Abstract.

We have investigated the potential impact on organic aerosol formation from biotic stress-induced emissions (SIE) of organic molecules from forests in Europe (North of Lat. 45°N). Emission estimates for sesquiterpenes (SQT), methyl salicylate (MeSA) and unsaturated C₁₇-compounds, due to different stressors, are based on experiments in the Jülich Plant Atmosphere Chamber (JPAC), combined with estimates of the fraction of stressed trees in Europe based on reported observed tree damage.

SIE were introduced in the EMEP MSC-W chemical transport model and secondary organic aerosol (SOA) yields from the SIE were taken from the JPAC experiments. Based on estimates of current levels of infestation and the JPAC aerosol yields, the model results suggests that the contribution to SOA in large parts of Europe may be substantial. It is possible that the SIE contributes as much, or more, to organic aerosol than the constitutive biogenic VOC-emissions, at least during some periods. Based on the assumptions in this study, SIE-SOA are estimated to constitute between 50 and 70% of the total biogenic SOA (BSOA) in a current-situation scenario where the biotic stress in Northern and Central European forests causes large SIE of MeSA and SQT. An alternative current-situation scenario with lower SIE, consisting solely of SQT, leads to lower SIE-SOA, between 20 and 40% of the total BSOA.

Hypothetical future scenarios with increased SIE, due to higher degrees of biotic stress, show that SOA formation due to SIE can become even larger.

Unsaturated C₁₇-BVOCs emitted by spruce infested by the forest honey generating bark louse *Cinara pilicornis* have a high SOA-forming potential. A model scenario investigating the effect

of a regional, episodic infestation of *Cinara pilicornis* in Baden-Württemberg, corresponding to a year with high production of forest honey, shows that these types of events could lead to very large organic aerosol formation in the infested region.

We have used the best available laboratory data on biotic SIE applicable to Northern and Central European forests. Using these data and associated assumptions we have shown that SIE are potentially important for SOA formation but the magnitude of the impact is uncertain and needs to be constrained by further laboratory, field and modelling studies. As an example, the MeSA, which is released as a consequence of various types of biotic stress, is found to have a potentially large impact on SIE-SOA in Europe but e.g. different assumptions regarding the nighttime chemistry of MeSA can change its SOA potential substantially. Thus, further investigations of the atmospheric chemistry of MeSA and observational field studies are needed to clarify the role of this compound in the atmosphere.

1 Introduction

The emissions of biogenic volatile organic compounds (BVOC) by forests are the major sources of hydrocarbons to the atmosphere (Guenther et al., 2012; Lamarque et al., 2010; Simpson et al., 1999). Photo-oxidation of BVOC, in the presence of nitrogen oxides (NO_x), contributes to the formation of tropospheric ozone and leads to secondary organic aerosol (SOA) particle formation (Hallquist et al., 2009). Many BVOCs, e.g. isoprene, α -pinene, and sesquiterpenes (SQT), are unsaturated and react with all main oxidants in the atmosphere: OH, ozone and NO₃, while the saturated BVOC preferably react with OH. SOA formation is caused by the gas to particle transformation of some of the oxidation products, depending on e.g. their vapour pressure. Studies using carbon-14 and other tracer compounds have shown that such biogenic SOA (BSOA) is often the major contributor to ambient organic aerosols (OA) at rural, and even some urban, sites in Europe (Gelencsér et al., 2007; Minguillon et al., 2011; Szidat et al., 2004, 2009; Yttri et al., 2011).

BSOA formation can play an important (but complex) role in the radiation balance of the Earth and thus for surface temperature (Arneth et al., 2010). In a future climate, vegetation growth may increase in many areas, especially in the boreal and temperate regions (e.g. Ahlström et al., 2012; Morales et al., 2007; Lathiere et al., 2005), with possible increases in BVOC emissions because of increasing foliar expansion and increasing temperatures (Lathiere et al., 2005; Guenther et al., 2006, 2012; Duhl et al., 2008; Arneth et al., 2011). Increased BVOC emissions will result in more and larger atmospheric particles (Joutsensaari et al., 2005; Allan et al., 2006; VanReken et al., 2006; Tunved et al., 2008; Mentel et al., 2009; Riipinen et al., 2011).

The emissions of BVOC are regarded as being 'constitutive' if produced and released in the unperturbed, non-stressed state of the vegetation. In BVOC emission algorithms, the constitutive emissions are assumed to be under the control of meteorological factors, especially temperature and light,

as well as phenological cycles (Guenther et al., 2012). The SOA forming potential of these emissions, especially isoprene and monoterpenes (MT), and to a lesser extent SQT, have been extensively investigated in laboratory studies over many years (e.g. Bonn and Moortgat, 2003; Lee et al., 2006; Hallquist et al., 2009, and references therein; Winterhalter et al., 2009; Donahue et al., 2012; Jaoui et al., 2013).

Algorithms derived from such laboratory data have been applied in atmospheric chemical transport models (CTMs), using a variety of techniques to treat BVOC emissions, chemistry and gas-particle partitioning (Bowman et al., 1997; Andersson-Sköld and Simpson, 2001; Schell et al., 2001; Kanakidou et al., 2005; Donahue et al., 2006, 2009; Simpson et al., 2007; Kroll and Seinfeld, 2008; Hallquist et al., 2009; Jimenez et al., 2009; Murphy and Pandis, 2009; Bergström et al., 2012; Li et al., 2013). For many years OA and SOA were largely underestimated by some CTMs compared to field observations (Heald et al., 2005; Kanakidou et al., 2005; Volkamer et al., 2006). This gap has been reduced in recent years, partly by improved gas-particle mechanisms considering higher generations of oxidation products of VOC as SOA sources, i.e. chemical ageing (Donahue et al., 2006, 2009, 2012). Indeed there are indications that with simplified models for ageing chemistry (lacking fragmentation reactions) newer schemes can even overestimate SOA in some cases (e.g. Bergström et al., 2012; Lane et al., 2008).

