °C) and high relative humidities (40–100 %) (Yao et al., 2003; Gupta et al., 2003; Trebs et al., 2005; Guo et al., 2010). Then, the new equilibrium dissociation constant  $K_n^*$  was derived by multiplying  $K_n$  with  $Y$ , providing a  $K_n^*$  value significantly lower than  $K_n$  at 25 °C (Fig. 6), with the exception of three days, 6, 9 and 11 in August, where  $K_n^*$  was higher than  $K_{mn}$ . This, almost on all days

the meteorological conditions favour the formation of  $\text{NH}_4\text{NO}_3$  at Beijing site in summer period.

An other possible explanation can be provided by recent studies on the solid phase changes of solid  $\text{NH}_4\text{NO}_3$ , leading to appreciable  $\text{NH}_4\text{NO}_3$  concentrations in the troposphere even at high temperatures ( $> 30^\circ\text{C}$ ). Furthermore, potassium ions, such as  $\text{KNO}_3$ , were found to co-exist with fine particulate  $\text{NH}_4\text{NO}_3$ , and they changed the phase transition behaviors of solid  $\text{NH}_4\text{NO}_3$ . The presence of potassium ions into particulate  $\text{NH}_4\text{NO}_3$  widened its stable temperature range ( $32\text{--}84^\circ\text{C}$ ) (Chan and Chan, 2004; Wu and Chan, 2008).

These results indicate that both  $(\text{NH}_4)_2\text{SO}_4$  and  $\text{NH}_4\text{NO}_3$  are formed in the urban of Beijing during summer season.

As far as the formation of solid  $\text{NH}_4\text{Cl}$  is concerned, the same procedure was applied. It is well known that the thermodynamic equilibrium conditions for the formation of  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$  aerosols are similar and depend on humidity and temperature, with  $\text{NH}_4\text{Cl}$  showing a volatility 2–3 times higher than that of  $\text{NH}_4\text{NO}_3$  (Stelson and Seinfeld, 1982a; Pio and Harrison, 1987; Casimiro and Nunes 1992; Matsumoto and Tanaka, 1996). At humidity lower than 75–85 % the particulate  $\text{NH}_4\text{Cl}$  exists in the solid phase in equilibrium with the gaseous products. The theoretical equilibrium constant  $K_c$  in units of  $\text{pbb}^2$  for solid  $\text{NH}_4\text{Cl}$  was calculated by Pio and Harrison (1987), when the ambient relative humidity is below the respective deliquescence relative humidity (DRH):

$$\ln K_c = 2.23581 \ln T - 2.13204 \times 10^4 T^{-1} + 65.4375 - 8.167 \times 10^{-3} T + 4.644 \times 10^{-7} T^2 - 1.105 \times 10^{-10} T^3 \quad (12)$$

Thus, Fig. 7 presents the measured concentration products,  $K_{\text{mc}}$ , for both winter and summer periods in Beijing, compared with  $K_c$ . The measured concentration products are plotted on a logarithmic scale against a reciprocal average absolute temperature. Since  $\text{HCl}$  is more volatile than  $\text{HNO}_3$ ,  $K_c$  for  $\text{NH}_4\text{Cl}$  was higher than the theoretical value for  $\text{NH}_4\text{NO}_3$  (Table 2), as seen in previous papers (Allen et al., 1989). The

Interactive Discussion

behaviour of ammonium chloride is also similar to that ammonium nitrate, thus  $K_{mc}$  exhibited a similar behaviour to  $K_{mn}$  during both winter and summer periods.

During the winter period, the results of these thermodynamic calculations (Fig. 7) showed that almost on all days  $\text{NH}_4\text{Cl}$  will be formed in the winter because the measured  $[\text{NH}_3][\text{HCl}]$  products are above the predicted equilibrium constant for  $\text{NH}_4\text{Cl}$ , as seen for  $\text{NH}_4\text{NO}_3$ . Some of the data points in Fig. 11 of 28 and 31 January and of 3, 5, 10 and 11 February appeared to indicate an insufficient gas phase concentration product to form  $\text{NH}_4\text{Cl}$  aerosol. Instead, our denuder data showed the presence of fine particulate chloride during these days.

