## Abstract

The partitioning of reactive nitrogen ( $\text{NO}_y$ ) was measured over the remote North Pacific during spring 2006. We use these observations to assess the impact of increasing emissions of nitrogen oxides in East Asia on ozone ( $\text{O}_3$ ) production rates over the remote Pacific and the intercontinental transport of  $\text{O}_3$  and its precursors to North America. Aircraft observations of speciated  $\text{NO}_y$ , made between  $25^\circ$  and  $55^\circ$  N, confirm a controlling role for peroxyacyl nitrates in  $\text{NO}_x$  production in aged Asian outflow, accounting for more than 60 % of  $\text{NO}_y$  above 5 km, while thermal dissociation limits their contribution to less than 10 % in the lower troposphere. The observations reveal the extreme sensitivity of the remote Pacific to future changes in  $\text{NO}_x$  loadings, with an experimentally determined crossover point between net  $\text{O}_x$  destruction and net  $\text{O}_x$  production of 60 pptv  $\text{NO}_x$ . Using simultaneous observations of speciated  $\text{NO}_y$  and wind speed, we calculate the flux of reactive nitrogen through the meridional plane of  $150^\circ$  W (between  $25^\circ$  and  $55^\circ$  N) to be  $0.007 \pm 0.002 \text{ Tg N day}^{-1}$ , which provides an upper limit of 15 % on the export efficiency of  $\text{NO}_y$  from East Asia. Analysis of the subsiding plumes in the sampling domains suggests that episodic dry subsidence events play an important role in the intercontinental transport of ozone and its precursors from East Asia to North America.

## 1 Introduction

The partitioning of reactive nitrogen ( $\text{NO}_y$ ), among the various oxides of nitrogen (e.g. nitric oxide ( $\text{NO}$ ), nitrogen dioxide ( $\text{NO}_2$ ), peroxyacyl nitrates ( $\Sigma\text{PNs}$ ), alkyl and multi-functional nitrates ( $\Sigma\text{ANs}$ ), nitric acid ( $\text{HNO}_3$ ) and others), determines the spatial scales by which  $\text{NO}_x$  ( $\text{NO}_x \equiv \text{NO} + \text{NO}_2$ ), or its temporary reservoirs, are transported. As a result,  $\text{NO}_y$  partitioning impacts the spatial distribution of nitrogen deposition and the production rates of both ozone ( $\text{O}_3$ ) and secondary organic and inorganic aerosol on local, regional and global scales.

Interactive Discussion

Determining the magnitude and distribution of the NO<sub>x</sub> oxidation products, which can act as either temporary or permanent NO<sub>x</sub> reservoirs, is critical for understanding the global distribution of NO<sub>x</sub> in the troposphere and its subsequent effects on O<sub>3</sub>. NO<sub>x</sub> is removed from the catalytic ozone production cycle following the three-body reaction of NO<sub>2</sub> with the hydroxyl radical to produce HNO<sub>3</sub>, as shown in Eq. (1). NO<sub>2</sub> can also react directly with peroxy radicals to form a peroxy nitrate (RO<sub>2</sub>NO<sub>2</sub>, Eq. 2), the most abundant being peroxy acetyl nitrate (or PAN) a derivative of acetaldehyde (Singh et al., 1985, 1986). Further, the NO<sub>x</sub> cycle can be terminated through the formation of alkyl or multifunctional nitrates (RONO<sub>2</sub>) following the reaction of NO with RO<sub>2</sub> (Eq. 3) (Calvert and Madronich, 1987; Trainer et al., 1991).

NO<sub>2</sub> also reacts directly with O<sub>3</sub>, producing the nitrate radical (NO<sub>3</sub>), which quickly reaches thermodynamic equilibrium with dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>) (Eqs. 4–5) (Noxon et al., 1978; Platt et al., 1980). This loss process occurs primarily at night due to the strong visible light absorption and subsequent dissociation of NO<sub>3</sub> as well as rapid reaction with NO (which is significantly reduced at night). Together these reactions limit the steady-state lifetime of NO<sub>3</sub> to seconds in daytime.

Additionally, nitrous acid (HONO), formed through the hydrolysis of NO<sub>2</sub> has been shown to be a significant component of NO<sub>y</sub> at night near the surface (Finlayson-Pitts et al., 2003). The partitioning of reactive nitrogen between the various NO<sub>x</sub> oxidation products is of great importance as each reservoir (e.g. RO<sub>2</sub>NO<sub>2</sub>, RONO<sub>2</sub>, HNO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>) has a drastically different lifetime in the atmosphere. ΣPNs are largely insoluble (e.g. the Henry's Law Constant for PAN is 2–5 Matm<sup>-1</sup> at 273 °K) (Sander, 1999),