Still, with the exception of Berg et al. (2013), all model studies to date, that we are aware of, have only considered the standard constitutive emissions discussed above. Besides constitutive emissions, vegetation also releases so called induced emissions to the atmosphere. Induced emissions are often caused by 'biotic stress' — by infestation of insects, viruses, fungi, etc. (e.g. Arneth and Niinemets, 2010; Amin et al., 2012, 2013; Berg et al., 2013), but they are also affected by other stressors like heat or drought (e.g. Kleist et al., 2012). In this paper we will collectively denote these emissions as stress-induced emissions (SIE).

Berg et al. (2013) investigated the impact of bark beetle infestations on MT emissions and SOA formation in western North America. MT emissions due to bark beetles may both increase (during attack) and decrease (after tree-death) and Berg et al. found that beetle infestations in pine trees can have a significant regional impact on SOA concentrations (up to 40% increase) during some years; responses may be substantially larger if spruce trees are infested (Berg et al., 2013).

Recently, SOA mass yields from the laboratory studies in the Jülich Plant Atmosphere Chamber (JPAC), with real plants as sources, showed that terpenoidic SIE, such as sesquiterpenes, and phenolic BVOC (e.g. methyl salicylate, MeSA), originating downstream of the shikimate pathway (e.g., Wildermuth 2006), are very efficient in forming SOA (Mentel et al., 2013). Their particle mass yields are 3-4 times larger than those of MT, see Sect. 2.2. In a case where a spruce was infested by *Cinara pilicornis* (honeydew generating lice) unsaturated C₁₇-BVOC (mainly 8-heptadecene, 6,9-heptadecadiene, and 3,6,9-heptadecatriene) were observed with particle mass yields six times higher than those of MT (Mentel et al., 2013). Given that SIE are a ubiquitous source of BVOC and thus

95 SOA in forests, these laboratory findings suggest that SIE may account for a significant fraction of ambient SOA mass. Neglect of the SIE in models might explain some of the discrepancies between observed OA and model predictions.

If the SIE increase in the future (e.g. with increasing frequencies of insect damage, Jonsson et al. 2009), the SIE-SOA concentrations will also rise; and indeed the role of SIE in a changing climate is attracting increasing attention (Peñuelas and Staudt, 2010; Holopainen, 2011). Even current-
100 condition SIE, due to e.g. biotic stressors, are difficult to assess; inherent difficulties include the episodic character and time lags of the emissions, dependencies on plant history, and adaption to stresses, as well as the scaling of emissions from leaf-level to regional scale (Arneth and Niinemets, 2010; Niinemets et al., 2010). All of these aspects require substantial research, and, as discussed by
105 Arneth and Niinemets (2010), building modules that simulate induced emissions is a difficult if not impossible task at the current level of understanding.

SIE are generally not explicitly included in atmospheric models because of (i) a lack of awareness of their possible importance, (ii) lack of suitable data and information about the distribution of stress and its specific effects, and (iii) lack of appropriate SOA formation algorithms. However, given these
110 difficulties, it is still appropriate and important to assess the order of magnitude of such SIE-SOA contributions to ambient aerosol. Here we want to demonstrate how the neglect of SIE in models may affect *current* SOA predictions and the possible effects of SIE on SOA in the future.

The goal of this model study is to draw attention to the possible importance of SIE emissions, and to make a first estimate of their contribution to SOA formation; both in current conditions and with
115 a projection of what could happen in the future under the assumption that stress to plants becomes more frequent or severe. We combine experimental emission and SOA-formation results from JPAC with estimates of the possible geographical extent of the SIE, and use the EMEP MSC-W regional chemical transport model (Simpson et al., 2012; Bergström et al., 2012) to assess potential SOA formation over Europe. To construct continental scale emission scenarios for the SIE, we make use
120 of European and national forest damage reports. These are in general based on ocular inspection of defoliation and insect infestation in European forests; the inspections are performed regularly and follow well defined protocols (Lorenz, 2010; Ferretti et al., 2010).

A major strength of this study is that both the emission factors of SIE/constitutive emissions and SIE-SOA mass yields are determined from the same experimental JPAC data for relevant forest
125 species. As shown for new particle formation and SOA yields the results from the JPAC studies can be transferred to atmospheric situations (Mentel et al., 2009). Uncertainties arise from the estimates of the fraction and spatial distribution of infested trees, as well as limited knowledge of the seasonal variation of some of the infestations. Despite these uncertainties, this work, by use of selected scenarios, clearly shows that SIE and SIE-SOA deserve closer consideration as potentially significant
130 sources of organic aerosol in Europe.

2 Methods

This model sensitivity study of potential effects of biotic SIE is based on: 1) Evaluation of experimentally observed BVOC emissions by insect infested plants and their photochemical conversion to SOA, 2) Estimation of the potential fraction of infested trees in European forests, 3) Construction of future scenarios with increased fractions of infested trees. The stepwise procedure employed in the present study is described in detail below and a summary of the resulting model scenarios is given in Table 1.