During the summer period, the results of thermodynamic calculations (Fig. 7) showed that on all days  $\text{NH}_4\text{Cl}$  would not be formed (Allen, 1989; Matsumoto and Tanaka, 1996). In fact, the measured concentration product values are below the thermodynamically predicted equilibrium constants (Table 2). Instead, our denuder data are in disagreement compared with theory because our denuder data showed that, on average, more than 70% of the fine particulate chloride is recovered on back-up filters (Fig. 4) in the summer season indicating the presence of  $\text{NH}_4\text{Cl}$  as constituent of atmospheric particulate chloride. Thus, ammonium chloride was also generated in the high temperature range, despite the fact that these particles should be volatilized according the thermodynamic predictions. This disagreement can be understood taking into account the same interpretation for  $\text{NH}_4\text{NO}_3$  in the summer concerning the internal mixture of the volatile ammonium salts (Wu et al., 1987; Matsumoto and Tanaka, 1996). Indeed, a strong and significant correlation between sulphate and chloride was observed ( $R^2 = 0.75$ ,  $p < 0.001$ ), and a high concentrations of sulphate and chloride were found at high levels of RH (35–83%). Indeed, a good and significant correlation between fine particulate chloride and RH ( $R^2 = 0.35$ ,  $p < 0.001$ ) were observed. In this case, the amount of the gaseous precursors has relatively less influence on the formation of the fine particulate chloride. This will minimise the thermodynamic constant dissociation  $K_c$  for  $\text{NH}_4\text{Cl}$  which can be generated from HCl and  $\text{NH}_3$  through heterogeneous reactions on neutralized sulphate particles.

Interactive Discussion

These results indicate that  $\text{NH}_4\text{Cl}$  is formed in the urban atmosphere of Beijing during winter and summer seasons.

## 3.2 Diurnal variation

### 3.2.1 Winter

The diurnal variations of fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and gaseous  $\text{HNO}_3$ ,  $\text{HCl}$  and  $\text{NH}_3$  along with meteorological parameters (temperature,  $T$ , relative humidity, RH, wind speed and direction) during the intensive winter measurements are reported in Fig. 8.

The weather conditions during this study were described in detail in Ianniello et al. (2010). Both the temperature and relative humidity exhibited strong diurnal variation patterns during the entire sampling period. The mean temperature was  $6.67^\circ\text{C}$  and increased at 08:00 reaching maxima values of about  $13.98^\circ\text{C}$  between 12:00 and 16:00, while the relative humidity peaked between 04:00 and 08:00 with a maximum value of 40.10%. The mean wind speed was  $2.18\text{ m s}^{-1}$  ( $0.02\text{--}8.85\text{ m s}^{-1}$ ) and blew mainly from northwest, southwest and southeast.

The mean concentrations of fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$  for the entire data ( $N=23$ ) were  $1.14\pm 0.82\text{ }\mu\text{g m}^{-3}$ ,  $2.01\pm 1.09\text{ }\mu\text{g m}^{-3}$ ,  $3.26\pm 1.50\text{ }\mu\text{g m}^{-3}$  and  $3.42\pm 1.47\text{ }\mu\text{g m}^{-3}$ , respectively. Besides, the concentration ranges were  $0.28\text{--}3.22\text{ }\mu\text{g m}^{-3}$ ,  $0.55\text{--}7.28\text{ }\mu\text{g m}^{-3}$ ,  $1.35\text{--}7.25\text{ }\mu\text{g m}^{-3}$  and  $1.53\text{--}8.98\text{ }\mu\text{g m}^{-3}$  for fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$ , respectively.

The diurnal variations are evaluated applying the paired  $t$  test ( $p \leq 0.05$ ) to day and night samples. Data were grouped into sunrise (between 06:00 and 18:00) and sunset (between 18:00 and 06:00) times during the intensive winter and summer measurements at Beijing. On applying paired  $t$  test to day and night samples, fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$  and  $\text{NH}_4^+$  exhibited significant diurnal variations ( $p = 0.034$ ,  $p = 0.008$ ,  $p = 0.013$  and  $p = 0.016$ , respectively) in the winter period.

