## 1 **Abstract**

2 Aerosol effects on low-level clouds over the Nordic Countries are investigated by combining  
3 in-situ ground-based aerosol measurements with remote sensing data of clouds and  
4 precipitation. Ten years of number size distribution data from two aerosol measurement  
5 stations (Vavihill, Sweden and Hyytiälä, Finland) provide aerosol number concentrations in  
6 the atmospheric boundary layer. This is combined with cloud satellite data from the Moderate  
7 Resolution Imaging Spectroradiometer and weather radar data from the Baltic Sea Experiment.  
8 Also, how the meteorological conditions affects the clouds are investigated using reanalysis data  
9 from the European Centre for Medium-Range Forecasts.

10 The cloud droplet effective radius is found to decrease when the aerosol number concentration  
11 increases, while the cloud optical thickness does not vary with boundary layer aerosol number  
12 concentrations. Furthermore, the aerosol cloud interaction parameter (ACI), a measure of how the  
13 effective radius is influenced by the number concentration of cloud active particles, is found to be  
14 somewhere between 0.10 and 0.18 and the magnitude of the ACI is greatest when the number  
15 concentration of particles with a diameter larger than 130 nm is used. Lower precipitation  
16 intensity in the weather radar images is associated with higher aerosol number concentrations. In  
17 addition, at Hyytiälä the particle number concentrations is generally higher for non-precipitating  
18 cases than for precipitating cases. The apparent absence of the first indirect effect of aerosols on  
19 low-level clouds over land raises questions regarding the magnitude of the indirect aerosol  
20 radiative forcing.

## 1 Introduction

Aerosol particles are required for clouds to form at atmospheric conditions. The aerosol loading in the atmosphere has significantly increased since the beginning of the industrial revolution, which may have altered the microphysical properties of clouds (Boucher et al., 2013). For the same amount of liquid water, polluted clouds with more and smaller droplets reflect more sunlight than non-polluted clouds with few large droplets (Twomey, 1974). Smaller cloud droplets have also been hypothesized to lead to a reduction in drizzle from the clouds which could lead to a prolonged cloud lifetime (Albrecht, 1989). These anthropogenic impacts that the aerosols have on clouds are named the first and second indirect aerosol effects.

The estimates of the indirect aerosol effects are associated with large uncertainties (Lohmann et al., 2010). One reason for this is that different types of clouds are more or less sensitive to changes in aerosol number concentrations and that the prevailing cloud types vary across the globe. The fact that different types of clouds have diverse effects on climate also introduces uncertainties. Low-level stratiform clouds mainly reflect incoming short wave solar radiation but do not affect the outgoing longwave radiation to any great degree (Boucher et al., 2013). These clouds are very common over subtropical oceans but are also present over land and other parts of the ocean.

The first indirect aerosol effect in stratiform clouds has been investigated using a range of techniques such as in-situ measurements with aircraft, remote sensing from the ground and space, model simulations and combinations of these. Many previous studies have found that increased aerosol index or aerosol number concentration are associated with smaller cloud droplet sizes (Costantino and Breon, 2013; Twomey et al., 2005; Menon et al., 2008). The results regarding the hypothesized increase in cloud albedo or cloud optical thickness (COT) due to smaller and more numerous droplets, are however not as consistent. Some studies (Sporre et al., 2012; Chameides et al., 2002; Guo et al., 2007) have indeed found that the COT increases in polluted air masses while other studies find no correlation between COT and higher particle concentrations (Twomey et al., 2005; Costantino and Breon, 2013). The reasons for the diverging results are thought to be enhanced entrainment of dry air into the clouds due to increased cloud droplet number concentrations (Ackerman et al., 2004; Wood, 2007; Bretherton et al., 2007) or/and that air masses with higher aerosol loading often are associated with drier meteorological conditions (Brenguier et al., 2003). Both these effects lead to cloud thinning due to reduced LWP (liquid water path) and/or the vertical extent of the clouds.

The second indirect aerosol effect (cloud lifetime effect) has also been investigated by various methods with varying results. Several studies using different methods have found that precipitation or precipitation rates decrease in low-level clouds formed in environments with high aerosol number concentrations (Ferek et al., 2000; Lu et al., 2009; Cheng et al., 2007). Whether a suppression of precipitation causes an increased cloud lifetime has however been very complicated to determine (Stevens and Feingold, 2009).