2.1 Experimental

SOA mass yields and emission ratios were determined in the same experiments in the JPAC as published in Mentel et al. (2013). In short, JPAC consists of three continuously stirred flow reactors, made of Borosilicate glass, which are placed in temperature controlled housings. One of these is operated as a reaction chamber and SOA is formed therein by photooxidation- and ozonolysis products (Mentel et al., 2009). One of the other chambers serves as plant chamber and house the plants under controlled conditions. The plant chamber is permanently flushed with clean air to which CO₂ and water vapour are added. A fraction of the outflow of the plant chamber is led into the reaction chamber; ozone and water vapour are added by a second stream. Switching on a UV lamp ($\lambda_{max}=254$ nm) initializes the photochemistry. The strength and pattern of the plant emissions are measured by GC-MS (e.g. Kleist et al., 2012) in the outflow of the plant chamber, i.e. in absence of oxidants and chemical reactions. For the emission factors applied here, the concentrations of MT and the respective SIE in the outgoing airstream of the plant chamber were averaged for the same time intervals as in which the SIE-SOA mass yields were determined.

2.2 BVOC emission factors for infested trees

In order to keep our model results transparent we used a simplified direct approach for preparing the model emission scenarios. We used the standard EMEP emissions for monoterpenes (Simpson et al., 2012) and applied emission ratios for SIE/MT based on experimental data from JPAC (Mentel et al., 2013) to set the SIE in the model. The SIE considered here (SQT and MeSA) are of *de novo* type (Kleist et al., 2012), i.e. they are emitted in connection with biosynthetic production.

Monoterpene emissions (from storage pools) are often increased due to plant stress (especially as a consequence of mechanical wounding; Juuti et al. 1990, Schade and Goldstein 2003, Haase et al. 2011, Kaser et al. 2013). However, in this study all MT emissions were assigned to the constitutive emissions, based on the fact that the MT emissions measured during the JPAC experiments were quite similar to those measured for unstressed plants of the same species.

The emission ratios were determined in JPAC under steady state conditions as described above. The direct use of JPAC-derived data for application or extrapolation to ambient conditions has been

165 confirmed in earlier studies for particle formation rates and SOA mass yields for Boreal tree species
(Mentel et al., 2009), the chemical composition of the resulting SOA (Kiendler-Scharr et al., 2009b),
interaction of isoprene and MT emissions (Kiendler-Scharr et al., 2009a), and the distribution of
highly oxidized aerosol precursors (Ehn et al., 2012). The use of real plant emissions and close
to ambient concentrations make us think that the laboratory-derived data from JPAC provide the
170 best-available estimate of SIE-SOA yields for our purposes.

From the observations by Mentel et al. (2013), we constructed three biotic stress scenarios. Case 1
treats aphid infestation with enhanced SQT emissions with $SQT/MT = 2.4$ (mass based ratios). Case
2 covers aphid infestations which caused enhanced emissions of SQT ($SQT/MT = 4.9$) and triggered
MeSA emissions via the shikimate pathway ($MeSA/MT=3.75$). Case 1 and Case 2 were assumed to
175 be typical for all trees of Boreal and Central European forests. As the SIE emissions studied here
are of *de novo* type, they were only switched on during daytime.

A further Case 3 was constructed from an experiment investigating infestation of a spruce by
Cinara pilicornis, which led to strong emissions of several unsaturated linear C_{17} -BVOC with an
emission factor C_{17} -BVOC/MT = 18. Mentel et al. (2013) did not determine whether the C_{17} -
180 compounds originated from the plant or the infesting insects; the C_{17} -BVOC emissions were con-
sidered as originating from the coupled plant-insect system.

The louse under consideration here, *Cinara pilicornis*, belongs to the family of bark lice that
produce honeydew, which is collected by bees. Such bark lice are of economic interest for bee-
keepers; observations by beekeepers in Baden-Württemberg (BW) in south west Germany, show
185 that such infestations (or more precisely the honey production from *Cinara pilicornis* and simi-
lar infestations) are strongly varying from year to year and have high seasons during June/July
(<http://www.stockwaage.de/>). Accordingly we constructed a SIE emission pulse of C_{17} -BVOC,
which was limited in time and spatial extension. As the C_{17} -BVOC emissions in JPAC were 2–3
times larger at daytime than during night, we switched them on only during daytime in the model,
190 like the other two SIE.

Mentel et al. (2013) focused on tree species from the Boreal region and from Central Europe.
Therefore, we have focused our analysis on Northern and Central Europe, and implement SIE for
areas north of Lat. 45° N, although it may be assumed that stress also affects the emissions from
plants growing in other regions.

195 2.3 Estimation of fraction of infested trees

Since the observed emission factors only consider infested trees, the fraction of infested trees has to
be estimated. It is difficult to estimate the degree of insect infestations on larger scales in real forests.
In the present study we chose a relatively simple approach to make what we believe to be a rough
but reasonable estimate of the present-day situation. We base the estimate on regular surveys of the
200 European forests. ICP Forests (the International Co-operative Programme on Assessment and Mon-

itoring of Air Pollution Effects on Forests operating under the UNECE Convention on Long-range Transboundary Air Pollution) provides annual executive reports on the conditions of the forests in Europe (<http://www.icp-forests.org/>); they also publish reports of the national member forest agencies. From these, Fischer et al. (2012) provide details of tree crown damage and defoliation in many European countries; they report that a fifth of all trees are rated as damaged and that “defoliation represents a valuable early warning system for the response of forest ecosystems to different stress factors”. They also report that insects are the most frequent cause of damage to trees in Europe.