The diurnal variation of fine particulate  $\text{Cl}^-$  showed broad peaks in the morning (between 08:00 and 10:00) and in the evening (between 20:00 and 22:00). Indeed, the

Interactive Discussion

mean chloride concentrations ranged from 0.28 to 3.51  $\mu\text{g m}^{-3}$  during the day and from 0.50 to 2.85  $\mu\text{g m}^{-3}$  during the night.

The ammonium concentrations followed the chloride, nitrate and sulphate concentrations in time (Fig. 8) with higher peaks between 08:00 and 10:00, indicating the presence of  $\text{NH}_4\text{Cl}$ ,  $\text{NH}_4\text{NO}_3$ , and ammonium sulphate salts. In addition, the similar diurnal variations of these measured species are consistent with the strong correlations between  $\text{NH}_4^+$  and  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ . Indeed, the correlation coefficients were 0.86 ( $p < 0.001$ ) for  $\text{NH}_4^+ - \text{Cl}^-$ , 0.90 ( $p < 0.001$ ) for  $\text{NH}_4^+ - \text{NO}_3^-$ , and 0.96 ( $p < 0.001$ ) for  $\text{NH}_4^+ - \text{SO}_4^{2-}$ .

Furthermore, the nitrate, sulphate and ammonium concentrations reached maxima values of 7.30  $\mu\text{g m}^{-3}$ , 7.25  $\mu\text{g m}^{-3}$  and 8.98  $\mu\text{g m}^{-3}$ , respectively, at daytime and of 2.76  $\mu\text{g m}^{-3}$ , 4.94  $\mu\text{g m}^{-3}$  and 4.04  $\mu\text{g m}^{-3}$ , respectively, at nighttime. The highest daytime concentrations of these species measured on 9 February might be related to the weather conditions and to emissions from Friday traffic during this day (Ianniello et al., 2010). Indeed, lower wind speeds between 00:00 and 12:00 (0.02–1.53  $\text{m s}^{-1}$ ) and southeasterly and southwesterly wind directions (60%) on 9 February, in combination with higher  $\text{NO}_x$  concentrations and relative humidities, and lower temperatures during this time period, resulted in higher peaks of all four species between 08:00 and 10:00 (Ianniello et al., 2010). Obviously,  $\text{NH}_4^+$  was strongly influenced by its gas phase precursor, such as  $\text{NH}_3$ , peaking between 08:00 and 10:00 in the morning and revealing much higher concentrations than the anionic species. Possible evaporation of  $\text{NH}_3$  from wet surfaces at sunrise, when relative humidities were still high might have caused a significant fraction of gaseous ammonia to dissolve in still humid particles, therefore enhancing particulate  $\text{NH}_4^+$  (Trebs et al., 2004, Ianniello et al., 2010).

In addition, thermodynamic calculations obtained by 2-h samplings over the 9–10 February in winter showed the same results to that obtained during 24-h samplings. The only difference was that the measured concentration products and the equilibrium constants tend to be higher on the average than those derived from longer sampling periods (Table 2). The mean values of  $K_{\text{mn}}$  and  $K_{\text{n}}$  for  $\text{NH}_4\text{NO}_3$  were 1.49  $\text{ppb}^2$  and

Interactive Discussion

0.35 ppb<sup>2</sup>, respectively, and the mean values of  $K_{mc}$  and  $K_c$  for NH<sub>4</sub>Cl were 0.78 ppb<sup>2</sup> and 0.60 ppb<sup>2</sup>, respectively, during the intensive winter measurements. As discussed above, the atmosphere is ammonia rich in Beijing during winter period and, thus, ammonium nitrate and chloride formations were permitted.

To gain an insight into the impact of regional transport on NH<sub>3</sub> at Beijing, 24-h backward trajectories were calculated by using NOAA ARL HYSPLIT trajectory model (<http://ready.arl.noaa.gov/Hysplit.php>) for winter and summer intensive measurements in Ianniello et al. (2010). The dominant transport of air masses in the winter period originated in the northwest (83%) of Beijing, coinciding with the direction of Inner Mongolia and Hebei province. These air masses arrived at higher speeds (8.17–15.70 m s<sup>-1</sup>), which results in less accumulation of air pollutants. Instead, the local wind speeds, coming mainly from southeast and southwest of Beijing, arrived slower (0.02–8.85 m s<sup>-1</sup>), especially on 9 February between 00:00 and 12:00 (0.02–1.29 m s<sup>-1</sup>), which results in more accumulation of air pollutants. This implies that local emissions contributed greatly to the fine particulate matter in Beijing, where morning peaks of these fine particulate species correlated with morning traffic emissions such as with higher NO<sub>x</sub> concentrations in rush hours.