Sporre et al. (2014) combined ground-based measurements of aerosol number concentrations with satellite cloud retrievals and weather radar precipitation data to

investigate convective clouds over Sweden and Finland. This study utilizes the same datasets although the focus here is on low-level clouds. Ten years of aerosol number concentration measurements from the two ground-based aerosol monitoring stations Vavihill (Sweden) and Hyytiälä (Finland) have been combined with satellite data from the MODIS instrument onboard the Terra and Aqua satellites to find out whether or not aerosol number concentrations affect cloud properties such as  $r_e$  and COT. Weather radar data from the BALTEX project are used as well to determine if the aerosol number concentrations affect drizzle formation. Furthermore, how the meteorological conditions affect the low-level clouds and the indirect aerosol effects is investigated by utilizing reanalysis data from the ECMWF (European Centre for Medium-Range Weather Forecasts). Table 1 summarizes the datasets and display where they can be accessed (all datasets are free to use for research purposes). Marine low-level clouds have been the subject of many previous investigations but this study instead focuses on continental low-level clouds that are more frequently influenced by anthropogenic aerosols.

## 2 Method

### 2.1 Aerosol Measurement Stations

Data from ground-based aerosol measurement stations at Vavihill and Hyytiälä (Fig. 1) for the periods 2001-2009 and 2000-2009 respectively, have been used in this investigation. Both stations are part of ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) network. The stations have similar seasonally averaged aerosol number size distributions but Vavihill is more influenced by continental aerosols than Hyytiälä. Hyytiälä on the other hand have a greater seasonal variation in number concentrations than Vavihill (Asmi et al., 2011).

The Vavihill station (Kristensson et al., 2008) is located in southern Sweden ( $56^{\circ} 01$  N,  $13^{\circ} 09$  E, 172 m a.s.l.). Aerosol number size distributions between 3 and 900 nm have been measured by a Differential Mobility Particle Sizer (DMPS) since 2001. In this study, data from a cloud condensation nuclei (CCN) counter (Fors et al., 2011) that was placed at the station in 2008 and 2009 has also been used. Vavihill is a background station without any large pollution sources nearby.

The other station SMEARII ( $61^{\circ}51$  N,  $24^{\circ}17$  E, 181 m a.s.l.) in Hyytiälä in Southern Finland (Hari and Kulmala, 2005) is also a background station. Number size distribution measurements have been ongoing since 1996 (Aalto et al., 2001), starting at size ranges 3-500 nm which was extended up to 1000 nm in December 2004. Only data from February 2000 and onwards were used here, since for this period the in-situ measurements coincide with the satellite observations. Data from a CCN counter that was operated in Hyytiälä during parts of the year 2008 and 2009 (Sihto et al., 2011) have also been analysed. Since the CCN counter data are not available during the entire investigation period, the aerosol number concentration of particle with sizes greater than 130 nm ( $N_{130}$ ) will be used as a proxy for the CCN.

The particle number concentrations measured at both stations were averaged over 5 hours (2.5 hour before and after the satellite overpass) to obtain values representative for the entire area captured by the satellite sensor. Using longer (up to 24 hours) or shorter (down to

1 hour) time intervals did not alter the results considerably. Days with a high variation in aerosol particle number concentrations during these 5 hours were removed from the study to ensure that the clouds investigated were formed under similar conditions.

## 2.2 Satellite Data

The satellite data used in this investigation have been obtained by the MODIS sensors onboard the polar orbiting Terra and Aqua satellites. The instruments provide satellite scenes over Sweden and Finland sometime between morning and early afternoon, local time. The scenes were manually screened for low-level clouds over the aerosol stations by studying true colour visible, COT and cloud top temperature satellite scenes, and one image per day was selected. The true colour visible and the COT images were first investigated to ensure that the cloud cover was extensive and that the clouds were not convective while top temperature was investigated to ensure that the clouds were low-level clouds. Images when the stations were situated as close to the middle of the satellite scene as possible were chosen to minimize the distortion of the pixels that occurs at the edge of the swath. In each scene, a smaller area of pixels (90 km by 62 km) surrounding each station is included in the study (Fig. 1). The investigation areas mainly contain forests which provide a dark homogeneous background to the clouds.

