Abstract

Sulfur dioxide (SO₂) is a major atmospheric pollutant with a strong anthropogenic component mostly produced by the combustion of fossil fuel and other industrial activities. As a precursor of sulfate aerosols that affect climate, air quality, and human health, this gas needs to be monitored on a global scale. Global climate and chemistry models including aerosol processes along with their radiative effects are important tools for climate and air quality research. Validation of these models against in-situ and satellite measurements is essential to ascertain the credibility of these models and to guide model improvements. In this study the Goddard Chemistry, Aerosol, Radiation, and Transport (GOCART) module running on-line inside the Goddard Earth Observing System version 5 (GEOS-5) model is used to simulate aerosol and SO₂ concentrations. Data taken in November 2010 over Frostburg, Maryland during an SO₂ field campaign involving ground instrumentation and aircraft are used to evaluate GEOS-5 simulated SO₂ concentrations. Preliminary data analysis indicated the model overestimated surface SO₂ concentration, which motivated the examination of mixing processes in the model and the specification of SO₂ anthropogenic emission rates. As a result of this analysis, a revision of anthropogenic emission inventories in GEOS-5 was implemented, and the vertical placement of SO₂ sources was updated. Results show that these revisions improve the model agreement with observations locally and in regions outside the area of this field campaign. In particular, we use the ground-based measurements collected by the United States Environmental Protection Agency (US EPA) for the year 2010 to evaluate the revised model simulations over North America.

1 Introduction

Sulfur dioxide (SO₂) is a trace gas which poses significant health threats near the surface, with consequences on human health (Ware et al., 1986; US EPA, 2011) and

Interactive Discussion

on the ecosystem acidification (Schwartz, 1989). With a mean lifetime of few days in the troposphere (Lee et al., 2011; He et al., 2012), emitted SO₂ is quickly oxidized to form sulfate aerosols. The resulting aerosols exert influences on the atmospheric radiative balance and cloud microphysics (e.g., McFiggans et al., 2006). SO₂ is emitted into the atmosphere mainly from anthropogenic sources such as fossil fuel combustion and industrial facilities. In the US these emissions represent more than 90% of SO₂ released into the air (US EPA, 2011). Since the implementation of national environmental regulations (e.g. 1990 Clean Air Act Amendments in the United States), a significant decrease of these emissions has been observed over the past 30 yr. To keep track of SO₂ emissions, this gas is monitored throughout the country by a system of continuously sampling ground-based instruments, and also by episodic intensive field campaigns. These campaigns are particularly valuable because the instruments deployed on the ground and from aircraft give not only the opportunity to validate and improve the ability of space-based instruments to monitor air pollutants, but also provide the opportunity to evaluate chemical transport models that simulate the SO₂ and sulfate lifecycle (Chin et al., 2000b; Easter et al., 2004; Liu et al., 2005; Goto et al., 2011). Generally, the studies above found that modeled SO₂ concentrations at the surface were overestimated over Europe and North America, which could be attributed to too high SO₂ emission rates or deficiencies in SO₂ losses due to oxidation. Also, uncertainties in the model surface fields may be different from the total column, and must be evaluated separately. For example, in the GEOS-5 global model it is possible to constrain the total column aerosol loading through assimilation of aerosol optical depth (AOD) from satellite observations. Assimilation of AOD, however, does not correct errors in either aerosol vertical placement or composition, so it remains important to evaluate these aspects of the model. Here we focus particularly on the surface SO₂ and sulfate concentrations. The purpose of this paper is to take advantage of the data measured during the Frostburg field campaign held in Maryland during November 2010 to evaluate the SO₂ simulated with the GEOS-5/GOCART model. We first describe in Sect. 2 the aerosol model and give a brief description of the SO₂ sources and the

chemical processes considered within the model. In Sect. 3 we start by validating the modeled SO_2 at the surface over the continental US using the data collected by EPA. In Sect. 4 we evaluate the GEOS-5 simulated SO_2 with measurement data taken during the campaign. Section 5 reports the conclusions.