Relatively large fractions of the Northern and Central European trees show a significant degree of defoliation (>25%, rated as damaged by Fischer et al., 2012); the fractions of damaged trees are 11% for Northern boreal forests, 19% for North-Central coniferous/mixed forests (e.g., southern Sweden and Germany), 28% for Central European deciduous forests, and 24% for beech forests, as can be seen in the top two bars and 4th to 5th bar of Fig. 1. We suggest that the reported defoliation damage can be used as a measure of stress effects. The applicability of our assumption is supported by the large European forest survey 2010 (ICP Forests, 2011), which found that insects are the greatest cause of damage to trees; 17% of all investigated trees were damaged by insects (corresponding to 27% of the total number of damaged trees). For comparison, about 10% of the trees were damaged by ‘fungi’ and ca 9% by abiotic factors (e.g., drought, frost) (for more details about different damaging agents see Fig. 2-5, in ICP Forests, 2011).

Insect infestations are well distributed over the Northern and Central European forests as shown by Fischer et al. (2012) (see their Fig. 2-3). For the Boreal forests, the Finnish forest damage report from Merilä et al. (2007) stated that about 10–12% of the pines showed a significant degree of defoliation (>25%). Similar to the European situation about the same order of trees (about 10%) showed damage by insects and fungi with in general more importance of fungi. By combining these two types of forest observation, we conclude for our cases that the fraction of trees with significant defoliation (>25%) may serve as a first order approach to assess the fraction of stressed trees in the current situation. Consequently, we adopt these numbers and assume that the fraction of currently stress affected trees is 10% for Lat. >60°N and 20% between 45°N and 60°N. This will constitute our base case for impact of contemporary SIE (Case 1 and Case 2).

2.3.1 Increased degree of infestation - possible future scenarios?

For the future scenarios our hypothesis is that the degree of infestation may increase if climate changes unfavorably for an established vegetation. Considering that the knowledge about the present-day degree of infestation is limited, it is even more problematic to describe how SIE will develop in the future. However, we use a similar approach as for the current situation but take it a step further and assume that insect infestations may affect trees that today are at the next reported degree of defoliation (>10%). This will then include about 2/3 of the trees in Central Europe (Fischer et al., 2012) and about 50% of the trees in the Boreal forests (Finnish National Report 2007: Merilä et al.,

2007). This may be considered as a severe-case scenario of a possible future. These high degrees of infestation were used to illustrate how severe biotic stress can enhance SIE and contribute to SOA and we address these as two extreme future scenarios, Case 1F and 2F. Given the uncertainty of
240 estimating future SIE emissions, the MT emissions were, for simplicity, kept at the current level.

2.3.2 Regional episodic infestation by bark lice

The construction of the Case 3 with C_{17} -BVOC emission from the *Cinara pilicornis* infestation is somewhat more indirect. Here we make use of the fact that the honeydew produced by *Cinara pilicornis* (and other bark lice) is a source of a certain kind of honey, the forest honey. Detailed observational data on forest honey production exist in Baden-Württemberg (see <http://www.stockwaage.de/>)
245 so we select this region of south west Germany for an episodic test case. The relation between infestation and forest honey production is well known to beekeepers (e.g. see <http://stockwaage.de/>) and from their statistics we can extract the seasonality and the annual variation of the forest honey production as related to *Cinara pilicornis* infestation. In a good honey year the infestation is widespread,
250 even if there are some local variations, and lasts through the summer months.

Since Mentel et al. (2013) observed C_{17} -BVOC emission from the *Cinara pilicornis* / Norway spruce system, we assume for simplicity that all spruce in BW are infested and the resulting SIE occur during the months June and July, with the given C_{17} -BVOC/MT ratio of 18. The forests in BW consist of 38% spruce (http://www.mlz.baden-wuerttemberg.de/Die_Baumarten/507.html).
255 Other conifers, mainly fir and pine, make up another 19% of the forest. The rest are broadleaf species mainly beech (21%) and oak (7%). This causes a small flaw in our concept of applying the emission ratios as observed in JPAC, as the emission strength of spruce and the other conifers and specifically of the broadleaf species may be different. For simplicity, we assume that during an active year all spruce are affected and that these also accounts for 38% of the emissions. As a
260 consequence the C_{17} -BVOC/MT emission ratio from the JPAC experiment is weighted by the factor 0.38 in BW. Although the assumption that all spruce trees in BW are heavily infested may be viewed as an extreme case we note that other tree species may also be simultaneously infested by lice and, on the beekeeper web page <http://stockwaage.de/index.php/rueckblick>, there is indeed a year described (2006) when lice even infested deciduous trees and contributed to honeydew production.

265 2.4 The EMEP MSC-W model

The standard EMEP MSC-W chemical transport model has been described in detail by Simpson et al. (2012); a research version of the model (Bergström et al., 2012), with extended treatment of particulate carbonaceous matter, has been used in the present study. The EMEP MSC-W model is a development of the 3-D CTM of Berge and Jakobsen (1998), extended with photo-oxidant and
270 aerosol chemistry. The model domain used in this study covers the whole of Europe, and includes a large part of the North Atlantic and Arctic areas. The standard grid system of the model is based on

a polar stereographic projection, with a horizontal resolution of ca. 50 km × 50 km at latitude 60°N. The model includes 20 vertical layers, using terrain-following coordinates, and the lowest layer has a thickness of about 90 m. The model has been extensively compared with measurements of many
275 different compounds (e.g. Jonson et al., 2006; Simpson et al., 2006; Fagerli and Aas, 2008; Aas et al., 2012; Bergström et al., 2012; Sakalli and Simpson, 2012; Genberg et al., 2013; Gauss et al., 2014). For short-lived radicals, evaluation against measurements is problematic for regional scale CTMs. The EMEP MSC-W chemical mechanism has been shown to provide results for OH and NO₃ in line with other (more detailed) models (Andersson-Sköld and Simpson, 1999; Kuhn et al., 1998;
280 Karl et al., 2014). Model results for NO₃ are discussed further in Sect. 3.3. For the present study meteorological data from the European Centre for Medium Range Weather Forecasting Integrated Forecasting System (ECMWF-IFS) model (<http://www.ecmwf.int/research/ifsdocs/>) were used; all simulations were performed for the (meteorological) year 2007.