MODIS Level 2 (Collection 5.1) cloud parameters (Platnick et al., 2003) have been analysed in this study. The cloud products include an effective radius ( $r_e$ ) at 2.1  $\mu\text{m}$  and COT that are derived from reflectance measurements at two MODIS wavelength channels and a LWP that is calculated from these (King et al., 2006). The  $r_e$  derived from another wavelength channel (3.7  $\mu\text{m}$ ) rather than the standard at 2.1  $\mu\text{m}$  is used in this study, because the  $r_e$  at 2.1  $\mu\text{m}$  is sometimes overestimated due to reflectance variability on a sub-pixel scale (Zhang et al., 2012). Other cloud parameters used are: Cloud Top Temperature (CTT), Cloud Phase Optical Properties, Cirrus Reflectance and Multilayer Cloud Warning. The three latter are used to sort out pixels that do not contain low-level clouds. Pixels that are classified as containing ice are excluded from the study and pixels with multilayer cloud warnings are also omitted. Furthermore, the cloud top temperature is used to screen out clouds with too cold CTT to ensure that only low-level clouds are studied. The derivation of the temperature limit from ECMWF data is described in Section 2.4. Cloud retrievals become uncertain for pixels with a  $\text{COT} < 5$  (Zhang et al., 2012) and therefore, pixels with such values are not included in the study. Pixels where  $r_e$  at 3.7  $\mu\text{m}$  is more than 10  $\mu\text{m}$  less than the  $r_e$  at 2.1  $\mu\text{m}$  were also removed since this indicates an overestimation of the  $r_e$  at 2.1  $\mu\text{m}$  and uncertainties in the  $r_e$  retrievals. At least 50 satellite pixels must pass the above criteria for the scene to be included in the study. Furthermore, scenes where less than 5% of all cloud pixels are classified as low-level clouds are excluded from the study. All MODIS products used here have a horizontal resolution of 1 km at nadir, with the exception for the CTT that has a resolution of 5 km at nadir.

Vavihill and Hyytiälä are located at quite high latitudes which means that the solar zenith angle (SZA) will be high during large parts of the year. A recent study (Grosvenor and Wood, 2014) found that the COT values increase considerably and  $r_e$  decrease somewhat with SZA, at SZA higher than 65°. In the current dataset, no significant trends of COT or  $r_e$  with SZA have been found. The results were also recalculated without the cases with a  $\text{SZA} > 65^\circ$  and the results regarding how aerosol number concentrations affect  $r_e$  and COT were barely

altered. To investigate whether cloud heterogeneity have affected the results, the CTT and COT variability was calculated according to the method presented in Grosvenor and Wood (2014). However, none of heterogeneity parameters were found to be affected by N<sub>130</sub> or SZA.

### 2.3 Precipitation Data

The BALTEX (the Baltic Sea Experiment) project is a regional hydroclimate project that focuses on the Baltic Sea and the surrounding drainage basin. The project provides composite radar images from 30 C-band weather radars covering the entire Baltic region, which includes both Vavilhill and Hyytiälä. The images are produced every 15 minutes and have a 2 km horizontal resolution (Michelson, 2006; Michelson and Sunhede, 2004). Because the radar images are generated with such high temporal frequency, the time difference between the satellite overpass and the corresponding radar image is only 5 minutes.

The areas surrounding the stations seen in Fig. 1 are also analysed in the radar images. The pixels in the satellite and radar images cannot be matched to each other due to the different resolution and positioning systems of the images. However, since not all pixels in the satellite images are included in the study (Section 2.2) precipitation that does not originate from the low-level clouds is included in the study if one includes all radar pixels. Therefore, the distance between each radar pixel and the satellite pixel was calculated and only radar pixels within 3.5 km distance from a low-level cloud pixel are included in the study.

To obtain one precipitation value for each composite radar image the average of only those pixels with a reflectance value greater than -10 dBZ (no precipitation) were calculated. For images with 4 pixels or less containing values greater than -10, the precipitation value is set to -30 dBZ.

### 2.4 Meteorological Data

Reanalysis data from the ECMWF have been used to estimate the meteorological conditions that the clouds form in. The relative humidity (RH) and specific humidity (SH) at 1000 hPa were used to estimate the humidity conditions in the lower atmosphere. Furthermore, the low-tropospheric static stability (LTSS), defined as the difference in potential temperature at 700 hPa and the surface (Klein and Hartmann, 1993), was calculated from the ECMWF data. Also, Convective Available Potential Energy (CAPE) has been used to screen out cases with convective clouds (CAPE > 100 J/kg) from the study.

Reanalysis data was also used to calculate the lower temperature limit for the low-level clouds. The maximum cloud top height was set to 1500 m to select clouds affected by boundary layer aerosol particles since ground-based measurements of aerosol number concentrations are used. The ECMWF model level closest to 1500 m was found using the hydrostatic equation to calculate the height of the levels. To account for inversions, the coldest temperature of all pressure levels up to the one at 1500 was used as the limit to sort out low-level clouds in the satellite data.

