7

8 **Abstract**

9

10 We apply an off-line process-based vegetation model (the Yale Interactive Terrestrial

11 Biosphere model) to assess the impacts of ozone (O_3) vegetation damage on gross

12 primary productivity (GPP) in the United States during the past decade (1998-2007). The

13 model's GPP simulation is evaluated at 40 sites of the North American Carbon Program

14 (NACP) synthesis. The ecosystem-scale model version reproduces interannual variability

15 and seasonality of GPP at most sites, especially in croplands. Inclusion of the O_3 damage

16 impact decreases biases of simulated GPP at most of the NACP sites. The simulation

17 with the O_3 damage effect reproduces 64% of the observed variance in summer GPP and

18 42% on the annual average. Based on a regional gridded simulation over the U.S.,

19 summertime average O_3-free GPP is 6.1 g C m^{-2} day^{-1} (9.5 g C m^{-2} day^{-1} in the East of

20 95°W and 3.9 g C m^{-2} day^{-1} in the West). O_3 damage decreases GPP by 4-8% on average

21 in the eastern U.S. and leads to significant decreases of 11-17% in east coast hotspots.

22 Sensitivity simulations show that a 25% decrease in surface O_3 concentration halves the

23 average GPP damage to only 2-4% suggesting the substantial co-benefits to ecosystem

24 health that may be achieved via O_3 air pollution control.

30

1 Introduction

The effects of tropospheric ozone (O_3) damage on U.S. forests have been studied for half a century (Karnosky et al., 2007), but the impacts of O_3 on the North American carbon balance are still relatively poorly understood (Felzer et al., 2004; Huntingford et al., 2011). O_3 is a secondary pollutant produced in the troposphere during the photochemical oxidation of carbon monoxide, methane, and volatile organic compounds (VOCs) by the major tropospheric oxidant, the hydroxyl radical, in the presence of sunlight and nitrogen oxides. Fossil-fuel, biofuel and biomass burning since the industrial and agricultural revolutions have greatly increased the emissions of O_3 precursors and led to an approximate doubling of O_3 levels over the U.S. since the preindustrial. Deposition through stomatal uptake is an important sink for O_3 but damages photosynthesis, reduces plant growth and biomass accumulation, limits crop yields, and affects stomatal control over plant transpiration of water vapor between the leaf surface and atmosphere (Ainsworth et al., 2012; Hollaway et al., 2012).

Understanding the O_3 pollution influence on the North American forest sink is crucial to any effort to mitigate climate change by stabilizing atmospheric carbon dioxide (CO_2) concentrations. Currently, North America is acting as a net source of CO_2 to the atmosphere (King et al., 2012). Sequestration of atmospheric CO_2 by forest ecosystems is a major control on atmospheric CO_2 abundance and its growth rate (Pan et al., 2011). Terrestrial ecosystems of North America absorb the equivalent of about 35% of North America's fossil fuel based CO_2 emissions, representing a source-to-sink ratio of nearly 3:1. Forest regrowth in the U.S. is responsible for 30–70% of this North American CO_2 sink, which varies significantly from year to year (Pacala et al., 2001; Goodale et al., 2002; Pan et al., 2011; King et al., 2012). Worse still, there is evidence that the summer continental U.S. is more sensitive than other world regions to climate forcing (Levy et al., 2008).

Experimental studies that examine O_3 impacts on plant productivity are typically performed for individual vegetation types, on the scale of sites, and within a limited time

62 period (e.g. Wittig et al., 2007; Feng et al., 2008; Lombardozzi et al., 2013). For example,

63 based on measurements reported from over 100 studies, Wittig et al. (2007) estimated

64 that chronic O_3 exposure depressed photosynthesis by 11% and stomatal conductance by

65 13% for several tree species at the ambient O_3 level of ~45 ppbv relative to that in O_3-

66 free air. The O_3 damage effect is strongest for crops. With datasets from ~50 peer-

67 reviewed studies, Feng et al. (2008) estimated that elevated O_3 levels significantly

68 decrease wheat photosynthetic rates by 20% and stomatal conductance by 22%.

69 Emerging research has found that the O_3 vegetation damage effects may result in a loss of

70 plant stomatal control, and a consequent decoupling of the stomatal response from

71 photosynthesis inhibition (Lombardozzi et al., 2012a, 2012b, 2013).

72

73 Previous work has found that in the U.S. region during 1989-1993, O_3 pollution reduced

74 net primary productivity (NPP) by 3-7% overall, and up to 13% in hotspots including the

75 southeast and in the Midwest agricultural lands (Felzer et al., 2004, 2005). The indirect

76 CO_2 radiative forcing due to the vegetation damage effects of anthropogenic O_3 increases

77 since the industrial revolution may be as large as +0.4 Wm^{-2} (Sitch et al., 2007), which is

78 25% of the magnitude of the direct CO_2 radiative forcing over the same period, and of

79 similar magnitude to the direct O_3 radiative forcing. Through this perturbation of the

80 carbon cycle, O_3 pollution affects the climate system on considerably longer timescales

81 than its own atmospheric lifetime (Unger and Pan, 2012). Over the past decade since this

82 previous assessment surface O_3 levels in most of the U.S. have decreased (Lefohn et al.,

83 2010) due to domestic emission reductions following the implementation of air quality

84 control legislation (Bloomer et al., 2010). However, increasing O_3 concentration is

85 observed over western U.S. (Jaffe and Ray, 2007). Such a trend may in part be related to

86 the inter-continental flow from Asia (Cooper et al., 2010) and the global increase in

87 methane (Rigby et al., 2008).

88

89 The major goal of this study is to assess O_3 damage effects on gross primary productivity

90 (GPP) in the U.S. for the recent decade 1998-2007 using a data-constrained vegetation

91 model. In this work, we describe the implementation of a semi-mechanistic O_3 damage

92 function (Sitch et al., 2007) into the **Y**ale **I**nteractive Terrestrial **Bio**sphere model (YIBs)

93   that includes enzyme-kinetic biophysics (Unger et al., 2013). In the first stage of the

94   study, we utilize eddy-derived GPP flux measurements at 40 sites across the U.S. and

95   Canada that have been collated for the North American Carbon Program (NACP) site-

96   level interim synthesis (Huntzinger et al., 2012; Schaefer et al., 2012; Barr et al., 2013;

97   Ricciuto et al., 2013) to evaluate an off-line version of the vegetation model's site level

98   GPP simulation and to assess the impact of surface O_3 damage at those sites. In the

99   second stage of the study, the impacts of O_3 damage on GPP throughout the entire U.S.

100   region are quantified using a regionally distributed configuration of the vegetation model.