2 Representation of Aerosols in the GEOS-5 Earth Modeling System

The Goddard Earth Observing System version 5 (GEOS-5) model, the latest version from the NASA Global Modeling and Assimilation Office (GMAO), is a weather and climate capable model described by Rienecker et al. (2008). The GEOS-5 system includes atmospheric circulation and composition, oceanic and land components. By including an aerosol transport module based on the Goddard Chemistry Aerosol Radiation and Transport (GOCART) model (Chin et al., 2002), GEOS-5 provides the capability of studying atmospheric composition and aerosol–chemistry–climate interaction (Colarco et al., 2010). In addition to providing reanalyses of traditional meteorological parameters (winds, pressure and temperature fields, Rienecker et al., 2008), the inclusion of aerosols provides the background information for GEOS-5 to produce reanalyses of aerosol fields using retrieved AOD from the space-based instrument Moderate Resolution Imaging Spectroradiometer (MODIS). The GEOS-5 near-real time system runs at a nominal 25 km horizontal resolution with 72 vertical levels between the surface and about 80 km. For this study, the model was run at various horizontal resolutions, $0.25^\circ \times 0.315^\circ$ with sensitivity experiments also carried out at $0.5^\circ \times 0.625^\circ$ latitude by longitude.

GEOS-5 can be run in climate simulation, data assimilation, or replay modes. In the data assimilation mode, a meteorological analysis is performed every six hours to constrain the meteorological state of the model. In the replay mode, a previous analysis, generated with the same version of model, is used to adjust the model's meteorological state much like a Chemical Transport Model (CTM) with the difference that in GEOS-5 the aerosol transport dynamics are entirely consistent with the model

Interactive Discussion

thermodynamical state at every time step between analysis updates. For this study GEOS-5 is run in replay-mode using the GMAO atmospheric analyses from the Modern Era Retrospective analysis for Research and Applications (MERRA) (Rienecker et al., 2011) available every six hours.

5 The GOCART module simulates five aerosol types: dust, sea salt, black carbon, organic carbon and sulfate aerosol. The sulfur chemistry processes considered are based on Chin et al. (2000a). Sulfate aerosol is mostly formed from the oxidation of SO₂. All simulations include emissions of dimethylsulfide (DMS), SO₂ and sulfate and we use prescribed oxidant fields (hydroxyl radical (OH), nitrate radical (NO₃) and hydrogen peroxide (H₂O₂)) from a monthly varying climatology produced from simulations
10 in the NASA Global Modeling Initiative (GMI) model (Duncan et al., 2007; Strahan and Douglas, 2004). A small amount of SO₂ is produced by the oxidation of DMS, which is emitted naturally from marine phytoplankton. We use a monthly varying climatology of oceanic DMS concentrations (Kettle et al., 1999), with emissions calculated using
15 the surface wind-speed dependent (Liss and Merlivat, 1986) parameterizations of air-ocean exchange processes. The main source of SO₂ is anthropogenic, mainly from fossil fuel combustion from power plants and industrial activities (US EPA, 2011).

Figure 1 maps the emissions of SO₂ released from coal fired power plants (in tons) over the US in 2007. In this study, two different data sets of anthropogenic emissions and two assumptions about the injection height are considered in our simulations to
20 assess the effect of the emissions on SO₂ surface concentration. At the time of the campaign, the annual anthropogenic emissions of SO₂ were taken from Streets et al. (2009). In the GEOS-5 control simulation (replay-mode), this emission was injected into the lowest model level. All simulated results using this configuration are hereafter
25 called the “Control Run” or CR.

Recently, a new Emission Database for Global Atmospheric Research (EDGAR) version v4.1 dataset (European Commission, 2010) became available at 0.5° horizontal resolution and has the advantage of providing the 2005 anthropogenic emissions of SO₂ by source categories. This new set of emissions allowed us to emit the non-

energy emissions (from transportation, manufacturing industries, residential) into the lowest GEOS-5 layer and the energy emissions from power plants at higher levels between 100 and 500 m (between the 2nd and 4th model layers). The results (using a replay simulation) are herein referred to as the “Revised Run” or RR.