### 2.5 Trajectory Analysis

To estimate the origins of the air masses arriving at the two ground-based stations, back-trajectories were calculated with the Hysplit4 model trajectory (Draxler and Hess, 1997). The meteorological data used in the calculations are from the GDAS (Global Data

190 Assimilation System) and provided by the NCEP (National Centre of Environmental  
Predictions). Back trajectories (72 h) starting at 100 m above ground level were calculated  
hourly and an average air mass origin was calculated for the 5 hours of aerosol measurements  
by calculating a centre of gravity of the 5 trajectories. The azimuth angle between the station  
and the centre of gravity was then calculated.

## 195 **2.6 Aerosol Cloud Interaction**

A way to compare results from different type of studies concerning the first indirect  
aerosol effects was proposed by McComiskey and Feingold (2008). The concept has been  
named the aerosol cloud interaction (ACI) and is defined as:

$$ACI = \left. \frac{\partial \ln COT}{\partial \ln \alpha} \right|_{LWP} = - \left. \frac{\partial \ln r_e}{\partial \ln \alpha} \right|_{LWP} = \frac{1}{3} \frac{d \ln N_d}{d \ln \alpha} \quad (1)$$

200 where  $\alpha$  is a proxy for the number of cloud condensation nuclei,  $r_e$  is the cloud effective  
radius and  $N_d$  is the cloud droplet number concentration. The first two parts of eq. 1 requires  
that the data are divided according to LWP to ensure equality between the different parts of  
the equation. In this study the ACI is only calculated from the  $r_e$  i.e. the second part of eq. 1.  
The ACI has been used frequently in previous studies and aircraft in-situ measurements  
205 generally obtain higher values than remote sensing studies (McComiskey and Feingold,  
2008).

## **3 Results and discussion**

The number of cases included in the study are 122 for Vavihill and 261 for Hyytiälä. In  
Table 2, the amount of days in each step of the analysis is shown. There are more days with  
210 DMPS data available for Hyytiälä than Vavihill, but since Hyytiälä is located further north  
with less daylight in winter there are less satellite data available for this station. Low-level  
clouds seem to be more common over Hyytiälä than Vavihill since a larger percentage of the  
scenes investigated over Hyytiälä contain low-level clouds. Most cases that were excluded in  
the automatic screening, although classified as low-level clouds in the manual screening, were  
215 omitted because the CTT was too cold.

The  $r_e$ , COT and LWP values from each satellite scene are generally lognormal  
distributed and the geometrical average of each scene of these parameters have therefore been  
calculated.  $N_{130}$  was the aerosol number concentration subset that correlated best with the  $r_e$  in  
this study and was therefore chosen as a proxy for CCN. When convective clouds were  
220 studied over the same region (Sporre et al., 2014)  $N_{80}$  (aerosol number concentration of  
particles with sizes greater than 80 nm) was found instead to best correlate with the  $r_e$ . This  
finding is expected since low-level clouds have a lower maximum supersaturation than  
convective clouds. Table 3 shows the average ratios between  $N_{130}$  and the number  
concentrations measured by the CCN counter at different supersaturations. At 0.1 %  
225 supersaturation the ratios are greater than one implying that  $N_{130}$  is higher than the number of  
aerosol particles that are activated by the CCN counter. At 0.2 % supersaturation the ratio is  
lower than one and hence  $N_{130}$  corresponds to a supersaturation somewhere between 0.1 and  
0.2 %, which is reasonable for low-level clouds.

The seasonal variation in number of cases,  $N_{130}$ , CTT, RH at 1000 hPa and the LTSS  
230 for the days included in the study is shown in Figure 2. There are generally more days with

low-level cloud cover in winter than in summer at both stations. Janssen et al. (2011) studied seasonal variations of low-level clouds over Hyytiälä using satellite data from 9 out of the 10 years used in this study. The focus in that study was however on cloud droplet number concentrations derived from  $r_e$  and COT and the areas investigated in the satellite scenes differ somewhat between that and the current study. Janssen et al. (2011) found no seasonal variation in the occurrence of low-level clouds, which does not agree with the results in this study. Since no manual screening of the satellite scenes and higher maximum cloud tops (2500 m) were used in their study, shallow convective clouds present in summer may have been included in their study. This may be the cause for the differences found regarding seasonal variation in the occurrence of low-level clouds between the two studies.