101

102   **2 Methodology and data**

103

104   **2.1 Vegetation biophysics**

105

106   Here, we apply an off-line version of the YIBs model that previously was implemented

107   into the NASA Goddard Institute for Space Studies global chemistry-climate model

108   (Unger et al., 2013). The off-line model can be run at the site-level or in distributed mode

109   for a designated region. The vegetation biophysics module computes the photosynthetic

110   uptake of CO_2 coupled with the transpiration of water vapor at the 1-hour physical

111   integration time step of the off-line model. The vegetation biophysics calculates C3 and

112   C4 photosynthesis using the well-established Micheallis-Menten enzyme-kinetics leaf

113   model of photosynthesis (Farquhar et al., 1980; von Caemmerer and Farquhar, 1981) and

114   the stomatal conductance model of Ball and Berry (Collatz et al., 1991). The coupled

115   photosynthesis/stomatal conductance leaf model has been widely used to project

116   terrestrial biosphere responses to global change. The model is briefly summarized here

117   for transparency and completeness. The leaf model assumes that the rate of net CO_2

118   assimilation (A_{net}) in the leaves of C3 and C4 plants is limited by one of three processes:

119   (i) the capacity of the ribulose 1,5-bisphosphate (RuBP) carboxylase-oxygenase enzyme

120   (Rubisco) to consume RuBP (J_c); (ii) the capacity of the Calvin cycle and the thylakoid

121   reactions to regenerate RuBP supported by electron transport (J_e); (iii) the capacity of

122   starch and sucrose synthesis to consume triose phosphates and regenerate inorganic

123   phosphate for photo-phosphorylation in C3 and phosphoenolpyruvate (PEP) limitation in

4

124 C4 (J_s). J_c, J_e, and J_s are described as functions of the maximum carboxylation capacity

125 (V_{cmax}) at the optimal temperature, 25°C, and the internal leaf CO_2 concentration (C_i). The

126 gross rate of carbon assimilation from photosynthesis (A) is given by:

127 $$A = \min(J_c, J_e, J_s) \tag{1}$$

128 Net carbon assimilation is given by:

129 $$A_{net} = A - R_d \tag{2}$$

130 where R_d is the rate of dark respiration:

131 $$R_d = 0.015 \cdot V_{cmax} \tag{3}$$

132 Leaf stomata control the uptake of CO_2 versus the loss of H_2O. At equilibrium, the

133 stomatal conductance of water vapor through the leaf cuticle (g_s in mol [H_2O] m^{-2} s^{-1})

134 depends on the net rate of carbon assimilation:

135 $$g_s = m \frac{A_{net} \cdot RH}{c_s} + b = \frac{1}{r_s} \tag{4}$$

136 where m and b are the slope and intercept derived from empirical fitting to the Ball and

137 Berry stomatal conductance equations, RH is relative humidity, c_s is the CO_2

138 concentration at the leaf surface, and r_s is the stomatal resistance to water vapor.

139 Appropriate photosynthesis parameters for the local vegetation type are taken from

140 (Friend and Kiang, 2005) and the Community Land Model (Oleson et al., 2010) with

141 updates from Bonan et al. (2011) (Table 1). In both the site-level and distributed models,

142 we apply these model PFT-specific photosynthesis parameters and do not tune or

143 calibrate to the local vegetation properties. The model calculates evapotranspiration as a

144 function of the stomatal conductance. However, we do not consider the feedback of the

145 changes in evapotranspiration to the boundary-layer meteorology because we use

146 prescribed meteorological variables from reanalyses in the simulations.

147

148 The canopy radiative transfer scheme assumes a closed canopy and layers the canopy for

149 light stratification using an adaptive number of layers (typically 2-16) (Friend and Kiang,

150 2005). Each canopy layer distinguishes sunlit and shaded regions for which the direct and

151 diffuse photosynthetically active radiation (PAR) is computed (Spitters et al., 1986). The

152 coupled photosynthesis and stomatal conductance equations are solved analytically using

153 a cubic function of A_{net}. C_i is calculated explicitly at the leaf level. Scaling of the leaf to

154 canopy level is through stratification of canopy light levels and leaf area profiles. The

155 photosynthetic uptake of CO_2 is accumulated into a carbon reserve pool, from which

156 other processes may allocate uses.

157

158 **2.1.1 O_3 damage effect on photosynthesis**

159

160 O_3 oxidizes cellular membranes and photosynthetic tissues when it enters leaves through

161 stomata, leading to reductions in photosynthesis and GPP. O_3 damage inhibits stomatal

162 conductance, which is closely related to the photosynthetic rate, resulting in a reduction

163 in transpiration. A semi-mechanistic parameterization is employed to estimate the O_3

164 damage effects to both photosynthesis and stomatal conductance (Sitch et al., 2007). The

165 exposure to O_3 leads to reductions in photosynthesis:

166 $$A' = F \cdot A_{net} \tag{5}$$

167 where F is the reduction fraction calculated as

168 $$F = 1 - a \cdot U_{>O3T} \tag{6}$$

169 where a is the O_3 sensitivity coefficient derived from observations. Two cases are

170 examined: high and low O_3 sensitivity following Sitch et al. (2007). $U_{>O3T}$ is the

171 instantaneous leaf uptake of O_3 flux above a plant function type (PFT)-specific threshold

172 of O3T (Table 1),

173 $$U_{>O3T} = \max[(F_{O3} - O3T), 0] \tag{7}$$

174 here F_{O3} is the O_3 flux entering the leaf through the stomata,

175 $$F_{O3} = \frac{[O_3]}{r_b + \kappa \cdot r_s'} \tag{8}$$

176 where $[O_3]$ is the O_3 concentration at the top of the canopy, r_b is the boundary layer

177 resistance. The stomatal resistance to O_3 is calculated based on stomatal resistance to

178 water r_s with a ratio constant $\kappa = 1.67$. From Equation (4), the decrease in A_{net} reduces the

179 stomatal conductance g_s proportionally,

180 $$r_s' = \frac{1}{g_s'} = \frac{1}{F \cdot g_s} \tag{9}$$

181   The r_s' and g_s' are the O_3-damaged stomatal resistance and conductance, respectively.

182   When the plant is exposed to [O_3] (Equation 8), the excess O_3 flux entering leaves

183   (Equation 7) causes $F<1$ (Equation 6), decreasing A_{net} (Equation 5) while increasing the

184   stomatal resistance (Equation 9). The latter will act to reduce the O_3 uptake flux

185   (Equation 8) to protect the plant. Thus, the scheme considers associated changes in both

186   photosynthetic rate and stomatal conductance. When photosynthesis is inhibited by O_3,

187   the stomatal conductance decreases accordingly to resist more air passing through the

188   stomata, resulting in a decline of the oxidant fluxes inside leaves, as described through

189   equations (5)-(9). Consequently, this coupled scheme represents the equilibrium state

190   between the CO_2 demand for vegetation growth and the protection against O_3 damage by

191   plant. The parameters for the scheme, including the O_3 damage threshold and sensitivity

192   coefficients, were originally derived based on the calibration of the MOSES vegetation

193   model. Since the MOSES model employs the (almost) identical Farquhar-Ball-Berry

194   photosynthesis/stomatal conductance scheme as in the YIBs model, it is appropriate to

195   adopt the same parameters as those derived in Sitch et al. (2007) (Table 1). Evaluation of

196   the YIBs simulated O_3-induced GPP response with available field and laboratory

197   measurements across a range of PFTs in Section 3.4 indicates that our assumption is

198   reasonable.