Interactive Discussion

have low accommodation coefficients ( $\gamma = 0.0001$ ) for heterogeneous uptake (Kirchner et al., 1990), and measurements have shown them to have small deposition velocities relative to other constituents of  $\text{NO}_y$  (Farmer et al., 2006; Turnipseed et al., 2006; Wolfe et al., 2009) leading to longer atmospheric lifetimes. However,  $\Sigma\text{PNs}$  are thermally unstable at warm temperatures and will act as a net source of  $\text{NO}_x$  in warm climates (Lamarque et al., 1996; Moxim et al., 1996; Horowitz and Jacob, 1999; Heald et al., 2003; Hudman et al., 2004). The PAN lifetime against thermal decomposition increases from hours to days in the BL to months in the UT where lower temperatures drive the equilibrium shown in Eq. (2) to the right, toward  $\text{RO}_2\text{NO}_2$  (Talukdar et al., 1995). Nitric acid is largely soluble (e.g. the Henry's Law Constant for  $\text{HNO}_3$  is  $2\text{--}8 \times 10^5 \text{ Matm}^{-1}$  at  $273^\circ\text{K}$ ) (Sander, 1999), and has a significant accommodation coefficient for heterogeneous removal (Choi and Leu, 1998; Arora et al., 1999; Tolocka et al., 2002) and a large deposition velocity (Munger et al., 1996, 1998). As a result, production of  $\text{HNO}_3$  is viewed as an irreversible sink for  $\text{NO}_x$ . Alkyl nitrates ( $\Sigma\text{ANs}$ ) are removed following reaction with OH and  $\text{O}_3$ . In addition, hydroxyl- and multifunctional nitrates, which comprise a large fraction of  $\Sigma\text{ANs}$ , especially in regions of strong biogenic influence (Day et al., 2003), are thought to be removed effectively via deposition and heterogeneous removal processes (Farmer et al., 2006). In the presence of high surface area loadings  $\text{N}_2\text{O}_5$  can be hydrolyzed forming  $\text{HNO}_3$  or  $\text{ClONO}_2$  on chloride containing particles (Bertram and Thornton, 2009). These chemical lifetimes and the associated partitioning among different  $\text{NO}_y$  species determine the extent to which  $\text{NO}_x$  is present in the atmosphere far from its source and thus affect the rate of ozone production (e.g. Hudman, et al., 2004) and nitrogen deposition (e.g. Munger, et al., 1996), downwind of the source region.

$\text{NO}_y$  in the free troposphere is thought to be composed primarily of PAN and  $\text{HNO}_3$  (Li et al., 2004; Parrish et al., 2004b). This idea is based on the arguments that: (i)  $\text{NO}_x$  sources other than aircraft and lightning are confined to the boundary layer, (ii) the  $\text{NO}_x$  lifetime is significantly shorter than the time scale for transport to the free troposphere, and (iii)  $\Sigma\text{ANs}$  are not particularly important (Buhr et al., 1990; Shepson et al., 1993).

Interactive Discussion

The latter point has been challenged with direct observations of  $\Sigma$ ANs in the planetary boundary layer and in the free troposphere (Day et al., 2003).

Observations show that  $\text{NO}_x$  emissions are rapidly increasing in the developing world (Richter et al., 2005). These increases are projected to be responsible for an increase in  $\text{O}_3$  in the remote atmosphere, where  $\text{O}_3$  production is largely  $\text{NO}_x$  limited (Fishman et al., 1979). However, a thorough understanding of the export efficiency and the subsequent processes governing the transport and chemical evolution of  $\text{NO}_y$  in the outflow from urban centers is essential to determining the extent to which the dramatic regional changes observed by Richter et al. (2005) are having a global impact. Recent analyses of aircraft observations have provided important tests of the amount of  $\text{NO}_y$  exported from continental sources and the mechanisms by which it is injected into the free troposphere (Heald et al., 2003; Hudman et al., 2004; Li et al., 2004; Parrish et al., 2004a). The most rapid  $\text{NO}_x$  increases are in Eastern China (e.g. Richter et al., 2005; Q. Zhang et al., 2007, 2009; L. Zhang et al., 2008; Walker et al., 2010), making the study of Asian outflow plumes of particular interest (Heald et al., 2003).

Observations of the partitioning of  $\text{NO}_y$  (between  $\text{NO}_x$ ,  $\Sigma\text{PNs}$ ,  $\Sigma\text{ANs}$ ,  $\text{HNO}_3$  and other minor components) are limited in the free troposphere, particularly over the remote North Pacific. This is in part due to the difficulty of accessing the region and the requirement for multiple instruments to measure each individual component on a comparable sampling frequency. The free troposphere over the Pacific Ocean has been studied during multiple aircraft missions over the past 15 yr. However, these measurements were confined closely to either the Asian or North American Continents, with only a select number of transpacific flights that sampled the remote Pacific. The scientific objectives of earlier flight campaigns was the characterization of Asian outflow plumes near the source region (e.g. PEM West A, PEM West B and TRACE-P, Hoell et al., 1996, 1997; Jacob et al., 2003). Transit flights from the United States to the sampling region proved instructive in assessing the extent of transport and transformation of the Asian plumes (Heald et al., 2003). The Intercontinental Transport and Chemical Transformation 2002 (ITCT 2K2) Experiment made observations of Asian plumes transported to

Interactive Discussion

North America during spring (Parrish et al., 2004a). Until the spring of 2006, the main transport corridor between Asia and North America was left largely unmeasured. In the following we describe observations of the partitioning of  $\text{NO}_y$  in Asian outflow over the remote Pacific using direct measurements of speciated  $\text{NO}_y$  ( $\text{NO}_x$ ,  $\Sigma\text{PNs}$ ,  $\Sigma\text{ANs}$  and  $\text{HNO}_3$ ) made between the surface and 12 km during the spring of 2006 and discuss the implications of these observations for our understanding of atmospheric chemistry over the Pacific.