### 3.2.2 Summer

The diurnal variations of fine particulate species Cl<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup> and NH<sub>4</sub><sup>+</sup>, and gaseous HNO<sub>3</sub>, HCl and NH<sub>3</sub>, along with meteorological parameters (temperature,  $T$ , relative humidity, RH, wind speed and direction, and natural radioactivity) during the intensive summer measurements are reported in Fig. 9.

The weather conditions during this time period were described in detail in Ianniello et al. (2010). Both the temperature and relative humidity exhibited strong diurnal variation patterns during the entire sampling period. The temperature ranged between 23.86 °C and 33.22 °C reaching maxima between 12:00 and 14:00, while the relative humidity varied from 40 % to 80.77 % peaking between 04:00 and 06:00. The wind

Interactive Discussion

speed reached a maxima value of  $3 \text{ m s}^{-1}$  at 18:00 and blew mainly from south, north-west and southwest.

The mean concentrations of fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$  for the entire data ( $N = 47$ ) were  $1.87 \pm 1.05 \mu\text{g m}^{-3}$ ,  $17.92 \pm 8.38 \mu\text{g m}^{-3}$ ,  $37.40 \pm 10.80 \mu\text{g m}^{-3}$  and  $23.81 \pm 6.95 \mu\text{g m}^{-3}$ , respectively. Besides, the concentration ranges were  $0.07\text{--}5.52 \mu\text{g m}^{-3}$ ,  $0.45\text{--}44.65 \mu\text{g m}^{-3}$ ,  $14.56\text{--}83.71 \mu\text{g m}^{-3}$  and  $7.80\text{--}39.23 \mu\text{g m}^{-3}$  for fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$ , respectively. The presence of substantial amounts of fine particulate matter such as fine particulate  $\text{NO}_3^-$  in summer period is interesting since fine particulate ammonium salts ( $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ ) are volatile and tends to dissociate and remain in the gas phase under high temperatures. The possible explanation for the detection of high concentrations of fine particulate  $\text{NO}_3^-$  in August is that there was abundant  $\text{NH}_3$  to neutralize  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$  and  $\text{HCl}$ , which is consistent with the results obtained from our measurements on the predominance of overall neutralized particles, such as  $(\text{NH}_4)_2\text{SO}_4$  (see Sect. 3.1). In addition, the particulate matter in Beijing was likely humid due to high RH conditions, which might favor the absorption of  $\text{NH}_3$  and  $\text{HNO}_3$  (He et al., 2001; Yao et al., 2003; Chan and Yao, 2008; Sun et al., 2010).

All four measured species showed broadly similar patterns but only fine particulate  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  exhibited significant diurnal variations ( $p = 0.030$ ,  $p = 0.021$  and  $p = 0.025$ , respectively) in the summer in Beijing (Fig. 9). In addition, the similar diurnal variations of these measured species are consistent with the strong correlations between  $\text{NH}_4^+$  and  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ . Indeed, the correlation coefficients were 0.80 ( $p = 0.001$ ) for  $\text{NH}_4^+\text{--Cl}^-$ , 0.85 ( $p < 0.001$ ) for  $\text{NH}_4^+\text{--NO}_3^-$ , and 0.90 ( $p < 0.001$ ) for  $\text{NH}_4^+\text{--SO}_4^{2-}$ . The variation of  $\text{NH}_4^+$  coincided with those of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$  and  $\text{Cl}^-$ , indicating that  $\text{NH}_4^+$  largely originated from the neutralization between ammonia and acidic species.  $\text{NH}_4^+$  concentration peaked at around 08:00 due to its accumulation under humid conditions within the stable nocturnal boundary layer between 06:00 and 08:00. This can be explained by a significant fraction of  $\text{NH}_3$  dissolved in humid particles under high