199

200   **2.1.2 Vegetation structure**

201

202   The YIBs vegetation model simulates eight PFTs, using either C3 or C4 photosynthesis

203   (Table 1). We apply two different sets of land cover and leaf area index (LAI) in the

204   simulations. The first set is the PFT-specified vegetation cover fraction and LAI retrieved

205   by the Moderate Resolution Imaging Spectroradiometer (MODIS, Knyazikhin et al.,

206   1998). The value on a specific day is linearly interpolated from the monthly means of the

207   nearest two months based on the distance of this day to the middle dates of those two

208   months. The second set uses LAI from the Global Modeling and Assimilation Office

209   (GMAO) Modern Era-Retrospective Analysis (MERRA) dataset. The MERRA LAI is

210   assimilated based on radiance data retrieved by over 20 satellites (Rienecker et al., 2011)

211   and is available on daily scale from 1980 onwards. Since the MERRA LAI dataset does

212   not provide PFT-specific information, the actual site-level PFT is assumed for the site

213   level simulations. For the regional distributed simulations, the land cover is prescribed to

214   the gridded International Satellite Land-Surface Climatology Project (ISLSCP, Hall et al.,

215   2006).

216

217   2.1.3 Meteorological forcing

218

219   For the site-level simulations, we use hourly *in situ* measurements of surface

220   meteorological variables, including surface air temperature, specific humidity, wind

221   speed, surface pressure, and CO_2 concentrations. There are some missing values in the

222   measurements due to occasional instrument failure. We gap-fill the site-based

223   observations with that from the MERRA-land data (Reichle et al., 2011), which is

224   interpolated to each site based on the site location.

225

226   For the distributed simulations, the off-line YIBs model uses hourly MERRA-land data

227   climatic variables including: surface air temperature, specific humidity, wind speed,

228   surface pressure, precipitation, direct PAR, and diffuse PAR, and soil temperature and

229   soil moisture at 6 soil depths. The original data resolution of 0.5°×0.667° by latitude and

230   longitude is degraded to 1°×1.333° due to current disk space limitation.

231

232   2.1.4 Surface [O_3]

233

234   Hourly and daily maximum 8-hour average surface [O_3] representative of the present day

235   climate (~ 2005) are taken from previous simulations using NASA Model-E2 (Shindell et

236   al., 2013). The global model has 2°×2.5° latitude by longitude horizontal resolution with

237   40-vertical layers extending to 0.1 hPa. The gas-phase chemistry and aerosol modules are

238   fully integrated, so that these components interact with each other and with the physics of

239   the climate model (Bell et al., 2005; Shindell et al., 2006; Unger, 2011; Shindell et al.,

240   2013). The model surface O_3 is validated using measurements from 73 Clean Air Status

241   and Trends Network (CASTNET) sites operated by the Unitied States Environmental

242   Protection Agency (EPA) (http://epa.gov/castnet/javaweb/ozone.html) and ~1200

243 monitor sites managed by the EPA AIRDATA (http://www.epa.gov/airdata/). These sites

244 are operated on the county level scale. The CASTNET provides hourly $[O_3]$ at rural sites

245 from 1996-2005. The AIRDATA network provides daily maximum 8-hour average

246 (MDA8) $[O_3]$, covering both urban and rural regions. We use AIRDATA data for the

247 year 2005.

248

249 **2.2 Simulations**

250

251 **2.2.1 Site-level runs**

252

253 We configure a site-level version of the YIBs model for the 40 eddy covariance flux

254 tower sites described in detail in the NACP synthesis (Fig. S1 and Appendix Table A,

255 Schaefer et al., 2012). Measurements are available for a wide range of time periods

256 across the different sites ranging from the minimum of 1 year at Fermi Lab (US-IB1) and

257 the maximum of 15 years at Harvard Forest (US-HA1). These sites cover a range of

258 different vegetation types including: evergreen needleleaf forest, deciduous broadleaf

259 forest, grasslands, croplands, closed shrublands, mixed forests, permanent wetlands, and

260 woody savannas. Table S1 summarizes how the NACP vegetation types are mapped onto

261 the 8 model PFTs. For the site-level simulations, we assume C4 photosynthetic pathway

262 for all cropland sites, which are mainly corn (Schaefer et al., 2012).

263

264 For each site, a group of six sensitivity simulations are performed (Table 2). We conduct

265 the first four runs using different combinations of meteorological and vegetation forcings,

266 to assess the sensitivity of the results to local versus renalaysis meterological forcing and

267 LAI (Table 2). Two, METmerra_LAImodis and METmerra_LAImerra, use hourly

268 meteorology from MERRA-land reanalyses alone. The other two, METsite_LAImodis

269 and METsite_LAImerra, use site-based meteorology with gap-filled MERRA reanalysis.

270 Simulations use two datasets of LAI: (1) METmerra_LAImerra and METsite_LAImerra

271 use LAI from the MERRA-land reanalyses, which provide non PFT-specific LAI that we

272 assign to the local PFT type at each site (Table A), while (2) METmerra_LAImodis and

273 METsite_LAImodis use PFT-specific LAI retrieved by the MODIS. We perform two

9

274   additional site-level simulations, which use the same forcings as that for
275   METsite_LAImerra but with the impact of O_3 uptake on photosynthesis. These two
276   experiments, METsite_LAImerra_HO3 and METsite_LAImerra_LO3, use either high or
277   low O_3 sensitivity as defined by the coefficient a in Table 1.