## 2 Experimental methods

### 2.1 Intercontinental chemical transport experiment – phase B (INTEX-B)

We use observations obtained during the INTEX-B campaign, conducted out of Honolulu, HI and Anchorage, AK during April and May of 2006 using the NASA DC-8. Research flights were primarily conducted during daytime (88 % of the observations were made at  $\text{SZA} < 90^\circ$ ); the only nighttime flight was the transit between Honolulu and Anchorage. In the following analysis all observations were used. The principle objective of the INTEX-B campaign was to characterize the transport of Asian pollution, which is most frequent and rapid in spring, during periods of strong frontal activity (Yienger et al., 2000). Research flights were designed to sample pollution lofted from the Asian boundary layer (BL) by cold frontal activity and transported across the Pacific toward North America in the free troposphere. Observations highlighted in this study include in situ measurements of ozone, NO,  $\text{NO}_2$ , total peroxy nitrates ( $\Sigma\text{PNs}$ ), total alkyl and multifunctional nitrates ( $\Sigma\text{ANs}$ ) and nitric acid ( $\text{HNO}_3$ ) (Thornton et al., 2000; Day et al., 2002; Fairlie et al., 2007). Aircraft flight tracks are shown in Fig. 1a, where sampling legs north of  $35^\circ\text{N}$  are shown in black and sampling legs south of  $35^\circ\text{N}$  are shown in grey. The  $35^\circ\text{N}$  threshold was chosen as satellite observations and model analyses of enhancements in carbon monoxide, indicative of transpacific transport of Asian pollution, have shown strong influence north of  $35^\circ\text{N}$  (L. Zhang et al., 2008; Hsu et al.,

Interactive Discussion

2012) coinciding with the westward movement of air above the Pacific High. The corresponding mean vertical profile in temperature for the two sampling regions is shown in Fig. 1b, highlighting an approximately 10 °C difference in temperature between the two regions from the surface through the mid troposphere. The implications of the observed temperature difference on the reactive nitrogen budget are discussed in detail in Sect. 3.2.

## 2.2 Thermal dissociation – laser induced fluorescence

Observations of NO<sub>2</sub>, ΣPNs, ΣANs and HNO<sub>3</sub> were made using Thermal Dissociation – Laser Induced Fluorescence (TD-LIF) (Thornton et al., 2000; Day et al., 2002). Briefly, NO<sub>2</sub> fluorescence is detected following excitation of a specific jet-cooled rovibronic transition at 585 nm. The resulting fluorescence is collected by a PMT at 90° to the laser axis, which is both optically and temporally filtered to remove laser scatter. The measured fluorescence is directly correlated to NO<sub>2</sub> following calibration to a NIST traceable NO<sub>2</sub> calibration standard (accuracy of ±5 %). The NO<sub>2</sub> calibration constant was determined and applied as a function of inlet pressure due to the non-linear response of the system to pressure, a result of reduced jet-cooling of NO<sub>2</sub> at low ambient pressures. Higher order reactive nitrogen classes (ΣPNs, ΣANs and HNO<sub>3</sub>) are detected by coupling a thermal dissociation inlet to the LIF sensor (Day et al., 2002). In this system, we heat the ambient air stream to the dissociation threshold for the class of NO<sub>y</sub> species of interest (200 °C for ΣPNs, 350 °C for ΣPNs + ΣANs, and 550 °C for ΣPNs + ΣANs + HNO<sub>3</sub>) and detect the NO<sub>2</sub> dissociation product using NO<sub>2</sub> LIF. As configured for INTEX-B N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> if present would be detected in the ΣPNs channel. The resulting system has an NO<sub>2</sub> detection limit of 8 pptv/10 s at 760 Torr (ground) and 25 pptv/10 s at 10 km at S/N = 2. The sensitivity of the TD-LIF technique toward ΣPNs, ΣANs and HNO<sub>3</sub> is determined by the partitioning of the individual components of NO<sub>y</sub> as discussed in Day et al. (2002).

## 3 Results

### 3.1 Observations of reactive nitrogen during INTEX-B

The vertical distribution in the sum of the measured gas-phase components of  $\text{NO}_y$  (here defined as  $\text{NO}_x + \Sigma\text{PNs} + \Sigma\text{ANs} + \text{HNO}_3$ ) are shown in Fig. 2, alongside the vertical profile in ozone for observations made both North (Fig. 2a) and South (Fig. 2b) of  $35^\circ\text{N}$ . Observations were separated into 1 km altitude bins, where the median in each bin is shown with a solid line, and the shaded region represents the interquartile range of the observations. The fraction of  $\text{NO}_y$  carried by particulate  $\text{NO}_3^-$  is not shown in Fig. 2, due to sparse data coverage, and limited sampling during vertical profiling. The contribution of particulate  $\text{NO}_3^-$ , as measured using mist chamber – ion chromatography (Talbot et al., 1997), to the  $\text{NO}_y$  budget is shown in Fig. 3, and discussed below. The observed range in gas-phase  $\text{NO}_y$  mixing ratio (200–400 pptv) is broadly consistent with the small set of previous observations of  $\text{NO}_y$  in the Pacific. Further, the vertical distribution of  $\text{O}_3$  and  $\text{NO}_y$  are correlated in the troposphere reflecting their coupled source and sink mechanisms.