The meteorological parameters in Fig. 2f, 2h and 2j, with the exception for LTSS at Vavihill (Fig. 2j), vary considerably with season. None of the meteorological variables on the other hand show a strong variation with air mass origin (Fig. 2e, 2g and 2i). Furthermore, Figure 2d shows that  $N_{130}$  at both stations does not vary with season in this dataset, while a previous study utilising 2 years of DMPS data from both stations, found a seasonal variation in  $N_{100}$  (number of particles above 100 nm) at both stations (Asmi et al., 2011). That the seasonal variation is missing in the current study is most likely because the study has less temporal resolution than the Asmi et al (2011) study. Moreover,  $N_{130}$  is higher at both stations when the air masses arrive from south to southeast (Fig. 2c), where various sources of anthropogenic aerosols are located.

### 3.1 Effective Radius

In Table 4 (Vavihill) and Table 5 (Hyytiälä) correlation coefficients between several of the variables investigated in the study are presented. The upper right-hand of the tables contain the linear correlation coefficients while the lower left-hand contain the correlation coefficients between the natural logarithm of the parameters. The logarithm has not been applied to the parameters that contain mainly negative values (CTT and dbzc). The  $r_e$  (at 3.7  $\mu\text{m}$ ) is best correlated with LWP and second best with  $N_{130}$  at both stations. The high correlation coefficients with LWP are expected since LWP is calculated from the  $r_e$  at 2.1  $\mu\text{m}$  (Section 2.2) which have similar values to the  $r_e$  at 3.7  $\mu\text{m}$ . The correlation coefficients between the logarithms of the  $N_{130}$  and  $r_e$  are higher than the linear correlation coefficients, implying that the relationship between the two parameters is best described by an exponential function. This type of relationship has been widely used in previous studies (Twohy et al., 2005; McComiskey and Feingold, 2008). Furthermore, the  $r_e$  is positively correlated with the RH at 1000 hPa, which indicate that the cloud droplet size is affected by the RH in the boundary layer.

Figure 3a shows the relationship between the logarithms of  $r_e$  and  $N_{100}$  obtained in this study, as well as relationships from 2 previous studies of low-level clouds over the ocean. The  $N_{100}$  instead of  $N_{130}$  are used in this figure since this is the CCN proxy used in the previous studies. Figure 3a shows that the relationships from Vavihill and Hyytiälä are similar with a slightly steeper slope for Hyytiälä. The large scatter in the figures is expected, since clouds formed in various conditions during different seasons are studied. The relationship found by Sporre et al. (2012) was obtained using satellite cloud observations over sub-polar oceans combined with ground-based in-situ measurements of aerosol number concentrations. Figure

275 3a shows that the  $r_e$  in their study is generally higher than in the current study, which may be  
caused by differences in dynamical and/or thermodynamical conditions in the investigation  
areas. The  $r_e$  values obtained from aircraft measurements by Twohy et al. (2005) shown in  
Fig. 3a, are similar to the current satellite values for low  $N_{100}$  values, but the slope of the  
relationship is substantially steeper than the ones obtained here. The measurements by Twohy  
et al. (2005) were however performed in a relatively clean marine atmosphere. Dissimilar  
280 LWP of the clouds in the different studies could also be a factor explaining why the slopes of  
the relationships differ.

The variation in  $r_e$  with season and air mass origin are shown in Fig. 4a-4b. The  $r_e$  does  
not vary much with season, but a small number of relatively high values are present in winter  
at both stations and also in autumn at Hyytiälä. These high values may have been caused by a  
285 combination of high RH and low  $N_{130}$  values. Janssen et al. (2011) found that the  $r_e$  over  
Hyytiälä have a minimum in spring but no minimum in  $r_e$  in spring over Hyytiälä has however  
been found in the present study (Fig. 4b). The  $r_e$  at Vavihill and Hyytiälä vary with air mass  
origin and is generally lower when the air masses are arriving from the south (Fig. 4a), which  
is the sector where the  $N_{130}$  is high (Fig. 2a).

290 Several previous studies of aerosol indirect effects have divided their cloud data  
according to the presence of drizzle or only studied clouds that are non-drizzling. When the  
present data were divided according to precipitation (precipitating cases defined as cases with  
more than 4 pixels with dbcz greater than -10 dbZ), no significant difference in the results are  
nonetheless found compared to when the whole dataset is used.