278

279   To quantify the performance of the vegetation model, we estimate the χ^2 for each site
280   following the method described in Schaefer et al. (2012),

281    $$\chi^2 = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{r_i}{\varepsilon_i}\right)^2 \qquad\qquad (10)$$

282   where

283    $$r_i = \left(GPP_{si} - GPP_{oi}\right) \qquad\qquad (11)$$

284   is the difference between the pair of simulated and observed GPPs. ε_i are the
285   observational uncertainties. n is the length of observations (e.g. the number of days for
286   the daily variables). The lower the χ^2, the smaller the model biases. If $\chi^2 < 1$, the
287   simulation bias is on average smaller than the measurement uncertainty, indicating a
288   good performance of the model. Here, we define a reasonable performance of $\chi^2 < 4$,
289   when the residual is less than twice the measurement uncertainty. We also calculate the
290   root mean square error (RMSE) as follows:

291    $$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(GPP_{si} - GPP_{oi}\right)^2} \qquad\qquad (12)$$

292

293   We validate the simulated O_3 damage effect with measurements from literature. Field and
294   laboratory experiments may have different $[O_3]$ compared to the ambient level we used
295   complicating the validation. As a result, we perform 14 additional sensitivity simulations
296   for each of NACP sites. All tests use meteorological and vegetation forcings the same as
297   METsite_LAImerra (Table 2), except for the different $[O_3]$ and O_3 sensitivity. These
298   experiments are divided into two groups, 7 in each, using either low or high O_3
299   sensitivity. In each group, simulations are performed with constant $[O_3]$ at 20, 40, 60, 80,
300   100, 120, 140 ppbv, respectively. We do not include diurnal and seasonal variations of
301    $[O_3]$ in these sensitivity simulations as that in METsite_LAImerra for two reasons. First,

302   field measurements for the O_3 vegetation damage are usually performed with fixed $[O_3]$

303   during the growth season (e.g. Ishii et al., 2004; Zhang et al., 2012). Second, the diurnal

304   cycles and seasonality of $[O_3]$ are very different for different sites (Bloomer et al., 2010),

305   making it difficult to apply a uniform temporal cycle for all the NACP sites. The

306   reductions in GPP at these simulations are compared with results from field

307   measurements at the corresponding $[O_3]$ level.

308

309   **2.2.2 Distributed run over U.S. region**

310

311   A gridded version of the YIBs model at $1°×1.333°$ latitude by longitude horizontal

312   resolution for the U.S. region is driven with MERRA meteorological forcings for the

313   period 1998-2007. In the distributed model, vegetation cover types are from the ISLSCP

314   and LAI is form the MERRA-land reanalysis. We assign the MERRA LAI to the

315   corresponding PFT types defined by ISLSCP (Fig. S2). The 18 ISLSCP land types are

316   converted to 8 PFTs used in the model (Table S1). Some of the ISLSCP land types, such

317   as the deciduous needleleaf forest, are not represented in the YIBs model. However, the

318   coverage of these types is very small in the U.S. (Fig. S2) and will not influence the

319   regional simulation after the conversion to the model types. For the regional simulation,

320   we assume that the total crop area in each crop grid cell is split 50% C3 and 50% C4 to

321   account for the dominance of both soybean (C3) and corn (C4) crops in the central and

322   northern U.S. agricultural regime. We perform 2 simulation cases with high and low O_3

323   damage sensitivity. Finally, to understand how the O_3 vegetation damage effect may

324   respond to possible future changes in $[O_3]$, we perform four additional sensitivity

325   experiments with ±25% changes in $[O_3]$ for each O_3 sensitivity case.

326

327   **3. Results**

328

329   **3.1 Evaluation of O_3-free GPP at NACP sites**

330

331   We compare the monthly mean LAI from MERRA and MODIS at each NACP site (Fig.

332   1). For each site, the MERRA LAI is averaged for the period when GPP measurements

333 are available. The two datasets show similar annual cycles at several sites but are
334 inconsistent for 7 out of 20 evergreen sites (CA-Ca1, CA-Ca2, CA-Ca3, CA-NS1, US-
335 Me2, US-Me3, and US-Me5) and 2 out of 5 shrubland sites (US-SO2 and US-Ton). In
336 addition, for grasslands and croplands, the datasets exhibit different seasonality, with
337 MERRA LAI near zero during the cold season in contrast to the MODIS LAI that is
338 positive all year round. It must be emphasized that the MERRA and MODIS LAI
339 represent the average state in the retrieval product grid cells and as such may not
340 represent the local LAI for the actual PFT species at each site. The local site LAI values
341 are not available for comparison. For example, for most of the evergreen NACP sites, the
342 MERRA and MODIS LAI indicate large seasonality.

343

344 The long-term monthly mean O_3-free GPP from the simulation METsite_LAImerra is
345 compared with observations at individual NACP sites (Fig. 2). Both the observation and
346 simulation are averaged over the measurement period at each site. The simulations
347 capture the magnitude and seasonality of GPP for most sites especially for deciduous
348 broadleaf and shrubland. The largest model overestimate (factor of 3-8) occurs at CA-SJ1
349 and CA-SJ2. For the grassland sites US-ARM (in Great Plains) and US-Var (in
350 California), the model maximum GPP occurs in summer (July), 2-3 months later than in
351 the measurements (April). This incorrect model seasonality is a result of the MERRA
352 LAI (compare Fig. 1) that does not begin to increase rapidly until after May and is not
353 consistent with the local LAI at the site. In reality, California grasslands exhibit rapid
354 growth in spring then mature and die after April or May (Chiariello, 1989). The
355 grasslands in the Great Plains may have up to six different phenological groups, including
356 some species active in spring (e.g. in US-ARM) while some others peak in summer (e.g.
357 in US-Shd) (Henebry, 2003). The correlation coefficient between simulated annual mean
358 GPP and observations at all 40 sites is 0.65. The correlation is higher (0.81) for summer
359 (June-August, Fig. S3). The annual GPP averaged over all sites is 3.8 g C m^{-2} day^{-1}, 27%
360 higher than the observational average (3.0 g C m^{-2} day^{-1}).

361

362 Among the 40 NACP sites, 22 have reasonable performance with $\chi^2 < 4$ (Fig. 3a). The
363 simulation is the best ($\chi^2 =1.2$) at the evergreen needleleaf site US-Dk3 (Fig. 2). For the

364   top 10 sites with the lowest biases, 8 are based in evergreen needleleaf forests. These

365   sites usually have multiple years of measurements and provide good samples for testing

366   the consistency between simulations and observations. Simulations at 4 broadleaf forest,

367   4 cropland, and 3 shrubland sites have $\chi^2 < 4$, and the latter usually has low GPP whose

368   peak is not higher than 10 g C m^{-2} day^{-1} (Fig. 2). Compared with the 24 land surface

369   models in Schaefer et al. (2012), the YIBs model shows significant improvement at the

370   crop PFT sites ($\chi^2 < 4.1$ vs. $\chi^2 > 6$). YIBs simulates GPP with $\chi^2 < 4$ at 22 sites in total

371   compared to 16 sites for the ensemble simulations in Schaefer et al. (2012). YIBs GPP

372   simulation is weaker ($\chi^2 > 4$) at 18 sites including 9 needleleaf forest, 2 broadleaf, and 2

373   shrubland PFTs. The common feature of the biases at these sites is the overestimation of

374   peak GPP during summer (e.g. CA-SJ1, CA-SJ2, CA-Mer, Fig. 2). It is possible that the

375   model does not represent the full realism of the biophysical processes accurately.