This study focuses on OA from biogenic emissions. The constitutive emissions of monoterpenes
285 and isoprene are calculated in the model, using near-surface air temperature (T_{2m}) and photosynthetically active radiation. Standard condition emission factors for forests are based on tree species specific monoterpene emission factors for 115 different tree species, combined with detailed maps of the distribution of the trees in Europe, as described by Simpson et al. (2012). Such emissions are of course very uncertain given the lack of underlying measurements for European ecosystems,
290 as discussed in more detail in Simpson et al. (1999, 2012) and Keenan et al. (2009), and illustrated for European isoprene emissions (with results from 4 models) in Langner et al. (2012). The EMEP values are believed to be well grounded in recent reviews of emissions rates (Simpson et al., 2012).

As with most BVOC emission databases, the standard EMEP system does not explicitly include SIE emissions. Sesquiterpene emissions were also deliberately omitted in earlier studies because it
295 was judged that the emission rates and underlying emissions algorithms were too uncertain compared to even those of isoprene and monoterpenes (e.g. Duhl et al., 2008). Other models do include some sesquiterpene emissions, but with the assumption that these are a fraction of the normal constitutive emissions (e.g. Fountoukis et al., 2011; Aksoyoglu et al., 2011). Some level of SIE may be included in the emission measurements which underlie the BVOC emission factors inventories used. To our
300 knowledge, no other CTM has so far treated SIE-SOA production from MeSA or the C₁₇-BVOC included in the present study.

All SOA in this work is assumed to be formed through gas-particle partitioning to the accumulation mode, which in the EMEP MSC-W model has a mass-median diameter of 330 nm. This assumption is consistent with many studies over Europe and at Hyytiälä (e.g. Allan et al., 2006;
305 Beddows et al., 2014). This means that the difference between OA in PM₁ and PM_{2.5} is negligible in the model.

Some updates have been done to the model, compared to Bergström et al. (2012). As in the standard EMEP model (Simpson et al., 2012), emissions from open biomass fires were taken from

the FINNv1 inventory (Wiedinmyer et al., 2011), and hourly variation of anthropogenic emissions
310 were used instead of the simpler day-night system used in earlier EMEP models. For this study,
we use updated emissions of primary organic aerosol (POA), with a recently developed inventory
for residential combustion of biofuels (Denier van der Gon et al., 2014). In the present study we
set the background concentration of organic aerosol to $0.4 \mu\text{g m}^{-3}$, to prevent an overestimation of
OA seen at many sites when using the previous background concentration of $1 \mu\text{g m}^{-3}$ (Bergström
315 et al., 2012).

Bergström et al. (2012) implemented and tested a number of different organic aerosol schemes,
based on the volatility basis set (VBS) approach. The base case in the present study uses the PAP
version (Partitioning and atmospheric Ageing of Primary semi- and intermediate-volatility OC emis-
sions), from Bergström et al. (2012), that distributes the POA emissions over different volatilities and
320 assumes that the POA emissions are accompanied by emissions of intermediate volatility compounds
(IVOC) that react with OH in the atmosphere (as in Shrivastava et al. 2008); this “ageing” transforms
the species to lower volatilities that may partition to the particle phase. The base case OA scheme
used here is almost identical to the PAP-model in Bergström et al. (2012); the only difference is that
a small emission of sesquiterpenes is added (equal to 5%, by mass, of the daytime MT emissions)
325 based on observed emissions from plants with no observable biotic stress by Mentel et al. (2009).

Very simplified mechanisms for SOA formation from SQT, MeSA and C_{17} -BVOC were added to
the model. Fixed SOA (mass) yields, based on experimental data (Mentel et al., 2013), were used for
these three model compounds. Note that the SOA-yield from SQT oxidation (17 mass-%) is based
on experimentally determined yields from SQT-emissions from aphid infested Norway Spruce (see
330 Mentel et al., 2013); here we assume the same SOA-yield from all SQT-emissions. For MeSA and
 C_{17} -BVOC the yields are 22% and 33%, respectively:

where Ox is a general oxidant (O_3 or OH; NO_3 may also react with SQT, and possibly with
 C_{17} -BVOC, but, since we only consider day-time SIE in this study, the NO_3 -reaction is of minor
importance compared to the fast O_3 and OH reactions). The parentheses around the oxidants indi-
335 cate that these oxidants are not depleted in the chemical mechanism. As in Simpson et al. (2012)
and Bergström et al. (2012), gas-phase BVOC chemical mechanisms are only available for iso-
prene, for which the EMEP model traces degradation through species such as methyl-vinyl-ketone,
methacrolein and methylglyoxal. Other BVOC species are treated in a very simplified manner,
whereby oxidation of the BVOC produces only the compounds specified by the VBS scheme or the
340 fixed-yield non-volatile SIE-SOA components. For such compounds, the chemistry is assumed to be

‘oxidant-neutral’, that is, we assume that as much O₃ or OH or is reformed in the neglected part of the chemistry, as is consumed in the initial BVOC-reactions. This procedure ensures that the ozone chemistry will be the same as in the standard photochemistry version of the EMEP MSC-W model.

SOA-formation from sesquiterpenes is rapid; in the model we use rates based on the β -Caryophyllene chemistry scheme in the Master Chemical Mechanism (MCM v3.2 (Jenkin et al., 2012), via website: <http://mcm.leeds.ac.uk/MCM>). For the C₁₇-BVOC no kinetic information is available. As observed in JPAC, the C₁₇-BVOC had a short lifetime with respect to oxidation by O₃ and OH; for simplification, we therefore applied the same OH and O₃ reaction rate coefficients ($1.97 \times 10^{-10} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ and $1.16 \times 10^{-14} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$, respectively) for the C₁₇-BVOC as for β -Caryophyllene.