### 295 **3.2 Cloud Optical Thickness**

Very low, non-statistically significant correlations between COT and  $N_{130}$  have been  
found in this study (Tables 4 and 5). In addition, Fig. 3b shows that COT is more or less  
independent of  $N_{130}$ , but the variability in COT seem to increase with  $N_{130}$ . The decrease in  
droplet size associated with an increase in  $N_{130}$  found here hence does not result in an increase  
300 in the COT and the COT is positively correlated with  $r_e$  at both stations (Tables 4 and 5). The  
LWP is also well correlated with COT since the LWP is calculated from the COT (Section  
2.2). The only other parameter that may affect the COT is the RH (at 1000 hPa) (Tables 4 and  
5). Drier conditions in the boundary layer seem to be associated with lower COT, but since  
RH and  $N_{130}$  are not significantly negatively correlated (see Fig. 5 and Tables 4 and 5), the  
305 RH cannot explain the lack of correlation between COT and  $N_{130}$ . If RH at higher altitude in  
the atmosphere (850 or 700 hPa) is used instead, the correlation coefficients with COT  
decreased at both stations (not shown). The RH of the air entrained into the clouds from  
above does therefore not seem to be controlling the COT. The correlations between  $N_{130}$  and  
COT do not change significantly when scenes containing drizzle are excluded or when only  
310 scenes containing drizzle are investigated.

Twohy et al. (2005) and Costantino and Breon (2013) also found that the COT is  
unaffected by aerosol number concentrations and aerosol index, respectively. Moreover, these  
studies found that the missing first indirect effect could be explained by decreased LWP in  
polluted conditions. The clouds observed in the former study were geometrically thinner  
315 while, in the latter study it is hypothesized that the LWP decreases due to enhanced  
entrainment caused by aerosols. In cloud simulations, small cloud droplets and suppressed

precipitation associated with higher CCN concentrations has also been shown to enhance entrainment into the clouds, leading to a reduction in the LWP (Ackerman et al., 2004). Higher aerosol number concentrations are in the present study associated with both smaller droplets and decreased precipitation rates (Section 3.4). There is however, only a weak negative correlation between  $N_{130}$  and LWP (Tables 4 and 5 and Fig. 3c) obtained here for Hyytiälä. Even so, the weak correlation may partly explain why no change in COT with  $N_{130}$  is found in this study.

Figures 4 c-f show that neither COT nor LWP vary considerably with season or air mass origin. A minimum in COT has previously been found in spring (Janssen et al., 2011), but no seasonal minimum was found in the current dataset. The dissimilar results are most likely due to the different data selection used in the two studies (discussed in Section 3).

### 3.3 ACI

The ACI can be calculated from both the  $r_e$  and the COT but this requires that the data are divided according to LWP (Eq. 1). The LWP is directly calculated from the  $r_e$  at 2.1  $\mu\text{m}$  and the COT (Section 2.2) and hence is not independent of these parameters. The ACI has therefore only been calculated for the  $r_e$  at 3.7  $\mu\text{m}$  in this study.

Figures 6 a-c show how the ACI varies when calculated with different proxies for  $\alpha$  (eq. 1) which in this study is the aerosol number concentration above the diameter  $D_p$ . Included in the figure are also ACI  $r_e$  data from the study by Lihavainen et al. (2010) in which ground-based measurements of aerosols was compared with satellite data over northern Finland. The data from the current study have been divided into 4 subintervals of LWP, while the data from Lihavainen et al. (2010) includes all values of LWP. The corresponding  $r^2$  values are shown in Fig. 6 d-f and Fig. 6 g-i display the uncertainty in the ACI values. The solid markers in the figure denote statistically significant correlations at a 95% confidence interval. Since there are relatively few cases included from Vavihill not many of the corresponding ACI values are associated with significant correlations. Figures 6 a-c show that a peak in ACI around a  $D_p$  of 130 nm occur for most LWP intervals which coincides well with the results from Lihavainen et al. (2010). This means that  $r_e$  in this study is most sensitive to the number concentration of particles with a diameter above the diameter 130 nm. For most intervals, the ACI and  $r^2$  values decline as the lower cut-off diameter for the number concentrations  $D_p$  decreases below 100 nm or increases above 300 nm. Some LWP intervals display a second peak at a  $D_p$  of around 25nm. However, these results should be interpreted with caution, since these LWP intervals contain fewer data points and the uncertainty in the ACI values is higher (Fig 6 g-i).