5 Figure 2 shows a comparison of the SO₂ anthropogenic emissions by source category: energy-source sector and non-energy-source sector, based on the EDGAR 2005 database as used in our revised simulation. Most SO₂ emissions are released from power plants, so it is important to consider the emission injection above 100 m due to the stack height and plume rise. We assume these emissions are constant throughout the year. Furthermore, other anthropogenic emissions include aircraft and ship traffic
10 emissions from Mortlock et al. (1998) and Eyring et al. (2005) respectively. We assume 3% of the SO₂ anthropogenic emissions are directly emitted as sulfate. All the simulations include also biomass burning emissions of SO₂ following the Quick Fire Emission Dataset (QFED) inventory and SO₂ emissions from continuously eruptive volcanoes that are based on data from the Global Volcanism Program database (Siebert et al.,
15 2002) and Total Ozone Mapping Spectrometer (TOMS) and Ozone Monitoring Instrument (OMI)’s SO₂ retrievals (Carn et al., 2003; Krotkov et al., 2006) while emissions from explosive volcanoes follow the Aerocom inventories (Dentener et al., 2006). SO₂ is removed in the atmosphere by dry and wet deposition and oxidized to sulfate by
20 chemical reaction. The main oxidation pathways for SO₂ are the gas phase oxidation by OH and aqueous phase oxidation by H₂O₂ (Chin et al., 2000a), with the aqueous chemistry driven by the GEOS-5 cloud fraction and precipitation, which have been evaluated separately in (Molod et al., 2012). We save the model tracer fields every three hours during our simulation. Figure 3 shows results of the simulated SO₂ surface concentrations for January and July 2010. The highest SO₂ concentrations are found over
25 eastern Asia, Europe, and North America, which are major anthropogenic source regions. SO₂ concentrations are higher during the winter; this seasonal variation can be explained by the seasonal SO₂ oxidation rates, which are slower in winter than in the summer (Chin et al., 2000b). The planetary boundary layer (PBL) dynamics is also re-

sponsible for this seasonal cycle of SO₂ concentrations. Figure 4 shows an evaluation of the GEOS-5 simulation of the SO₂ lifetime in black by comparison with the analysis made by Lee et al. (2011) with the GEOS-Chem chemical transport model in red and in-situ measurements-based lifetime in blue. The mean SO₂ lifetime from GEOS-5 simulations are calculated over the eastern US (35.2° N–44.5° N, 68.4° W–81.6° W) and during daytime as Lee et al. (2011) but for the year 2010. The seasonal variation of the SO₂ lifetime from GEOS-5 is globally consistent with the seasonal variation found with the GEOS-chem model and the in-situ measurements. While the mean SO₂ lifetime from GEOS-chem are generally shorter than the in-situ measurement-based lifetime, the mean SO₂ lifetime from GEOS-5 simulations are generally higher than the in-situ measurements, except during the winter. However, the GEOS-5 SO₂ lifetime values are quite close or within the range defined by the uncertainty interval of in-situ measurements. The differences in the transport and in the emissions are among the possible reasons that may explain the discrepancy with the GEOS-Chem model. In addition the oxidant fields in GEOS-5 are not interactive and depend instead on fields from a different model from a different period.

3 Model comparison to EPA surface measurements

In this section we evaluate the modeled surface concentrations of SO₂ and sulfate over the US for the control and revised runs for the year 2010. For this study we used data collected by EPA, local and state control agencies which maintain air quality monitoring networks over the US available from the EPA Air Quality System (AQS) (US EPA, 2010).

3.1 Sulfur dioxide

Figure 5 shows the SO₂ daily mean comparisons for the control run (top) and the revised run (middle). The “EPA” daily averages of SO₂ concentration were calculated using hourly concentrations collected from 102 sites obtained from the EPA AQS. A ker-

Interactive Discussion

nel density estimation (KDE) (Silverman, 1986; Scott, 1992) was applied to approximate the joint probability density function (PDF) of observed and modeled SO₂ daily mean surface concentrations. Since SO₂ is usually lognormally distributed, the correlation coefficient r , the Root Mean Square of the differences (GEOS-5-EPA) (RMS), the standard deviation (STDV) and the mean differences are calculated for logarithmically transformed data (summarized in Table 1 as well as the parameters in the original units calculated using the equations described in Limpert et al., 2001 (Appendix A)). For both plots, the scatter between modeled and observed daily means is significant with correlation coefficients, $r = 0.49$ and $r = 0.42$ for the control and revised run respectively. However, the agreement between the observed and modeled daily mean is better with the revised run, with lower values for the RMS and the mean difference. The STDV is almost the same for both the control and revised runs. One of the reasons for this discrepancy might be attributed to the change in absolute magnitude of the SO₂ emissions datasets used in the control and revised runs, but we noticed only small differences between the two datasets. Another plausible explanation is the emission injection height considered in the model. The vertical placement of emissions in the revised run decreases the high bias between observations and simulations at the surface. The remaining bias between observations and revised model SO₂ simulations may be explained by the error of representativeness associated with the incompatibility between in-situ measurements and grid-box mean values predicted by the model. As an attempt to filter out the in-situ measurements that are very unrepresentative of the grid-box mean conditions, the bottom plot of Fig. 5 presents the results after a statistical quality control was performed with the adaptive buddy check of Dee et al. (2001). For a given observation, this method consists of looking at nearby model-observations discrepancies and discarding those observations that cannot be corroborated by their neighbors. A brief summary of the algorithm is given in Appendix B. After removing observations that failed this adaptive buddy check (Fig. 5, bottom plot), the new comparison is quite improved with r that increased and is equal to 0.66 and lower values of the RMS, SDTV and the mean difference. The explanation for the remaining bias observed after the