The partitioning of  $\text{NO}_y$ , between  $\text{NO}_x$ ,  $\Sigma\text{PNs}$ ,  $\Sigma\text{ANs}$ ,  $\text{HNO}_3$ , and aerosol nitrate is shown in Fig. 3 as a function of altitude. Here, the fraction of  $\text{NO}_y$  in each altitude bin was calculated from the mean profile in each of the individual constituents. In the upper troposphere (above 10 km),  $\text{NO}_y$  is largely composed of  $\text{HNO}_3$ , due to transport of stratospheric air, rich in  $\text{HNO}_3$ , to the upper troposphere and the occasional sampling of purely stratospheric air in the Northern Pacific where the tropopause height (less than 10 km) is lower than the DC-8 aircraft ceiling (12.5 km). In the mid troposphere (4–10 km)  $\Sigma\text{PNs}$  comprise as much as 80 % of total  $\text{NO}_y$ . The dominance of  $\Sigma\text{PNs}$  in the  $\text{NO}_y$  budget is expected in the mid-troposphere due to their extended lifetime with respect to chemical, photolytic and heterogeneous removal processes (Talukdar et al., 1995) and the presence of sufficient VOC precursors of the peroxy acetyl radical. In the lower troposphere (below 4 km), the  $\Sigma\text{PN}$  fraction again decreases. This is a result of the strong temperature dependence in the PAN thermal dissociation rate constant,

Interactive Discussion

where the thermal lifetime of PAN (at 35° N) goes from 20 days at 6 km to approximately two days at 4 km (Fig. 4). As a result, PAN thermal dissociation represents a significant source of NO<sub>x</sub> to the remote troposphere. However, the NO<sub>x</sub> lifetime with respect to reaction with OH is short, thus NO<sub>x</sub> produced by ΣPN decomposition is converted to HNO<sub>3</sub> on the time scale of days. The large fraction of HNO<sub>3</sub> in the lower troposphere is likely a result of the oxidation of NO<sub>x</sub>, formed from the thermal dissociation of PAN in subsiding air-masses. However, we cannot rule out the possibility of direct HNO<sub>3</sub> transport from the Asian continent to the sampling region. In the presence of mineral dust aerosol, gas-phase HNO<sub>3</sub> readily reacts heterogeneously with CaCO<sub>3</sub> resulting in the sequestration of nitrate in the particle phase as shown in Fig. 3 (McNaughton et al., 2009).

### 3.2 Latitudinal gradients in ΣPNs

Latitudinal gradients in PAN have been observed previously in the lower troposphere (Singh et al., 1998; Heald et al., 2003; Hudman et al., 2004). This is due to the strong temperature dependence in the PAN thermal dissociation rate as shown in Fig. 4. At 2 km altitude, the PAN lifetime to thermal dissociation increases from 12 h at 30° N to over 10 days at 50° N, at which point photolysis becomes the dominant loss process. The effect of PAN thermal dissociation is shown clearly in the vertical distribution of NO<sub>y</sub> partitioning as a function of latitude. As shown in Fig. 3, ΣPNs comprise over 40 % of NO<sub>y</sub> from the surface to the tropopause north of 35° N. In contrast, southern samples (latitudes below 35° N) show a strong shift from the NO<sub>y</sub> budget being controlled by ΣPNs to being dominated by the sum of HNO<sub>3</sub> and particulate NO<sub>3</sub><sup>-</sup> at low altitudes, consistent with the profile shape of the PAN thermal dissociation rate.

## 4 Discussion

### 4.1 Implications of Rising NO<sub>y</sub> on Ozone Production Rates

The production rate of O<sub>3</sub> in the troposphere is primarily controlled by the cycling of NO<sub>x</sub> in the presence of volatile organic carbon (VOC), oxidants and sunlight. In order to accurately model current O<sub>3</sub> abundances and assess the impact of future control strategies, it is critical to attain a mechanistic understanding of the chemical processes that drive O<sub>3</sub> production in the troposphere.

Since the steady-state relationship of NO and NO<sub>2</sub> directly impacts both O<sub>3</sub> concentrations and our interpretation of the production and loss mechanisms that control its abundance, it is useful to think separately about the abundances of odd oxygen, O<sub>x</sub> = O<sub>3</sub> + NO<sub>2</sub> + O(<sup>3</sup>P) + O(<sup>1</sup>D), and to partition O<sub>x</sub> according to the steady-state relationships. To investigate the dependence of O<sub>x</sub> production on NO<sub>x</sub>, we calculate the instantaneous net O<sub>x</sub> production rate (ΔO<sub>x</sub>) directly from measurements of NO (chemiluminescence), NO<sub>2</sub> (LIF; Thornton et al., 2000), OH and HO<sub>2</sub> (LIF; Faloona et al., 2004), H<sub>2</sub>O (Diode laser hygrometer; Diskin et al., 2002), and O<sub>3</sub> (chemiluminescence; Fairlie et al., 2007), and calculations of O(<sup>1</sup>D) and RO<sub>2</sub> made using a photochemical box model constrained by observations of C1-C5 straight chain hydrocarbons, acetone, acetaldehyde, and peroxy nitrates using Eqs. 6–8 (Thornton et al., 2002).