Interactive Discussion

RH conditions which increases  $\text{NH}_4^+$  formation (Stelson and Seinfeld, 1982b,c; Baek and Aneja, 2004). The observed diurnal pattern of fine particulate  $\text{NO}_3^-$  also peaked at around 08:00 within a thermally stable nocturnal boundary layer. After 08:00,  $\text{NO}_3^-$  concentrations dropped and remained at low levels between 12:00 and 18:00 due to the gas to particle partitioning of  $\text{NH}_4\text{NO}_3$  precursors ( $\text{HNO}_3$  and  $\text{NH}_3$ ), which is favored by the lower temperature and high RH during night and early morning. In addition, the low concentrations of fine particulate  $\text{NO}_3^-$  were also due to when the convective mixing of the atmosphere occurred between the late morning (12:00–13:00) of previous day and the early morning (03:00–04:00) of the subsequent day (Fig. 9). The  $\text{NO}_3^-$  concentration peaked at around 08:00 as a result of the accumulation under high RH conditions. As for  $\text{NH}_4^+$  and  $\text{NO}_3^-$ , after 08:00, the observed diurnal pattern of fine particulate  $\text{Cl}^-$  showed a decrease trend during daytime due to increase of the boundary layer height and dissociation of  $\text{NH}_4\text{Cl}$  at high temperatures (Fig. 9).

Fine particulate  $\text{SO}_4^{2-}$  concentrations did not show a pronounced diurnal variation as that of other fine particulate species ( $\text{NH}_4^+$ ,  $\text{NO}_3^-$  and  $\text{Cl}^-$ ), being relatively stable throughout day and night. This might be explained by a more regional formation originating from distant sources. Indeed, high sulphate concentrations occurred between 08:00 and 14:00 in combination with high RH conditions and high peaks of  $\text{NO}_x$  and  $\text{PM}_{2.5}$ , supporting the hypothesis that the traffic was also an important mobile source of fine particulate matter. These results are consistent with the good correlations between  $\text{SO}_4^{2-}$  and RH,  $\text{NO}_x$  and  $\text{PM}_{2.5}$ . Indeed, the correlation coefficients were 0.52 ( $p = 0.001$ ) for  $\text{SO}_4^{2-}$ -RH, 0.35 ( $p = 0.001$ ) for  $\text{SO}_4^{2-}$ - $\text{NO}_x$ , and 0.50 ( $p < 0.001$ ) for  $\text{SO}_4^{2-}$ - $\text{PM}_{2.5}$ .

In addition, thermodynamic calculations obtained by 2-h samplings over the 17–21 August in summer showed the same results to that obtained during 24-h samplings. The only difference was that the equilibrium constants tend to be higher on the average than those derived from longer sampling periods (Table 2). The mean values of  $K_{\text{mn}}$  and  $K_{\text{n}}$  for  $\text{NH}_4\text{NO}_3$  were 51.35  $\text{ppb}^2$  and 116.26  $\text{ppb}^2$  for  $K_{\text{mn}}$  and  $K_{\text{n}}$ , respectively,

and the mean values of  $K_{mc}$  and  $K_c$  for  $\text{NH}_4\text{Cl}$  were  $18.72 \text{ ppb}^2$  and  $267.01 \text{ ppb}^2$ , respectively, during the intensive summer measurements. As discussed above, even if the atmosphere is ammonia rich in Beijing during summer period, ammonium nitrate and chloride would not be expected to be formed but the meteorological conditions favoured their formations at Beijing site in summer period.