376   However, we assert that the most likely cause of the model overestimate is the uniform

377   application of model PFT-specific photosynthesis parameters that are not tuned to local

378   site level vegetation parameters and, for instance, do not take into account plant

379   speciation and age. Similar to the multi-model results in Schaefer et al. (2012), YIBs

380   performance is weakest at the 5 grassland sites. In this case, the bias is mainly due to the

381   delayed LAI seasonality in the MERRA satellite dataset (Figs. 1 and 2). In general,

382   application of the remotely sensed LAI is a source of error because the gridded satellite

383   data may not represent the local site changes in plant growth and phenology, especially

384   for vegetation types with low biomass. The limitation of the satellite LAI spatial

385   resolution implies that the model is unable to resolve GPP variability for sites in close

386   proximity. For example, sites CA-SJ1, CA-SJ2, and CA-SJ3 are located close to each

387   other. Simulations at these sites have similar magnitude in simulated GPP while

388   observations show distinct variability between the sites.

389

390   We compare R^2, RMSE, and χ^2 for the different sensitivity experiments in order to

391   ascertain which combination of meteorological and LAI forcings best reproduces the

392   measured GPP over North America (Table 3 and Fig. 4). CA-Let, CA-NS1, US-Var, CA-

393   SJ1, and CA-SJ2 are excluded from the analysis because of the excessive bias at those

394   sites (Fig. 3a). The average R^2 increases while RMSE decreases when MERRA

395 reanalyses are substituted with site-based meteorology, or the MERRA LAI is used

396 instead of MODIS LAI (Table 3). The choice of LAI forcing has the most significant

397 impact on YIBs simulation performance consistent with previous work that demonstrated

398 the dominance of phenology over meteorology in controlling local terrestrial carbon

399 exchange (Desai et al., 2008; Puma et al., 2013). Using MODIS LAI, YIBs has a total χ^2

400 of 9.2 that shows an average reduction of 4.7 (52%) with MERRA LAI (Table 3 and Fig.

401 4). Applying the site meteorology relative to MERRA meteorological forcings offers

402 smaller improvements. For example, the total χ^2 value decreases by 5% in

403 METsite_LAImodis compared with that in METmerra_LAImodis and 15% in

404 METsite_LAImerra relative to that in METmerra_LAImerra (Table 3).

405

406 **3.2 Evaluation of modeled surface [O_3]**

407

408 We validate summertime surface O_3 simulated by the NASA Model-E2 chemistry-

409 climate model with observations from the CASTNET and AIRDATA (Fig. 5). High O_3

410 level appears in the eastern U.S. due to anthropogenic emissions and in the mountainous

411 western U.S. due to high elevation. The model generally captures this spatial pattern with

412 a correlation coefficient of 0.39 against observations over the selected 73 CASTNET

413 sites (Figs. 5a-b). The simulation overestimates the O_3 level by ~4 ppbv (12%) in the East

414 and ~1 ppbv (3%) in the West. The CASTNET sites are located in rural sites, which

415 usually have lower [O_3] than that in urban areas, except for some megacities where the

416 excessive NO_x emissions result in lower O_3 level (Gregg et al., 2003). Therefore, we also

417 compare the simulated MDA8 [O_3] with monitored at ~1200 AIRDATA sites, which

418 covers both urban and rural regions (Fig. 5c). In the eastern U.S., the model captures high

419 [O_3] centers around Michigan, Indiana, and Ohio states and that along the northeast coast.

420 In the West, the simulation reproduces high [O_3] over mountain regions and in California.

421 On average, the simulated MDA8 [O_3] is lower by ~0.5 ppbv (1%) in the East and ~3.5

422 ppbv (7%) in the West. The correlation coefficient between simulations and observations

423 is as high as 0.51 (Fig. 5d).

424

425 **3.3 O_3 damage effects at NACP sites**

14

426

427   We must apply the simulated O_3 to quantify the O_3 vegetation damage at the NACP sites

428   because the sites do not monitor local $[O_3]$. The summer average $[O_3]$ is 30-50 ppbv at 24

429   U.S. sites (Fig. 6a). The O_3 damage effect is relatively stronger at sites with both high O_3-

430   free GPP and ambient $[O_3]$ (Fig. 6d). The most significant damages are predicted at US-

431   MMS (DBF) and US-Dk3 (ENF) sites, where the GPP reductions are 5-14% depending

432   on the low or high O_3 sensitivity (Fig. 6d). At these two sites, the high stomatal

433   conductance (4.0 and 3.4 mm s^{-1}, Fig. 6b) and ambient $[O_3]$ (both 43 ppbv, Fig. 6a) result

434   in the largest O_3 stomatal flux (both ~0.3 mmol m^{-2} d^{-1}, Fig. 6c) among the 24 sites. The

435   lowest O_3 damage (1-2% GPP reduction) appears in the 3 shrub sites, US-Ton, US-SO2,

436   and US-Los, although mean $[O_3]$ there is as high as 43 ppbv. The main reason for the

437   limited O_3 damage is the low stomatal conductance (average 1.4 mm s^{-1}, Fig. 6b) related

438   to the small O_3-free GPP (average 4.6 g C m^{-2} d^{-1}, Fig. 6d). Similarly, the O_3 damage for

439   C3 grass is as low as 1-2%, although the GPP of this plant is highly sensitive to O_3 (Table

440   1). For needleleaf and broadleaf forest sites, the average site-level O_3 damage effects are

441   estimated to be 2-5% and 3-9% respectively with differences between these ecosystem

442   types predominantly driven by differences in sensitivity to O_3. The four C4 crop sites,

443   US-Ne1, US-IB1, US-Ne2, and US-Ne3, exhibit the highest O_3-free GPP but show only

444   moderate O_3 damage effects (GPP reductions of 4-6%, Fig. 6d). This result is driven by

445   low ambient $[O_3]$ at the C4 crop sites (average 32 ppbv, Fig. 6a) in combination with the

446   reduced C4 stomatal conductance (higher water use efficiency) relative to C3 plants

447   (average 3.2 mm s^{-1}, Fig. 6b). Indeed, the C4 photosynthetic pathway has been observed

448   to offer protection against O_3 damage (Heagle et al., 1989; Rudorff et al., 1996).