$$\Delta O_x = P_{O_x} - L_{O_x} \quad (6)$$

$$P_{O_x} = k_{NO+HO_2}[NO][HO_2] + \sum_i k_{NO+RO_2(i)}[NO][RO_2(i)] \quad (7)$$

$$L_{O_x} = k_{OH+NO_2+M}[M][NO_2][OH] + k_{O(^1D)+H_2O}[O(^1D)][H_2O] \\ + k_{HO_2+O_3}[O_3][HO_2] + k_{OH+O_3}[OH] \quad (8)$$

The dependence of ΔO<sub>x</sub> on NO<sub>x</sub> is shown in Fig. 5a, where ΔO<sub>x</sub> is calculated from atmospheric measurements of the components defined in Eqs. (6)–(8), for all INTEX-B samples where the PAN lifetime was less than ten days. The frequency distribution of

Interactive Discussion

NO<sub>x</sub> mixing ratio is shown in Fig. 5b. While this analysis averages over a wide variety of chemical environments and VOC reactivity, it is instructive in describing the mean behavior of the lower troposphere over the remote pacific and its sensitivity to increasing NO<sub>x</sub> loadings.

5 As shown in Fig. 5a, ΔO<sub>x</sub> increases linearly with increasing NO<sub>x</sub>, exhibiting NO<sub>x</sub>-limited behavior over the entire sampling regime. In this low NO<sub>x</sub> regime, the crossover point between net O<sub>x</sub> destruction and net O<sub>x</sub> production, has been identified at around 60 pptv, consistent with the early work of Fishman et al. (1979). This key diagnostic is critical for assessing how future increases in NO<sub>x</sub> emissions will affect global O<sub>3</sub> abundances and illustrates the extreme sensitivity of the global O<sub>3</sub> budget to increasing  
10 NO<sub>x</sub>. As a result, quantifying the magnitude and spatio-temporal distribution of NO<sub>x</sub> and its transport and chemical evolution is crucial for modeling of tropospheric O<sub>3</sub>.

## 4.2 Intercontinental transport of reactive nitrogen

The extent to which the rapid increases in NO<sub>x</sub> emissions, observed over East Asia during the past decade (Richter et al., 2005; Q. Zhang et al., 2007), impact ozone production rates in the remote North Pacific and set the western boundary condition for North American regional air quality models is dependent on the chemical transformations that occur post emission and the export efficiency of NO<sub>y</sub> from the source region to the free troposphere. NO<sub>x</sub> emissions estimates over East Asia have been  
15 calculated using both top-down (Richter et al., 2005; L. Zhang et al., 2008; Walker et al., 2010) and bottom-up (Streets et al., 2003; Q. Zhang et al., 2009) techniques. Due to rapid increases in NO<sub>x</sub> emissions, we compare our observations with emission inventories that were calculated for the 2006 INTEX-B sampling period. Specifically, Zhang et al. (2009) estimated the total East Asian anthropogenic emissions of NO<sub>x</sub> to  
20 be 36.7 TgNO<sub>x</sub> yr<sup>-1</sup> for 2006, where 20.8 TgNO<sub>x</sub> yr<sup>-1</sup> were attributed to anthropogenic emissions in China. Using a top-down approach, L. Zhang et al. (2008) calculated that the 2000 TRACE-P East Asian anthropogenic NO<sub>x</sub> emissions inventory of Streets

Interactive Discussion

et al. (2003) ( $6.9 \text{ Tg Nyr}^{-1}$ ) needed to be increased by a factor of two to match 2006 OMI  $\text{NO}_2$  observations.

The fraction of reactive nitrogen emissions that leave the boundary layer is dependent on both the transport mechanism and the partitioning of reactive nitrogen between its soluble and insoluble forms. Measurements made during the TRACE-P field campaign in 2000 indicated that the time averaged export flux of  $\text{NO}_y$  across the  $130^\circ \text{E}$  meridional plane between  $30^\circ$  and  $40^\circ \text{N}$  was 8 % between 0 and 2 km and 10 % between 2 and 7 km (Koike et al., 2007). The measurements of Koike et al. indicate that a total of 18 % of emitted  $\text{NO}_y$  is transported out of the source region. Using a similar analysis applied to the East Coast of the US, Li et al. (2004) determined that 17 % of  $\text{NO}_x$  emissions were exported out of boundary layer.

During INTEX-B, the DC-8 sampled between  $25^\circ$  and  $55^\circ \text{N}$  in the region of  $135^\circ$ – $165^\circ \text{W}$  (Fig. 1a). This sampling domain is characterized by zonal flow from Asia to North America with higher wind speeds recorded at higher altitudes and in the Northern section of the sampling domain (Hudman et al., 2004). To calculate the flux of nitrogen across the North Pacific between  $25^\circ$  and  $55^\circ \text{N}$ , we first construct curtain plots from the mean values of the observed wind speed and gas-phase  $\text{NO}_y$  number density binned into 2 km altitude and  $5^\circ$  latitude bins. We then calculate the flux as the product of these two observable properties (Fig. 6). The total daytime flux through this window for the INTEX-B sampling period is  $0.007 \pm 0.002 \text{ Tg N day}^{-1}$ . The observed gas-phase  $\text{NO}_y$  flux is 10 %  $\text{NO}_x$ , 62 % total peroxyacyl nitrates, 5 % alkyl nitrates and approximately 23 % nitric acid. Particulate nitrate was not included in the above analysis due to sparse data coverage. Based on trajectory analysis, it is expected that the majority of Asian emissions lofted to the free troposphere pass through this sampling window. As a result, the calculated flux can be used as an upper limit to the product of the emission rate and export efficiency, as the observed  $\text{NO}_y$  is also impacted by other sources such as Siberian biomass burning and stratospheric exchange. Using the Zhang et al. bottom up inventory for East Asia ( $17.12 \text{ Tg Nyr}^{-1}$ ), our observation represents an upper limit of 15 % for the export of  $\text{NO}_y$  to the free troposphere.