MeSA is much more stable in the atmosphere (Canosa-Mas et al., 2002) and, based on experimental data from JPAC, an OH-reaction rate coefficient of $4 \times 10^{-12} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ was used. The low reaction rate of MeSA with OH allows for significant MeSA concentrations during the night and since MeSA is a phenolic compound we must also consider the reaction with NO₃:

The rate of the MeSA + NO₃ reaction is not known and neither is the SOA-yield (α) of the reaction; night-time degradation of MeSA by NO₃ reaction could possibly be fast (Canosa-Mas et al., 2002). Canosa-Mas et al. (2002) assumed that MeSA could react as fast with NO₃ as phenol does ($k=3.8 \times 10^{-12} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$), but the MeSA + NO₃ reaction may be slower, because the MeSA molecule may form an internal hydrogen bond between the OH-hydrogen and the ester group leading to an increased stability compared to phenol. The MeSA + OH reaction, for example, is seven times slower than the phenol + OH reaction (IUPAC: <http://www.iupac-kinetic.ch.cam.ac.uk> (2008)). Preliminary results from laboratory experiments in JPAC indicate that the MeSA+NO₃ reaction is about an order of magnitude slower than the phenol+NO₃ reaction. Details of the measurements regarding the determinations of the rate constants will be published elsewhere.

In the present study we therefore used $k = 5.4 \times 10^{-13} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ for the MeSA + NO₃ reaction, equal to the phenol + NO₃ reaction rate divided by seven (the scaling factor of the OH reaction).

The rate coefficient was combined with two different SOA-yields for the reaction, 0 or 22 mass-%, resulting in two different sensitivity test cases:

- a) $k_{R4} = 5.4 \times 10^{-13} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$, $\alpha = 0$
b) $k_{R4} = 5.4 \times 10^{-13} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$, $\alpha = 0.22$

Canosa-Mas et al. (2002) suggest that photolysis may be the most important day-time loss process for MeSA but other studies have shown that MeSA and related compounds have ‘striking photostability’ (e.g., Acuna et al., 1981) and therefore we neglect this process in the model simulations.

375 Deposition of gas-phase MeSA is a potentially important loss process since the oxidation rate is relatively slow. Karl et al. (2008) measured the Henry's law constant for MeSA and obtained a value of ca 34 M atm⁻¹, that is, MeSA is somewhat more soluble than CH₃CHO but much less soluble than HCHO. In the standard set-up of the present study we treat MeSA-deposition in the same way as CH₃CHO (and other higher aldehydes) in the EMEP model (Simpson et al., 2012); this means
380 wet deposition is neglected and that the dry deposition is relatively slow. Two sensitivity tests were performed regarding the MeSA deposition: A) neglecting both dry and wet deposition, B) assuming dry and wet deposition to be as efficient as for HCHO.

2.5 Model emission scenarios

In total five different biotic stress emission scenarios are explored in this study and compared to a
385 reference simulation without explicit stress induced emissions. The different scenarios are based on the combination of the biotic stress emission factors described in Sect. 2.2 and the fractions of infected forest from Sect. 2.3; the resulting emission scenarios are summarised below and in Table 1. Note that in all scenarios except Case 3, the SIE are assumed to occur during the whole period with MT-emissions (for Central and Northern Europe most of the MT-emissions occur between March
390 and October); i.e., biotic stress is assumed to be present during the whole growing season. This is a simplification, since many forms of biotic stress are of more limited duration (e.g. Hakola et al., 2006), but various stressors may be active at different times of the year. In the present study the focus is on getting estimates of the potential relative importance of SIE compared to the constitutive BSOA for long-term OA concentrations.

395 Case 0 – Reference scenario

Case 0 is a reference scenario excluding most stress induced emissions. The biogenic emissions are the same as in the standard EMEP MSC-W model for carbonaceous aerosol (Bergström et al., 2012; Simpson et al., 2012) except that some SQT emissions were added (5% of the MT emissions). The SOA-yield from SQT oxidation is set to 17 mass-% (Mentel et al., 2013). The addition of 5% SQT
400 is based on observations at the JPAC for experiments with no observable biotic stress. Since SQT emissions are mostly induced by biotic stress (Kleist et al., 2012; Mentel et al., 2013) the 5% SQT emissions used in Case 0 can be considered as covering a low “background” biotic stress situation.

Case 1 – Sesquiterpene emissions from biotic stress – Current situation

The first SIE scenario is based on experimental data for aphid infested Norway spruce with a
405 SQT/MT emission ratio of 2.4. In the EMEP model simulation for Case 1 we apply 10% of these emissions to all monoterpene emitting plants north of Latitude 60°N, during daytime, and 20% for 45°N–60°N. This means that the (daytime) SQT emissions are set to 24% and 48% of the MT emissions in the two different regions. The SOA-yield from the SQT is the same as for Case 0

(17%).

410 **Case 2 – Methyl salicylate + sesquiterpene emissions from biotic stress – Current situation**

The second scenario simulates an aphid infested boreal forest, based on chamber data from experiments with a combination of Silver birch, Scots pine and Norway spruce. Chamber emission ratios were $SQT/MT = 4.9$ and $MeSA/MT = 3.5$. The assumption of 10% infested trees in the Boreal forests (Lat. $>60^{\circ}N$) and 20% for $45^{\circ}N-60^{\circ}N$ leads to model SQT/MT and $MeSA/MT$ emissions
415 of 49% and 35% for the northern region and 98% and 70% in the central region. For $MeSA$ the SOA-yield from oxidation by OH is 22% (Mentel et al., 2013); the standard Case 2 simulation assumes that $MeSA$ only reacts with OH , see Sect. 3.3 for sensitivity tests of different assumptions regarding the $MeSA+NO_3$ reactivity and SOA-production.