449

450   Inclusion of O_3 damage effect improves the site-level simulations (Figs. 3b-c). For 36 out

451   of the 40 sites, the χ^2 of simulated GPP decreases when considering vegetation responses

452   to O_3, and the improvement is better when higher O_3 sensitivity is applied. At these sites,

453   for example, CA-TP4, US-Dk3, US-MMS, and US-PFa, the reduced GPP at peak seasons

454   is closer to measurements (Fig. S4), leading to smaller biases for simulations. On

455   average, the χ^2 decreases by 3-8% at these sites, depending on the O_3 sensitivity in the

456   simulation (Fig. 4). Finally, the simulated annual GPP averaged over all NACP sites

457   changes from 3.8 g C m^{-2} day^{-1} to 3.6 g C m^{-2} day^{-1} with the high O$_3$ sensitivity

458   simulation case, closer to the observations of 3.0 g C m^{-2} day^{-1}. The bias-correction from

459   O$_3$ damage is much smaller relative to the effect of phenology (Fig. 4). Moreover, the O$_3$-

460   induced damage does not improve the GPP correlation between observations and

461   simulations, which remains similar at ~0.8 (for 40 sites) with and without O$_3$ effects (Fig.

462   S3).

463

464   **3.4 Evaluation of simulated O$_3$ vegetation damage against field and laboratory data**

465

466   We compare the simulated O$_3$ damage effect with field and laboratory measurements

467   from the published literature (Fig. 7). In total, 14 additional sensitivity experiments are

468   performed with different levels of [O$_3$] at each NACP site (see section 2.2.1). GPP

469   reductions increase accordingly with the increasing [O$_3$] (Fig. 7). For a given [O$_3$], the O$_3$

470   damage effect is strongest for C4 crops (despite the lower g_s:A_{net} ratio) but weakest for

471   shrubland. YIBs simulates reasonable O$_3$ damage to GPP for all model PFTs compared to

472   the meta-analyses of Wittig et al. (2007) and Lombardozzi et al. (2013). Field studies in

473   shrubland are limited. Zhang et al. (2012) investigated the responses of four shrub species

474   to [O$_3$]=70 ppbv and found large reductions in net photosynthesis of 50-60%. The

475   average O$_3$-free A_{net} of those shrub species was 8-16 g [C] m^{-2} s^{-1}, much higher than even

476   the gross photosynthesis (A) of 6 g [C] m^{-2} s^{-1} at the shrub NACP sites, likely because the

477   latter are located in dry and/or cold areas (Fig. S1). The YIBs simulated O$_3$ vegetation

478   damage effects for C4 plants are in good agreement with field measurements from Taylor

479   et al. (2002) and Grantz et al. (2012). In the case of C3 grass and C3 crop, the model

480   simulates consistent GPP reduction percentages with observations from Feng et al. (2008)

481   for wheat, Foot et al. (1996) for colluna vulgaris, and Mulchi et al. (1992) for soybean.

482   However, these O$_3$ damage results are all >50% less than for available measurements in

483   rice crops (Ishii et al., 2004; Ainsworth et al., 2008), suggesting that rice may have much

484   higher O$_3$ sensitivity than other C3 plants. In the U.S. rice plantation area is much smaller

485   than that of soybean and corn. Therefore, we adopt the O$_3$ sensitivity parameters for

486   C3/C4 plants shown in Table 1 for the distributed regional simulations.

487

3.5 O₃ vegetation damage effect on GPP in U.S. region

High values of simulated summertime GPP (including O_3 damage effect) appear east of 95°W in the U.S. (Fig. 8a), because the land surface there is covered by crops and forests. A high center of GPP (> 10 g C m^{-2} day^{-1}) appears over cropland in the north central U.S. In the western U.S., the coverage of grass and shrub and the low water availability (low precipitation and soil moisture) over semi-arid regions lead to low carbon assimilation rate. The regional gridded simulated GPP reproduces the JJA growing season average NACP site-level fluxes with a correlation coefficient of 0.62 for 32 sites below 50°N (Fig. 8a). The correlation is lower than the 0.84 estimated for the site-level simulation METsite_LAImerra at the same sites and the same season. Since the meteorological forcings and LAI are similar, the difference in land cover, ISLSCP versus site definitions (Fig. S1 and Fig. S2), accounts for the discrepancy between regional and site-level simulations.

On average, the simulated summer GPP (including the high O_3 damage effect) is 9.5 g C m^{-2} day^{-1} in the eastern U.S. and 3.9 g C m^{-2} day^{-1} in the western U.S., giving a mean value of 6.1 g C m^{-2} day^{-1} for the U.S. region. The total carbon uptake is estimated to be 4.43 ± 0.18 Pg C during the summer growing season, accounting for 57-60% of the annual average value of 7.59 ± 0.25 Pg C over the 1998-2007 period. Our estimate of annual carbon uptake is consistent with previous published estimates. For example, Xiao et al. (2010) upscaled site-level GPP flux to continental scale with a regression tree approach based on both NACP fluxes and remote-sensing variables. They estimated that the total GPP in U.S. ranges from 6.91 to 7.33 Pg C per year during 2000-2006. Using the same observations but with a process-based biogeochemical model, Chen et al. (2011) estimated a range of 7.02-7.78 Pg C per year for 2000-2005, which is even closer to our estimate.

We calculate both O_3 stomatal flux (Fig. 8b) and the resultant damage on GPP (Fig. 9) in the U.S. region for the 1998-2007 period. High O_3 stomatal flux is predicted in the eastern U.S. due to co-location of the high GPP (medium to high stomatal conductance)

519 and the substantial ambient $[O_3]$. On average, the summertime O_3 plant uptake is 117

520 $\mu mol\ m^{-2}\ day^{-1}$, with 207 $\mu mol\ m^{-2}\ day^{-1}$ in the eastern U.S. and 59 $\mu mol\ m^{-2}\ day^{-1}$ in the

521 western U.S. Following the O_3 stomatal flux, the largest mean GPP reductions are

522 predicted for the eastern U.S. growing season, in the range 4-8% depending on the O_3

523 sensitivity applied in the simulations (Fig. 9). Locally, reduction fraction reaches as high

524 as 11-17% in areas with high $[O_3]$ pollution, such as Michigan, Indiana, Ohio, and states

525 along the northeast coast. Despite high surface $[O_3]$ over mountainous elevated areas in

526 the West (Fig. 5), impacts on GPP are limited due to the low stomatal conductance and

527 low photosynthetic rate there. The Pacific northwestern forests are an exception, with a

528 moderate GPP reduction of 1-7%. On average, the total summer GPP is reduced by 2-5%

529 due to O_3 damage effects in the U.S. Similar reduction fractions are predicted for the

530 annual GPP.

531

532 U.S. surface $[O_3]$ exhibits a decreasing trend over the past 2 decades, especially in the

533 eastern U.S., due to precursor emission controls (Lefohn et al., 2010). However, the

534 community continues to debate how surface $[O_3]$ will respond to future emissions and

535 climate change. On the one hand, surface $[O_3]$ may decline by the mid 21st century due to

536 large reductions in regional anthropogenic precursor emissions (Wu et al., 2008). On the

537 other hand, climate change effects alone may increase local surface $[O_3]$ due to the

538 warmer, drier, and more stable environment (Leibensperger et al., 2008; Wu et al., 2008).