### 4.3 NO<sub>x</sub> production rates

To investigate the chemical and thermal repartitioning of NO<sub>y</sub> in the INTEX-B sampling region, we calculate the diurnally averaged, altitude dependent NO<sub>x</sub> production rates (molecules cm<sup>-3</sup> s<sup>-1</sup>) from the thermal decomposition of ΣPNs and the photolysis and reaction of hydroxyl radicals with HNO<sub>3</sub> using our ambient observations coupled with the aforementioned time-dependent chemical box-model. As shown in Fig. 7, the fraction of NO<sub>x</sub> produced from ΣPNs is strongly altitude dependent, reflecting both the temperature dependence in the thermal decomposition rate and the concentration profile shown in Fig. 4. As a result, NO<sub>x</sub> production from HNO<sub>3</sub> becomes an increasing fraction of the total production rate with increasing altitude, accounting for nearly 30 % of in situ NO<sub>x</sub> production above 5 km. This further highlights the importance of accurate representation of HNO<sub>3</sub> in chemical transport models.

### 4.4 Role of episodic subsidence events in O<sub>3</sub> production

As discussed in Sect. 4.1, and shown in Eqs. 6–8, the net production rate of O<sub>3</sub> is not only dependent on the NO<sub>x</sub> mixing ratio, but can be significantly impacted by the scavenging of O(<sup>1</sup>D) radicals by H<sub>2</sub>O. As a result, we expect the most rapid net ozone production rates to be found in dry subsidence events where NO<sub>x</sub> concentrations are high and water vapor mixing ratios low. In Fig. 8, the vertical profile in atmospheric water vapor is shown colored by ozone (top), ΣPNs (middle) and net ozone production rate (bottom) as calculated using a time-dependent box-model. The observations were filtered to remove strong stratospheric influence (O<sub>3</sub>/CO > 1.25) and are for the Northern Pacific sampling domain (Latitude > 35° N). For comparison, the black hatched region in each panel corresponds to the range of conditions captured by the GEOS-CHEM model, sampled concurrently along the DC-8 flight track.

Both the calculated net ozone production rate, and the observed ozone mixing ratio indicate that rapid net ozone production (as high as  $5 \times 10^5$  molecules cm<sup>-3</sup> s<sup>-1</sup>) can occur at low water vapor mixing ratios, resulting in ozone concentrations that are on

average 19.4 ppb higher than the corresponding mean value at higher water vapor mixing ratios (e.g. mean  $\text{O}_3 = 73.2 \pm 14.4$  for measurements outside of the model domain, as compared to  $53.8 \pm 12.2$  for those within the model water vapor domain). Below 6 km, 14.7 % of the observations were outside the model  $\text{H}_2\text{O}$  domain. This analysis suggests that episodic dry subsidence events that are characterized by high net ozone production rates, a result of suppressed quenching of  $\text{O}(^1\text{D})$  at low water vapor mixing ratios, likely play an important role in the intercontinental transport of ozone and its precursors from East Asia to North America. Specifically, these observations suggest that accurate representation of low water vapor mixing ratios within subsiding plumes is required to replicate calculations of  $\Delta(\text{O}_3)$  as high as  $5 \times 10^5 \text{ molecules cm}^{-3} \text{ s}^{-1}$ .

## 5 Conclusions

The observations presented here provide experimental measures of the partitioning of reactive nitrogen in the remote Pacific and provide a novel opportunity to test model representations of the transport and chemical evolution of  $\text{NO}_y$  from the Asian continent. In agreement with previous studies, we find a dominant role for  $\Sigma\text{PNs}$  throughout the Pacific region, displaying a strong latitudinal dependence, consistent with the known temperature dependence in the thermal dissociation of PAN. The observations presented here reveal the extreme sensitivity of the remote North Pacific to future changes in  $\text{NO}_x$  loadings. Using simultaneous observations of speciated gas-phase  $\text{NO}_y$  and wind speed we calculate the net flux of reactive nitrogen through the meridional plane of  $150^\circ \text{W}$  to be  $0.007 \pm 0.002 \text{ Tg N day}^{-1}$ , providing an upper limit of 15 % on the export efficiency of  $\text{NO}_y$  from East Asia. Box-model calculations, constrained by in situ observations, indicate that net ozone production is rapid in dry subsidence events where  $\text{NO}_x$  concentrations are high and water vapor mixing ratios low, indicating that chemical transport models attempting to predict enhancements in net ozone production rates need to simultaneously predict increases in  $\text{NO}_x$  as well as decreases in  $\text{H}_2\text{O}$  mixing ratios in subsidence events.