quality control could be the year (2005) of the emission dataset with emissions too high for the year 2010. According to EPA (e.g., <http://www.epa.gov/air/airtrends/sulfur.html>) the average SO₂ concentrations have decreased substantially over the years because of the application of SO₂ control measures. Based on 341 US monitor sites, a 60 % decrease in national average was found between 2000 and 2010. If we look site by site, Fig. 6 presents the change in the r (top), the STDV(middle) and the absolute value of the mean difference (bottom) between modeled and observed daily averaged surface SO₂ for the control run on the left, the revised run in the middle and after the buddy check on the right. While the correlation coefficient increased from values lower than 0.4–0.6 for the control run to values greater than 0.6 after the buddy check, we see that the STDV increased over New England and slightly decreased elsewhere for the revised run, the decrease is more significant after the buddy check. Concerning the absolute value of mean difference, we notice a decrease more and more significant between the control, the revised run and after the buddy-check.

3.2 Sulfate aerosol

Figure 7 shows comparisons similar to the ones on Fig. 5, but for sulfate. The daily means are directly provided by the EPA AQS and are available every one, three or six days for a total of 250 sites. Figure 7 includes also a comparison with the sulfate simulated with the GEOS-5 aerosol assimilation system, assimilation of MODIS AOD in the revised version of the model has been performed. On average the modeled sulfate concentrations are higher than the observations, regardless of the model or data assimilation system used. The values of r , the RMS, STDV and the average differences are slightly different for the control, revised simulations and the reanalysis (summarized in Table 2). This suggests that the SO₂ emissions injections as well as the assimilation of AOD observations into the model have a low impact on the daily mean sulfate comparisons. Like for the SO₂ study, the measurements have been quality controlled using the buddy-check scheme (Fig. 7), permitting an increase r from 0.71 to 0.79, the RMS, the STDV and the mean difference have been divided by almost a factor 2. Cou-

pled with the longer lifetime of SO₂ in Figs. 4 and 5 and, hence, too slow production of sulfate, our results suggest we may strongly underestimate the losses of sulfate aerosol. When looking site by site (Fig. 8), while the values of r decrease with the revised simulations for some sites, the application of the buddy check lead generally to greater and significant correlation coefficient values; the STDV values have not really changed between the control and revised runs but the values tend to decrease after the buddy check. Finally we see also an improvement in the absolute values of the mean differences after the revised and more importantly after the buddy check simulations.

4 Evaluation of SO₂ in the model: comparison with measurement data during the Frostburg campaign in Maryland

In Sect. 4 we concentrate our evaluation of the model performance in a smaller region using data collected during an air quality campaign in western Maryland in November 2010. The Frostburg campaign was a regional air quality campaign conducted by investigators from Washington State University (WSU), the University of Maryland (UMD) and the NASA Goddard Space Flight Center (GSFC) during two weeks in November 2010. The campaign took place in Western Maryland and provided direct measurements of SO₂ among other atmospheric constituents. The interest of this region is based on the abundance of SO₂ from the Ohio River Valley, surrounded by several power plants (Fig. 9). In this section, we make use of several data sets available during this campaign to evaluate the anthropogenic SO₂ concentration simulated by GEOS-5.

4.1 Surface analysis: comparisons at Piney Run Station

The observed and simulated monthly mean SO₂ at the surface at Piney Run station are shown in Fig. 10. This site is located in a mountain valley close to Frostburg, and is an ideal location for SO₂ monitoring due to its close proximity to power plants stations,

with the nearest one, Warrior Run, located south of Cumberland. Globally, the model captures the observed month-to-month variability of SO₂ with a winter maximum for both the control run in red and the revised run in black, as stated in Sect. 2, the oxidation rates and the PBL dynamics are responsible for this seasonal variation.

In the control run (the red line in Fig. 10), we see that the model overestimates the observed SO₂ values by a factor of 4–5. This result is consistent with the general findings of Sect. 3: the revised vertical placement of SO₂ emissions has a positive impact on the simulated surface values of SO₂. This is shown with the revised run (in black) where the model values are in better agreement with the observations and the overestimation is less than a factor 2. Like seen previously, an explanation of the positive bias remaining might be attributed to the 2005 emissions inventory and the recent decreasing trend of SO₂ pollution over the US noted by EPA. In particular in Piney Run, the concentrations of SO₂ decreased 50 % between 2006 and 2010.