That the ACI increases significantly with LWP can be seen in Fig. 6, but also in Fig. 7 where the relationship between ACI and LWP is shown. The CCN proxy  $\alpha$  is set to  $N_{130}$  here and at least 10 cases are required in each LWP bin for the ACI to be calculated. The same  $\alpha$  was used by Lihavainen et al. (2010). Again, most ACI values from Vavihill lack significant correlations due to the low number of cases included. For the Hyytiälä and combined datasets ACI varies from 0.05 for low LWP to 0.25 for high LWP. For the Lihavainen et al. (2010) data no clear dependence of ACI on LWP can be found, but their ACI values also peak at high LWP values. For both studies, the high values of ACI at high LWP should be interpreted with some caution since the number of cases in these LWP bins are smaller than in the other bins. Even without the highest LWP point the ACI seem to increase, if only slightly, with

360 LWP for Hyytiälä or the combined data in the present study. The ACI have previously been  
found to decrease with LWP in marine stratus clouds (McComiskey et al., 2009), which does  
not agree with the results here. This may be explained by the different cloud types  
(marine/continental) investigated and/or, difference in cloud remote sensing (ground-  
based/satellite). The dissimilar results may also be due to different in-situ instruments  
365 (nephelometer/DMPS) used and/or that (McComiskey et al., 2009) have calculated the ACI  
from COT, while  $r_e$  is used in the present study.

### 3.4 Precipitation

In Tables 4 and 5, correlation coefficients obtained between the precipitation parameter  
and the aerosol, cloud and meteorological parameters investigated in the present study are  
370 shown. Only cases associated with precipitation are included in the correlation calculations.  
The dbcz is significantly correlated to CTT, SH and the logarithm of  $N_{130}$  at both stations. In  
Fig. 4 g-h it can be seen that the dbcz does vary neither with season nor with air mass  
direction.

Relationships between dbcz and  $N_{130}$  (linear and logarithm of) for only the precipitating  
375 cases for the two stations are shown in Fig. 8. The corresponding slopes, correlation  
coefficients and p-values are shown in Table 6. Both subfigures 8a and 8b display negative  
correlations between  $N_{130}$  and dbcz. Moreover, statistically significant correlations are  
obtained for Hyytiälä in both Fig. 8 a and b but only in the latter for Vavihill.

To determine if the high aerosol number concentrations are suppressing precipitation in  
380 the low-level clouds, histograms of  $N_{130}$  have been created separately for the precipitating  
cases and the non-precipitating cases (Fig. 9). For Vavihill (Fig. 9a), the distributions are not  
significantly different from each other and it even appears that cases with no precipitation  
have lower  $N_{130}$ . However, for Hyytiälä (Fig. 9b) the cases with no precipitation have on  
average higher  $N_{130}$  and the distributions are significantly different from each other with a  
385 95% confidence interval according to a t-test. Since the number of cases at Hyytiälä is greater,  
the results from this station are thought to be more reliable.

Even though only radar composite pixels adjacent to satellite low-level cloud pixels  
were included in the study, some precipitating pixels not belonging to the low-level clouds  
may have been included. Hence, some of the cases determined to be precipitating may not  
390 contain any precipitating low-level clouds which would affect the results in Fig. 9. That  
precipitation pixels not belonging to the low-level clouds may be included in the study also  
introduces uncertainties to the results in Fig. 8. Even so, the large scatter seen in Fig. 8 is  
expected since clouds formed in different meteorological conditions have been investigated  
here.

## 395 4 Conclusions

Ten years of ground-based aerosol measurements have been combined with satellite  
cloud retrievals and weather radar precipitation data to provide insights on how aerosols  
affect continental low-level clouds over the Nordic countries. Increasing aerosol number  
concentration is associated with decreasing  $r_e$ , but the COT appears to be unaffected by  
400 aerosol number concentration. The ACI values (calculated from  $r_e$ ) in this study are in the

range of 0.10-0.18 for most LWP bins and highest ACI values are obtained when the total number of particles with a diameter greater than 130 nm is used as the aerosol proxy. The precipitation rates are found to decrease for higher aerosol number concentrations. In addition, days with precipitation at Hyytiälä are generally associated with lower aerosol number concentrations than those without precipitation. The first indirect aerosol effect can hence not be verified in the present study, but the second indirect effect is noticeable. Similar results were found for convective clouds that were investigated over the same areas in Sweden and Finland (Sporre et al., 2014).