## Appendix A

### Stratospheric influence

The observations presented here were first filtered to remove strong stratospheric influence ( $O_3/CO > 1.25$ ). Figure A1 shows a correlation plot of water vapor and CO illustrating the choice of the  $O_3/CO = 1.25$  threshold for distinguishing samples that have strong stratospheric origin.

# On the export of reactive nitrogen from Asia

T. H. Bertram et al.

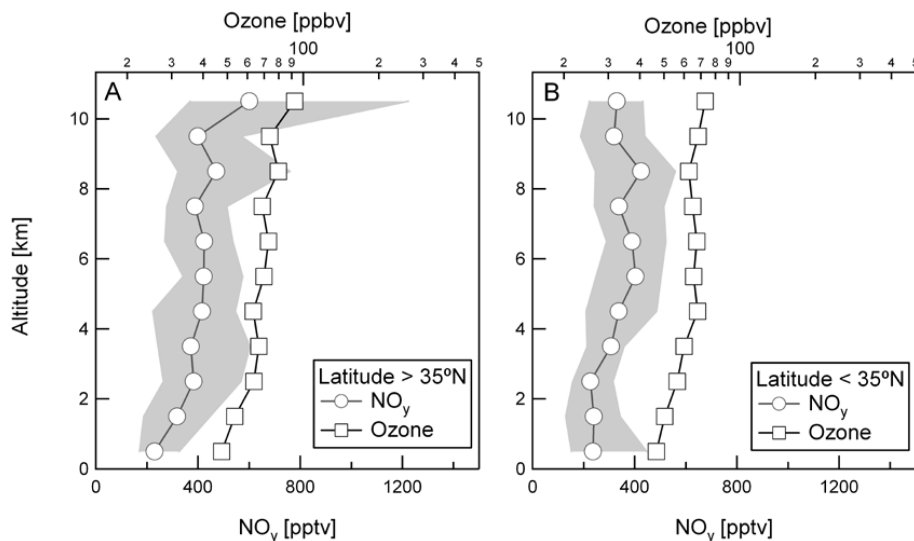

**Fig. 1.** Left panel: INTEX-B flight tracks made between 17 April 2006 and 15 May 2006 over the Northern Pacific Ocean. Sampling legs north of 35° N are shown in black, while legs south of 35° N are shown in grey. Right panel: observed mean temperature within 1 km altitude bins between 0–12 km divided into northern (black) and southern (grey) sampling bins. The dashed lines represent one standard deviation of the mean.

## On the export of reactive nitrogen from Asia

T. H. Bertram et al.

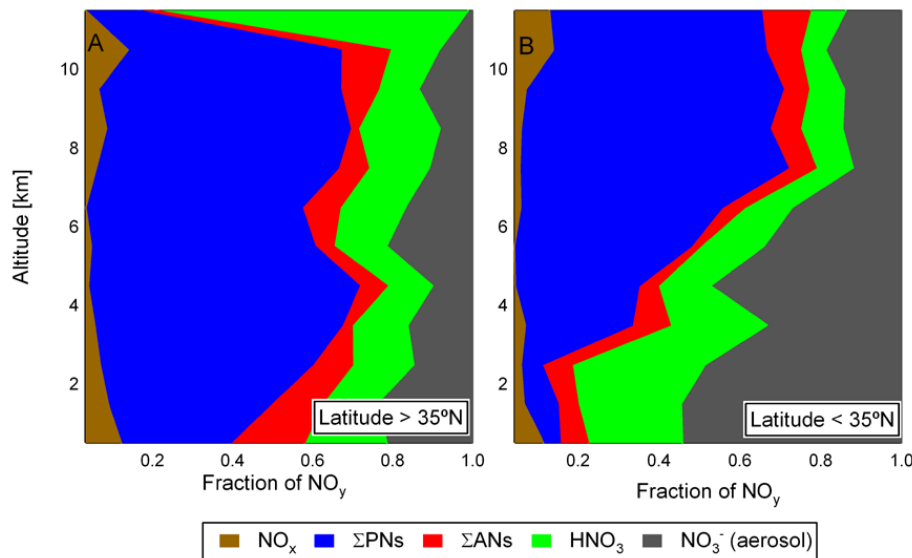

**Fig. 2.** Median vertical profile in ozone (black) and gas-phase  $\text{NO}_y$  (grey) ( $\text{NO}_y \equiv \text{NO}_x + \Sigma\text{PNs} + \Sigma\text{ANs} + \text{HNO}_3$ ) as observed during the INTEx-B field campaign over the North Pacific during the spring of 2006 (April–May), north of  $35^\circ\text{N}$  left panel and south of  $35^\circ\text{N}$  right panel. The solid line depicts the median value in 1 km altitude bins and the shaded regions represent the interquartile range.