Case 1F – Increased degree of infestation – sesquiterpene emissions

420 The first “future” scenario, Case 1F, use the same biotic stress emission ratios as Case 1 but a larger proportion of the vegetation is assumed to be infested: 50% in the boreal region (north of $60^{\circ}N$) and 2/3 of the trees in the $45^{\circ}N-60^{\circ}N$ region. This leads to SQT/MT emission ratios of 120% and 160%, respectively.

Case 2F – Increased degree of infestation – methyl salicylate + sesquiterpene emissions

425 The second scenario of increased biotic stress, Case 2F, use the same assumptions as Case 2 regarding the emissions from infested trees and the same proportion of infestation as in Case 1F. This leads to SQT/MT emission ratios of 245%, in the northern region, and 327%, in the central region. The corresponding $MeSA/MT$ emission ratios were 175% and 233%, respectively.

Case 3 – C_{17} -BVOC + sesquiterpene emissions from regional episodic infestation by bark lice

430 The Case 3 scenario, simulates an episodic infestation of Norway spruce by *Cinara pilicornis* in Baden-Württemberg (SE Germany, $47.8^{\circ}N-49.8^{\circ}N$, $8.0^{\circ}E-10.2^{\circ}E$). The emission ratios, C_{17} -BVOC/ $MT=18$ and $SQT/MT=1$, were applied to 38% of the BW-forests during June and July, leading to large C_{17} -BVOC emissions ($6.8 \times$ the MT emissions) and substantial SQT emissions ($0.38 \times$ MT) during this period. The SOA-yield from the oxidation of C_{17} -BVOC is 33% (Mentel et al.,
435 2013).

3 Results and Discussion

The EMEP MSC-W model for OA was thoroughly evaluated against observations by Bergström et al. (2012). One of the conclusions of that study was that simple VBS based OA models can give

reasonably good results for summer conditions. Since the biotic SIE primarily occur during the
440 summer half-year we focus mainly on results for this period here.

3.1 Current situation

Model calculated diurnal mean concentrations of organic carbon ($OC_{2.5}$) for the Finnish site Hyytiälä
(located in a forest area in south-central Finland) are compared to measured OC (219 measurements
in 2007 of OC in PM_{1}) in Fig. 2. The model OC from all three “current-situation” scenarios (Case
445 0, 1 and 2) are well correlated with the observations (R^2 -values are 0.56, 0.60 and 0.66 for Case 0,
1 and 2, respectively); the model calculated concentrations are close to the observations, the average
model bias is -0.12, -0.08 and +0.03 $\mu\text{g m}^{-3}$ (corresponding to -12%, -9% and +3% of the observed
average) and the relative mean absolute deviation of the model $OC_{2.5}$ from the observed OC_1 are
39%, 36% and 33%, respectively. The differences in performance between the three different model
450 scenarios are not very large but Case 2 is slightly closer to observations than Case 1 and both SIE-
scenarios are in better agreement with observations than the reference scenario (Case 0) that does
not explicitly treat biotic stress emissions.

Since the model SIE are treated as a simple fraction of the “unstressed” MT emissions an improve-
ment in model results when adding SIE is not a proof that the stress induced emissions are correctly
455 modelled; the model improvement could also be due compensation of underestimated regular BVOC
emissions (see the example given for the Swiss site Payerne in Bergström et al. 2012). However, the
model results for Hyytiälä shows that the additional SIE emissions do not lead to unrealistic model
OA concentrations, and that such SIE can have a significant effect on ambient OA levels during the
summer period.

460 Model calculated $OM_{2.5}$ (organic matter in $PM_{2.5}$) and the relative fraction of BSOA, from the
reference case model simulation without explicit SIE from vegetation (Case 0), for the summer
half-year (April–September) 2007, are shown in Fig. 3. The modelled BSOA is low in most of
Europe. The relative contribution of BSOA to modelled regional background $OM_{2.5}$ is below 20%
except in parts of Northern Europe (parts of Sweden, Finland, the Baltic states, Russia, Belarus
465 etc.) and some BVOC-emission hotspots. (The simulated absolute BSOA-concentrations are below
0.6 $\mu\text{g m}^{-3}$, except in the south-eastern Mediterranean region, parts of Russia and some smaller
high-BVOC-emission areas.)

The model calculated SIE-SOA for the two present-day biotic stress emissions scenarios (Case 1
and 2) are compared to the model BSOA from mostly unstressed plants (Case 0) in Fig. 4. Case 1-
470 type SIE (only SQT-emissions) contribute somewhat less to BSOA than the (unstressed) constitutive
BVOC emissions (SIE-SOA is below 0.3 $\mu\text{g m}^{-3}$ in most of Europe, for the 6-month (Apr-Sep)
mean and the SIE-SOA fraction of the total BSOA is between 20 and 40 % in most of Europe north
of Lat. 45°N). However, biotic SIE including MeSA (Case 2) give rise to high SIE-SOA in the
model (between 0.6 and 1 $\mu\text{g m}^{-3}$ in large parts of Eastern and Central Europe), clearly higher

475 than the unstressed BSOA-concentration for the same period (between 50 and 80 % of the total
BSOA is SIE-SOA, for most of Lat. $> 45^{\circ}\text{N}$, in the Case 2 scenario). This shows that, even with
realistic present-day levels of biotic stress, it is possible that, at least for some periods, the stress
induced emissions are more important for organic aerosol production than the constitutive emissions
of BVOC.