539 Due to the uncertainty in future surface $[O_3]$ projections, our strategy here is to perform

540 four additional sensitivity experiments with ±25% changes in $[O_3]$ for each O_3 sensitivity

541 case. Increases of 25% in $[O_3]$ may reduce GPP in the eastern U.S. by 6-11%, with a

542 maximum local reduction of 25% for the high O_3 sensitivity case (Fig. 10d). The damage

543 magnitude with low O_3 sensitivity (Fig. 10b) mimics the present-day estimate with high

544 O_3 sensitivity (Fig. 9b). In contrast, the O_3 damage to the eastern U.S. GPP is as low as 2-

545 4% in response to 25% decreases in $[O_3]$ (Figs. 10a, c), suggesting a substantial co-

546 benefit to ecosystem-health of O_3 precursor emissions control.

547

548 **4. Discussion and Conclusions**

549

550   We have performed an updated assessment of O_3 vegetation damage effects on GPP in

551   the U.S. for the 1998-2007 period using the YIBs vegetation model. The semi-

552   mechanistic parameterization of O_3 inhibition on photosynthesis proposed by Sitch et al.

553   (2007) has been implemented into this process-based vegetation model. The simulated O_3

554   damage effects are consistent with laboratory and field measurements reported in

555   previously published studies. We evaluated the simulated O_3-free and O_3-damaged GPP

556   with *in situ* measurements from 40 NACP sites. The O_3-free and O_3-damaged GPP

557   simulations capture the seasonality and interannual variability of GPP at most sites. The

558   model GPP biases are lowest at forest and cropland sites but highest at grassland sites.

559   Model GPP is highly sensitive to choice of LAI forcing. Simulations that apply MERRA

560   LAI generally perform better (show lower biases) than those with MODIS LAI. In

561   response to the simulated ambient $[O_3]$ of 30-50 ppbv, simulated GPP decreases by 1-

562   14% at the NACP sites, depending on the O_3 sensitivity and PFT types. Maximum

563   reductions of 5-14% occur in two forest sites, where both O_3-free GPP and ambient $[O_3]$

564   are relatively high. Inclusion of the O_3 damage offers only a small improvement to the

565   simulated annual average GPP at NACP sites (from 3.8 g C m^{-2} day^{-1} to 3.6 g C m^{-2} day^{-1}

566   ^{1}) such that the model still overestimates the observational average of 3.0 g C m^{-2} day^{-1}.

567   The model GPP overestimate is most likely related to the use of generic PFT-specific

568   photosynthesis parameters and the satellite prescribed LAI that may not represent the

569   local site LAI. In this work, we assumed a coupled response between photosynthesis and

570   stomatal conductance. Emerging research has found that the O_3 vegetation damage

571   effects can actually result in a loss of plant stomatal control, and a consequent decoupling

572   of the stomatal response from photosynthesis inhibition (Lombardozzi et al., 2012a, b).

573   Treatment of this decoupled response in the YIBs model would lead to a higher level of

574   O_3 flux entering leaves, thus causing stronger damage. Interestingly, this mechanism

575   would therefore provide a way to improve the simulated GPP overestimates. That said,

576   other studies have suggested that the O_3 damage effect is limited by carbon-nitrogen

577   interactions (Ollinger et al., 2002; Kvalevag and Myhre, 2013).

578

579   Regional distributed simulations for the U.S. yield a summertime GPP (with high

580   sensitivity O_3 damage) of 6.1 g C m^{-2} day^{-1} (9.5 g C m^{-2} day^{-1} in the eastern U.S. and 3.9

581   g C m^{-2} day^{-1} in the western U.S.). The total carbon uptake was estimated to be 4.43 ±

582   0.18 Pg C for the summer, accounting for 57-60% of the annual value of 7.59 ± 0.25 Pg

583   C over the 1998-2007 period. Carbon assimilation rate is suppressed by 4-8% on average

584   in the summertime eastern U.S. with maximum local damage of 11-17% in states close to

585   the Great Lakes and along the eastern coast. When [O_3] is decreased by 25%, O_3 damage

586   to GPP is only 2-4% in the eastern U.S., indicating substantial improvements to

587   vegetation health and carbon assimilation rate. Previously, Felzer et al. (2004) found

588   annual average O_3-induced NPP reductions of 3-7% over the U.S. for 1989-1993 and

589   simulated the largest reductions in states close to the Great Lakes and along the East

590   Coast, where the high O_3 sensitivity of crops makes the dominant contribution. Our study

591   examined O_3 damage effects a decade later than Felzer et al. (2004) but gives consistent

592   results. Qualitatively, this consistency between decades may be explained by the

593   offsetting influences of (i) surface O_3 reductions due to air quality control legislation and

594   (ii) GPP increases due to CO_2-fertilization and rising temperatures. Felzer et al. (2004)

595   estimated a maximum local NPP reduction of 34%, which is double the maximum of

596   17% in our analyses. Furthermore, Felzer et al. (2004) found widespread reductions of >

597   6% in the Midwest where there is almost no O_3 impact in this study (Fig. 9). Differences

598   between the studies are mostly likely driven by the use of different vegetation cover and

599   LAI datasets, and the use of a semi-mechanistic flux-based uptake in this study versus the

600   concentration-based uptake method elsewhere.

601

602   The current work has used an off-line approach. Yet, the O_3-vegetation-meteorology

603   system is strongly coupled. For instance, plant productivity itself controls the emission of

604   isoprene, a major O_3 precursor. The O_3-induced modification to stomatal conductance

605   may inhibit evapotranspiration, leading to changes in canopy temperature, precipitation,

606   soil moisture, and other surface hydrology and meteorology (Bernacchi et al., 2007;

607   vanLoocke et al., 2012). In future work, we will study O_3 vegetation damage effects

608   using YIBs embedded within a fully coupled global chemistry-climate model framework

609   in order to account for these feedbacks including altered canopy energy fluxes and

610   partitioning between latent and sensible heat that drive regional climate and hydrology. In

611   addition, future work will exploit recent extensive meta-data analyses (Lombardozzi et

612   al., 2013; Wittig et al., 2007) to refine the ozone damage parameterization in YIBs

613   including the decoupled modification of photosynthesis and stomatal conductance.

887
888 [a] Plant function types (PFTs) are tundra (TDA), C3 grassland (GRAC3), C4
889 savanna/grassland (GRAC4), shrubland (SHR), deciduous broadleaf forest (DBF),
890 evergreen needleleaf forest (ENF), tropical rainforest (TRF), and cropland (CRO).
891 [b] For site-level simulations, we consider CRO as C4 plant. For regional simulation, we
892 consider half CRO as C3 plants (soybean) and the rest C4 plant (corn).