## Acknowledgements

This work was carried out with the support of the FP6 European Commission project European Supersites for Atmospheric Aerosol Research, EUSAAR, contract No. RII3-CT-2006-026140, the European Integrated Project on Aerosol, Cloud, Climate and Air Quality Interactions, EUCAARI, contract number 036833-2, the European Seventh Framework Program, ACTRIS (EU INFRA-2010-1.1.16-262254), Aerosols, Clouds, and Trace gases Research Infra Structure Network, the Strategic Research Program MERGE, Modeling the Regional and Global Earth System, and Lund Centre for studies of Carbon Cycle and Climate Interaction – LUCCI. We also gratefully acknowledge the support by the Swedish Research Council and from the Nordic Council of Ministers for the Nordic Top-level Research initiative CRAICC: Cryosphere-atmosphere interactions in a changing Arctic climate. This work is supported by the Academy of Finland Centre of Excellence (grant no. 1118615), the European Research Council Projects ATMNUCLE (grant no. 227463).

The satellite data from the MODIS instruments have been supplied by the National Aeronautics and Space Agency and the modeled meteorological data were provided by the ECMWF. The weather radar data have been supplied by the BALTEX radar data centre. The authors would like to thank Daniel Michelson for his help with the manuscript.

Figure 1. Map showing the locations of the ground-based in-situ measurement stations and the surrounding areas used for the satellite retrieved cloud products.

600 Figure 2. Number of cases, number concentration of aerosol particles with a diameter larger than 130 nm ( $N_{130}$ ), cloud top temperature (CTT), relative humidity at 1000 hPa (RH) and low-tropospheric static stability (LTSS) plotted against air mass origin (a, c, e, g, i) and day of the year (b, d, f, h, j) for Vavihill (blue dots) and Hyytiälä (green dots). The lines in the figures are mean values over 22.5 degrees (a, c, e, g, i) and over 30 days (b, d, f, h, j).

605

Figure 3. Relationship between a)  $r_e$  and  $N_{100}$ , b) COT and  $N_{130}$  and c) LWP and  $N_{130}$  for Vavihill (blue line and dots) and Hyytiälä (green line and dots). Included in Fig. 3a is also relationships obtained by Sporre et al. (2012) and Twohy et al. (2005).

610 Figure 4. Effective radius ( $r_e$ ), cloud optical thickness (COT), liquid water path (LWP) and radar reflectance (dbcz) plotted against air mass origin (a, c, e, g) and day of the year (b, d, f, h) for Vavihill (blue dots) and Hyytiälä (green dots). The lines in the figures are mean values over 22.5 degrees (a, c, e, g) and over 30 days (b, d, f, h).

615 Figure 5. Relationship between relative humidity (RH) and aerosol number concentrations above 130 nm ( $N_{130}$ ).

Figure 6. Aerosol cloud interaction (ACI) versus  $D_p$ , which is the lower limit for the aerosol number concentration used to calculate the ACI, for a) Vavihill b) Hyytiälä and c) the  
620 combined dataset. Squared correlation coefficient ( $r^2$ ) between the aerosol and cloud parameter as a function of  $D_p$  are shown in d) for Vavihill, e) for Hyytiälä and f) for the combined datasets. Uncertainty in the calculated ACI as a function of  $D_p$  are displayed in g) for Vavihill, h) for Hyytiälä and i) for the combined datasets. The ACI is calculated from the  $r_e$  at 3.7  $\mu\text{m}$  and  $N_{130}$ . The ACI has been calculated for 4 subsets of the data according to LWP and for all LWP values together. The solid markers denote statistically significant correlations with a 95% confidence interval. Included in the figure is also results obtained by Lihavainen et al. (2010), which did not divide the data according to liquid water path (LWP).  
625

Figure 7. a) aerosol cloud interaction (ACI) as a function of liquid water path (LWP) and b)  
630 the corresponding squared correlation coefficients ( $r^2$ ) as a function of LWP for the two stations separately and combined. The ACI is calculated with  $\alpha=N_{130}$ . Results obtained by Lihavainen et al. (2010) are also included in the study. Filled markers in the figure denote statistically significant correlations at a 95% confidence interval.

635 Figure 8. Radar reflectance (dbcz) as a function of aerosol number concentrations above 130 nm ( $N_{130}$ ) for only precipitating cases. In b), the natural logarithm has been applied to the  $N_{130}$ . The dotted lines represent the 95% prediction intervals for the relationship of the combined dataset.

640 Figure 9. Histograms of aerosol number concentrations for particles larger than 130 nm ( $N_{130}$ ), subdivided according to precipitating and non-precipitating cases for a) Vavihill and b) Hyytiälä. Precipitating cases are defined as cases with more than 4 pixels with dbcz greater than -10 dbZ.