As in winter, to identify the impact on the regional transport of air masses on the sampled pollutants, 24-h backward trajectories were calculated for summer intensive measurements in Ianniello et al. (2010). The dominant transport of air masses in the summer period originated in the south (53%) and southeast (15%) of Beijing, coinciding with the direction of Hebei province and Tianjing municipality, which are highly industrialized and polluted areas. These polluted air masses from southern directions arrived slower ( $1.63\text{--}3.85 \text{ m s}^{-1}$ ) and had much time to accumulate air pollutants in the Beijing area. This suggests that the high concentrations of fine particulate species, such as  $\text{NH}_4^+$ ,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ , were due to the impact of regional sources in Beijing during the summer period. Thus, the presence of high concentration of primary precursors in the southern regions, such as  $\text{NH}_3$ ,  $\text{SO}_2$  and  $\text{NO}_x$ , led to the high particulate ammonium, sulfate and nitrate concentrations in the atmosphere of Beijing. The indication that the areas to the south of Beijing are major sources of particulate matter for Beijing have been reported in other studies (Xia et al., 2007; Streets et al., 2007; Wehner et al., 2008; Zhao et al., 2009; Wu et al., 2009). In addition, the urban area itself is a major source for traffic emission. Indeed, the local wind speeds, coming mainly from south and northwest of Beijing, arrived also slowly ( $0.02\text{--}3.83 \text{ m s}^{-1}$ ), especially between 06:00 and 10:00 ( $0.02\text{--}1.30 \text{ m s}^{-1}$ ) during all days, in combination with north-westerly wind direction, boundary layer variations and daytime traffic emissions in rush hours such as with highest concentrations of  $\text{NO}_x$  and  $\text{PM}_{2.5}$  between 06:00 and 10:00 (morning rush hour) for all days. Indeed, in Beijing 74% of ground  $\text{NO}_x$  originates from vehicular emissions (Hao et al., 2005; Xu et al., 2011), while  $\text{PM}_{2.5}$  accounted for 90% of total PM emissions from vehicle exhaust emissions (Zheng et al., 2005). The observed morning peaks of  $\text{NO}_x$  and  $\text{PM}_{2.5}$  were due to enhanced anthropogenic activity

Interactive Discussion

during rush hours and this suggests that the atmosphere of Beijing received regional polluted air from southern urban regions on locally produced particulate species.

These results indicate that reducing the concentrations of precursor gases, such as  $\text{NH}_3$  and  $\text{NO}_x$ , could be an effective method for alleviating secondary inorganic  $\text{PM}_{2.5}$  pollution in the urban atmospheres as in Beijing.

## 4 Conclusions

The atmospheric concentrations of gaseous  $\text{HNO}_3$ ,  $\text{HCl}$  and  $\text{NH}_3$  and their chemically related fine particulate species  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  have been measured at an urban site (Peking University) in Beijing (China) in the winter and summer of 2007.

These measurements were carried out by means of annular denuder and filter pack in order to determine the fine particulate inorganic ammonium salts without disturbing the partition equilibrium existing in the atmosphere between gaseous  $\text{NH}_3$  and the particulate components ( $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ ). All data were analyzed to investigate temporal and diurnal variations in fine particulate species and meteorological effects, and to examine the contribution of local and regional sources to fine particulate species. According to the results, the following conclusions were reached:

1. Fine particulate  $\text{Cl}^-$ ,  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  exhibited distinct temporal variations, while fine particulate  $\text{NO}_3^-$  did not show much variation with respect to season.
2. All measured particulate species showed diurnal similar patterns during the winter and summer periods with higher peaks in the early morning, especially in summer, when humid and stable atmospheric conditions occurred.
3. The atmosphere of Beijing was ammonia-rich in gas phase during the winter and summer periods. Thus, abundant  $\text{NH}_3$  was present to neutralized the acid components, such as  $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$  and  $\text{HCl}$ , and to form fine particulate ammonium

Interactive Discussion

salts, such as  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{NO}_3$  and  $\text{NH}_4\text{Cl}$ , in winter and summer periods at Beijing.

4. Significant amounts of fine particulate nitrate even in summer were found in disagreement with theoretical values predicted by thermodynamic equilibrium laws for  $\text{NH}_4\text{NO}_3$  formation. In the summer the presence of large amounts of  $\text{NH}_3$ , the domination of  $(\text{NH}_4)_2\text{SO}_4$ , the high relative humidity conditions seemed to dissolve a significant fraction of  $\text{HNO}_3$  and  $\text{NH}_3$  enhancing fine particulate  $\text{NO}_3^-$  and  $\text{NH}_4^+$  in the atmosphere of Beijing.
5. Moderate correlations were obtained between fine particulate species and pollutants emitted by motor-vehicle exhausts, such as  $\text{NO}_x$  and  $\text{PM}_{2.5}$ , indicating an influence by traffic emissions at Beijing.
6. Emissions from regional sources contributed also to the atmospheric levels of fine particulate species in winter and summer seasons at Beijing.