900   **Table 2.** Description of the site-level simulations.
901

| | | Meteorology | | Vegetation (LAI) | | |
ID	Simulations [a]	Site	MERRA	MODIS	MERRA	Incl. O$_3$ [c]
1	METmerra_LAImodis		Yes	Yes		
2	METsite_LAImodis [b]	Yes	Yes	Yes		
3	METmerra_LAImerra		Yes		Yes	
4	METsite_LAImerra [b]	Yes	Yes		Yes	
5	METsite_LAImerra_LO3 [b]	Yes	Yes		Yes	Low [d]
6	METsite_LAImerra_HO3 [b]	Yes	Yes		Yes	High [d]

902
903   [a] The name of each simulation is composed of at least two words. The prefix indicates the
904   source of meteorological forcings. The suffix or the second word indicates the sources of
905   vegetation forcings.
906   [b] For simulations with prefix 'SITE' use site-based meteorological forcings, which are
907   gap-filled with MERRA-land reanalyses.
908   [c] Ambient [O$_3$] is applied at each site.
909   [d] Low and high indicate the sensitivity of GPP to [O$_3$] defined by the coefficient a in
910   Table 1.

927

928 [a] Site information is adopted from Schaefer et al. (2012), except that the operational time
929 span listed here is only for the period when measurements of GPP are available.
930 [b] PFT names are: evergreen needleleaf forest (ENF), deciduous broadleaf forest (DBF),
931 grasslands (GRA), croplands (CRO), closed shrublands (CSH), mixed forests (MF),
932 permanent wetlands (WET), and woody savannas (WSA).

933 [c] The land type at US-ARM is cropland in Schaefer et al. (2012). However, the site is
934 covered by cattle pasture and wheat fields (https://www.arm.gov/sites/sgp), which are
935 more like C3 grassland.
936
937

938

Figure Captions

Fig. 1. Comparison of monthly mean leaf area index (LAI, m^2 m^{-2}) from the Modern Era-Retrospective Analysis (MERRA) reanalysis (red solid lines) and the Moderate Resolution Imaging Spectroradiometer (MODIS) (blue dashed lines) at each NACP site. The name and location (longitude, latitude) are shown in the title. The land types include evergreen needleleaf forest (ENF), deciduous broadleaf forest (DBF), shrublands (SHR), grasslands (GRA), and croplands (CRO).

Fig. 2. Comparison of long-term monthly mean GPP (g [C] m^{-2} day^{-1}) from observations (blue points with error bars indicating one standard deviation) and the O_3-free simulations (black lines with shadings indicating one standard deviation) averaged over measurement period at each site. The simulation, METsite_LAImerra, is driven with meteorological forcings from MERRA and site measurements. The LAI is from MERRA. The name and location (longitude, latitude) are shown in the title. The land types include evergreen needleleaf forest (ENF), deciduous broadleaf forest (DBF), shrublands (SHR), grasslands (GRA), and croplands (CRO).

Fig. 3. The calculated (a) χ^2 of GPP and changes in χ^2 after the inclusion of O_3 damage impact with (b) low and (c) high O_3 sensitivity at each site. The sites are sorted according to the values of χ^2 in (a). The land cover definitions are: GRA, Grasslands; CRO, Croplands; ENF, Evergreen Needleleaf Forest; DBF, Deciduous Broadleaf Forest; SHR, Shrubland. See section 2.2.1 for the definition of χ^2.

Fig. 4. The calculated average χ^2 of GPP over NACP sites for 6 different simulations as listed in Table 2. The blue bars are results for all 40 NACP sites. The red bars are results excluding sites CA-Let, CA-NS1, US-Var, CA-SJ1, and CA-SJ2, where the simulated site-level χ^2 is larger than 16 as shown in Fig. 3a.

Fig. 5. Validation of simulated summertime surface (a, b) diurnal mean and (c, d) daily maximum 8-hour average O_3 with *in situ* measurements from (a, b) the EPA Clean Air Status and Trends Network (CASTNET) and (c, d) the AIRDATA. For (b) and (d), the

970   blue points indicate sites East of 95°W and the red ones for West of 95°W. The

971   correlation coefficients between simulations and observations are shown in (b) and (d).

972   Please refer to Fig. S5 for separate results from GCM and observations.

973

974   **Fig. 6.** Simulated summertime (a) surface $[O_3]$, (b) stomatal conductance, (c) ozone

975   stomatal flux, and (d) damages to GPP at different O_3 sensitivity for 24 U.S. sites. The

976   sites are sorted according to the simulated O_3-free GPP in (d). For each site, the result is

977   averaged over the period when the site provides GPP measurements. The land cover

978   definitions are: GRA, Grasslands; CRO, Croplands; ENF, Evergreen Needleleaf Forest;

979   DBF, Deciduous Broadleaf Forest; SHR, Shrubland.

980

981   **Fig. 7.** Changes in GPP for all and individual PFTs in the presence of different levels of

982    $[O_3]$ as simulated by the vegetation model. Simulations are performed at 40 NACP sites

983   with a fixed $[O_3]$ for either low or high O_3 sensitivity. The short blue lines show the

984   damages ranging from low to high O_3 sensitivity, with the blue points indicating the

985   average reductions. The simulation results are averaged for all the sites or for the sites

986   with the same PFT. The number of sites used for average is shown in the title bracket of

987   each subplot. The solid squares with lines show the results (mean plus uncertainty) based

988   on measurements reported by multiple literatures. These measurements are collected by

989   Lombardozzi et al. (2013) for all PFTs, Wittig et al. (2007) for evergreen needleleaf

990   forest (ENF) and deciduous broadleaf forest (DBF). For C4 grass or crop (CRO_C4), we

991   have collected data from Taylor et al. (2002) for spartina alterniflora and Grantz et al.

992   (2012) for sugarcane hybrids. For C3 grass or crop (GRA_C3), we have collected data

993   from Feng et al. (2008) for wheat, Foot et al. (1996) for colluna vulgaris, Mulchi et al.

994   (1992) for soybean, and Ishii et al. (2004) and Ainsworth (2008) for rice. The values for

995   rice are denoted in green and others in red. The author initials are indicated for the

996   corresponding studies.

997

998   **Fig. 8.** Simulated summertime (a) O_3-exposed GPP and (b) O_3 stomatal flux over the U.S.

999   The simulated GPP is overlaid with *in situ* measurements from NACP. The simulations

1000   are performed with land cover from ISLSCP and meteorological forcings from MERRA

1001   reanalyses. Please refer to Fig. S6 for separate results from simulations and observations.

1002

1003   **Fig. 9.** Simulated reduction fraction in summer GPP in the U.S. due to (a) low and (b)

1004   high O_3 sensitivity for 1998-2007.

1005

1006   **Fig. 10.** Simulated changes in summer GPP due to (a, c) 25% reduction or (b, d) 25%

1007   increase in $[O_3]$ for (a, b) low or (c, d) high O_3 sensitivity.

1008