# On the export of reactive nitrogen from Asia

T. H. Bertram et al.

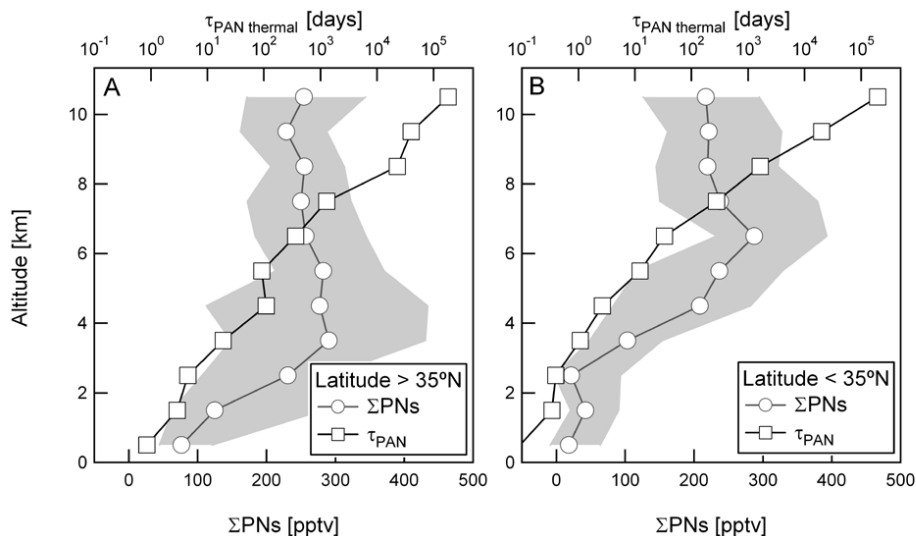

**Fig. 3.** Vertical distribution of the partitioning of reactive nitrogen ( $\text{NO}_y$ ) between  $\text{NO}_x$  (brown),  $\Sigma\text{PNs}$  (blue),  $\Sigma\text{ANs}$  (red),  $\text{HNO}_3$  (green) and particulate nitrate (grey) as observed during the INTEX-B field campaign over the North Pacific during the spring of 2006 (April–May), north of  $35^\circ\text{N}$  (A) and south of  $35^\circ\text{N}$  (B). The fraction of  $\text{NO}_y$  in each altitude bin was calculated from the median profile in each of the individual constituents.

## On the export of reactive nitrogen from Asia

T. H. Bertram et al.

**Fig. 4.** Median vertical profile in ΣPNs (grey, -o-) and PAN thermal lifetime ( $\tau_{\text{PAN}}$ ) (black, -□-) as observed during the INTEX-B field campaign over the North Pacific during the spring of 2006 (April–May), north of 35° N (left panel) and south of 35° N (right panel). The solid line depicts the median value in 1 km altitude bins and the shaded regions represent the interquartile range.

**Fig. 5.** Top panel: calculated instantaneous net ozone production rate as a function of  $\text{NO}_x$ . Bottom panel: observed frequency distribution of  $\text{NO}_x$  for air-masses where PAN lifetime ( $\tau_{\text{PAN}}$ ) is less than 10 days. Observations were filtered to strong remove stratospheric influence ( $\text{O}_3/\text{CO} > 1.25$ ) and are for the Northern Pacific (Latitude  $> 35^\circ \text{N}$ ).

**Fig. 6.** Daytime flux of reactive nitrogen ( $\text{g N m}^{-2} \text{ day}^{-1}$ ) calculated using all available observations of gas-phase  $\text{NO}_y$  and wind-speed gridded into  $5^\circ \text{ latitude} \times 2 \text{ km altitude}$  bins. Observations were filtered to strong remove stratospheric influence ( $\text{O}_3/\text{CO} > 1.25$ ).

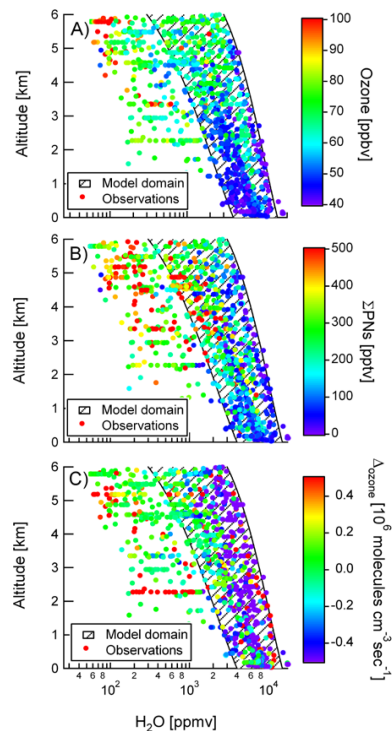

# On the export of reactive nitrogen from Asia

T. H. Bertram et al.

**Fig. 7.** Diurnally averaged  $\text{NO}_x$  production rates (molecules  $\text{cm}^{-3} \text{s}^{-1}$ ) from nitric acid (left) and  $\Sigma\text{PNs}$  (center) as a function of altitude. The fraction of  $\text{NO}_x$  production from each channel is shown in the right panel. Observations were filtered to strong remove stratospheric influence ( $\text{O}_3/\text{CO} > 1.25$ ) and are for the Northern Pacific (Latitude  $> 35^\circ \text{N}$ ).

**Fig. 8.** Vertical profile in atmospheric water vapor, color coded by ozone (top),  $\Sigma$ PNs (middle) and net ozone production rate (bottom) as calculated using a time-dependent box-model. The black hatched region in each figure corresponds to mean conditions captured by chemical transport models. Observations were filtered to remove strong stratospheric influence ( $O_3/CO > 1.25$ ) and are for the Northern Pacific (Latitude  $> 35^\circ$  N).

**Fig. A1.** Correlation plot of water vapor and carbon monoxide for the entire INTEX-B sampling domain. Observations that suggest strong stratospheric influence ( $O_3/CO > 1.25$ ) were removed from the analysis.