Figure 11 shows the comparison of the daily mean SO₂ surface concentrations to the measurements at Piney Run during 2010. Again, we see the better agreement between the revised run and the observations.

4.2 Column amount analysis: comparisons to a MF-DOAS instrument

Simulated SO₂ column amount is evaluated with measurements from the Multifunction Differential Optical Absorption Spectroscopy (MFDOS) instrument developed at WSU (Herman et al., 2009; Spinei et al., 2010), deployed on the roof of a building at Frostburg State University (FSU) for the campaign. This instrument measures the direct sun irradiance and scattered sunlight in spectral UV and visible wavelengths 281–498 nm at 0.83 nm spectral resolution recorded simultaneously with a CCD detector in the spectrograph focal plane. Analysis of the measured spectra is done using the DOAS technique which is based on the Beer–Lambert law which states that the relationship at a wavelength between the intensity of the incident solar light and the transmitted one attenuated due to absorption and scattering by aerosols and molecules in the atmosphere (e.g., Platt, 1994; Plane and Smith, 1995). SO₂ column density is measured

Interactive Discussion

with an uncertainty less than 0.03 DU. A description of this instrument as well as the DOAS technique can be found in Spinei et al. (2010). Figure 12 shows the comparison between the column density measured by the MFDOAS and simulated by GEOS-5 during daylight hours from 13:30 UTC until 21:00 UTC on 8 and 9 November. We notice that changing from one emission dataset to the other shows not much change on the total column amount between the two runs; it confirms the small changes in the absolute magnitude of the SO₂ emissions between the two datasets. Accounting for the uncertainty on the ground-based instrument, the comparison is rather satisfying with both the control and revised run but we notice that the model does not reproduce the observed diurnal variations. Besides the lack of diurnal variation in the prescribed emissions, an explanation might be the spatial resolution of the model (~ 25 km) and the offset pointing of the MFDOAS instrument when looking at the sun.

4.3 Vertical analysis: comparisons to aircraft measurements

The GEOS-5 simulated vertical distribution of SO₂ is compared to aircraft measurements conducted on two different days during the campaign. The flights were made on the UMD Cessna 402B aircraft, which was equipped with a modified pulse-fluorescence instrument to measure the in situ SO₂ concentration (Taubman et al., 2006). The aircraft flight path on 8 November is shown on Fig. 9. Important regional power plants are marked by yellow circles in Fig. 9, with the size of the circle indicating the magnitude of SO₂ emissions. 8 November 2010 featured sustained winds as high as 29 km h⁻¹ with gusts to 45 km h⁻¹ around the time of the flight. 9 November 2010 was considerably calmer, with sustained winds under 19 km h⁻¹ and gusts noted over Cumberland around the time of the flight. These information were recorded at the airport, which is not an official National Weather Service reporting station, but they were also backed up by the informal observations of the airplane's crew. Both flights lasted about two hours and were characterized by spiraling climbs and descents over Frostburg (39.65° N–78.93° W) and Cumberland, Maryland (39.62° N–78.77° W). Figure 13 shows the simulated vertical profile of SO₂ for the control (left) and revised (middle)

Interactive Discussion

The improvement in our treatment of the SO₂ anthropogenic emissions was confirmed with the analysis performed over the US using the EPA ground-based measurements.

The comparisons of the vertical profile with aircraft data showed that despite the spatial coarse resolution of GEOS-5, most of the major features of the aircraft observations were reproduced by the model on 8 November because the weather was dynamic with turbulent mixing and strong winds. In contrast the analysis on 9 November shows that during quiet days, GEOS-5 will have difficulty of detecting plumes, especially in the vicinity of point source. Concerning the GEOS-5 simulated sulfate, the comparisons with the EPA data show that the changes in the SO₂ emissions dataset and vertical distribution did not affect much the simulation of the sulfate at the surface, the positive bias observed with the control run remains with the revised run. These comparisons suggests that there might have an underestimated loss of sulfate in the model. A full analysis of the chemical processes could not be performed with the available data and there is a possibility that part of this process could also explain part of the bias remaining in the SO₂ and sulfate comparisons.

Appendix A

The lognormal distribution

A random variable X is lognormally distributed if $Y = \log X$ has a normal distribution. The mean \bar{X} and the standard deviation s_X of the normal variable are related to the \bar{Y} and s_Y of the lognormal variable by (Limpert et al., 2001):

$$\bar{X} = \exp(\bar{Y} + s_Y^2/2) \quad (\text{A1})$$

$$s_X = \bar{X} \sqrt{\exp(s_Y^2 - 1)} \quad (\text{A2})$$

Appendix B

Adaptive buddy check

In the buddy-check algorithm of Dee et al. (2001), first a background check is performed where differences between the observed and modeled daily means are analyzed in order to identify a set of suspect observations, given a specified tolerance. An iterative buddy-check is then performed on each suspect observation using the remaining reliable observations (called “buddies”) within a specified radius to perform a refined acceptance test. The tolerance used for this buddy check is adaptive in the sense that current values of the observation minus model departures are used as a local modulator of the innovation variances used in the threshold test. Notice that before applying the buddy check the observation-model departures must be unbiased by removing the mean value. Figure B1 shows the PDF of the points removed after the buddy check is performed for SO₂. Although in some cases GEOS-5 simulates lower SO₂ surface values than the ground-based measurements, the majority of points removed after the buddy check are due of an overestimation of the GEOS-5 simulations compared to EPA measurements. While misplacement of plumes by the model could account for some large discrepancies that would be flagged by the buddy check, there is no reason to expect that these discrepancies would be of a given sign. Therefore, the positive bias of the removed observations may point to excessive emissions by GEOS-5 at specific locations.

Acknowledgements. The campaign participants want to acknowledge significant logistical support from Dr. J. Hoffman (dean of Sciences) and the operations staff at Frostburg State University. WSU acknowledges NASA grant NNX09AJ28G for instrument development and deployment. The authors would like to thank Lacey Brent, flight scientist, for collecting the aircraft data.

Evaluation of GEOS-5
SO₂ simulations

V. Buchard et al.

Fig. 5. Comparison of daily averaged surface SO₂ concentration in 2010 for 102 EPA sites. The model results are from the control run (top), the revised run (middle) and after the adaptive buddy check of Dee et al. (2001) was performed on the model revised simulations (bottom) (RR/bc).

Evaluation of GEOS-5
SO₂ simulations

V. Buchard et al.

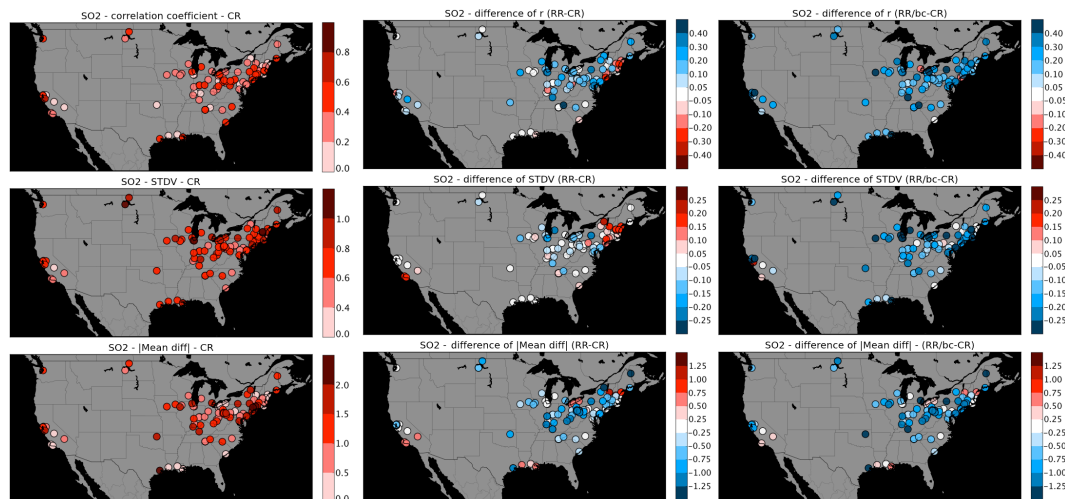

Fig. 6. The first column is r , the STDV and the absolute value of the mean difference between the modeled (control run) and observed daily averaged SO₂ surface concentrations for each SO₂ EPA site in 2010. The second column is the change in r , STDV, and absolute value of the mean difference for the revised run relative to the control run. The third column is the same, but showing the difference between the revised run (with buddy check of Dee et al., 2001) and the control run. The color coding in the second and third column is such that blue indicates improvement relative to the control run.