480 3.2 Future scenarios

We have estimated the potential increase of $\text{OM}_{2.5}$ due to the much higher degree of infestation
assumed in the two future scenarios (Case 1F and 2F). The differences in summer-half-year mean
 $\text{OM}_{2.5}$ between Case 1F and Case 1, and between Case 2F and Case 2 are shown in Fig. 5. If
the biotic SIE increase to the high levels tested in these scenarios a substantial increase in organic
485 particle mass can be expected. The results from the Case 2F (biotic MeSA+SQT) simulation indicate
that SIE-SOA could potentially become an important source of regional background $\text{PM}_{2.5}$ in large
parts of Central/Eastern Europe; the increase in $\text{OM}_{2.5}$ compared to the present-day Case 2-scenario
is larger than $1.5\mu\text{g m}^{-3}$ in parts of Central and most of Eastern Europe. The Case 1-type scenario,
with only SIE of SQT included, have a much lower BSOA-forming potential but still the SIE-SOA
490 production may become fairly substantial in the future scenario (Case 1F); the increase compared
to the corresponding current situation scenario (Case 1) is above $0.3\mu\text{g m}^{-3}$ in much of Central,
Northern and Eastern Europe.

3.3 Importance of stress induced MeSA emissions - sensitivity tests of MeSA chemistry and deposition

495 Considering the high emissions of MeSA and high SOA-yield from this component further con-
straints on MeSA emissions and their impact on organic aerosol are important. MeSA is emitted by
many different plant species, in response to various types of stress, not only the ones considered here
(e.g. Vuorinen et al., 2007; Blande et al., 2010; Schnitzler et al., 2010). Assuming Case 2 SIE, model
calculated MeSA concentrations in the gas-phase are relatively high; depending on the assumptions
500 regarding MeSA-deposition and NO_3 -reactivity, the average MeSA concentrations for the period
March-October at Hyytiälä are from 110 to 260 ppt(v); see Fig. 6, which shows the diurnal variation
of the modelled MeSA for four different model setups. If the model assumptions regarding the emis-
sions and reactivity are realistic, MeSA should be easily detected in the atmosphere e.g. by PTR-MS
or GC-MS. Our estimated MeSA concentrations are of the same order of magnitude as observed by
505 Karl et al. (2008). They found MeSA mixing ratios of ~ 100 ppt(v) within and above the canopy of
a walnut agroforest.

The amount of SIE-SOA produced in the model in Case 2 is based on the observed SOA formation
in the JPAC plant chamber experiments (Mentel et al., 2013); in addition it depends on the assump-
tions regarding the deposition of MeSA, the MeSA+ NO_3 -reactivity and the SOA-formation from

510 the NO_3 -reaction. We illustrate the sensitivities in Fig. 7, which shows the mean diurnal variation of SIE-SOA at Hyytiälä for the period March-October.

The modelled SIE-SOA is not very sensitive to the MeSA deposition; the differences between the setups with no deposition or faster deposition (as HCHO) to the base case deposition (as CH_3CHO) are only about +5 % and -7 %, respectively; similar differences (+3 – +7 % and -3 – -10 %) are seen
515 in the part of the model domain where the SIE are included in Case 2 (the *relative* differences are larger at longer distances from the SIE regions).

If the $\text{MeSA}+\text{NO}_3$ -reaction occurs at the rate tested in this study ($k_{R4}=5.4\times 10^{-13}\text{cm}^3\text{molecule}^{-1}\text{s}^{-1}$), and has the same SOA-yield as $\text{MeSA}+\text{OH}$, a substantial night-time production of SIE-SOA is seen in the model. The average modelled (total) SIE-SOA concentration at Hyytiälä is about 30% higher
520 when the NO_3 -reaction is included than for the case with only the OH-reaction (results are similar in most of Europe north of Lat. 45 °N, for April-September: typically +20 – +30 %). If the $\text{MeSA}+\text{NO}_3$ -reaction consumes the MeSA without SOA-production, the SIE-SOA formation is reduced compared to the case with only OH-reaction; at Hyytiälä modelled SIE-SOA is about 20% lower than for the case that neglects the $\text{MeSA}+\text{NO}_3$ -reaction (similarly, for most of the region with
525 significant SIE in Case 2, the modelled SIE-SOA is reduced by ca 15 – 25 %, compared to the base case with only OH-reaction included).

The standard Case 2 simulation (as used in Sect. 3.1), which neglects the $\text{MeSA}+\text{NO}_3$ reaction, leads to SIE-SOA concentrations between those obtained in the two test case simulations that include the $\text{MeSA}+\text{NO}_3$ reaction (with 0 and 22% SOA-yield); the average SIE-SOA (for Mar-
530 Oct) are $0.34\mu\text{g m}^{-3}$ (only OH-reaction), $0.27\mu\text{g m}^{-3}$ (incl. NO_3 -reaction with 0% SOA-yield) and $0.44\mu\text{g m}^{-3}$ (incl. NO_3 -reaction, 22% SOA-yield). Neglecting the NO_3 -reaction means that more MeSA survive during night-time and can produce SIE-SOA the following day, via OH-reaction. As seen in Fig. 6 almost all MeSA is lost during night when the NO_3 -reaction is taken into account.

The model calculated NO_3 concentrations are very high compared to the sub-ppt levels reported
535 by Rinne et al. (2012) at canopy-height in Hyytiälä. However, aloft levels of NO_3 are often observed or calculated to be far higher than ground-level data (Brown and Stutz, 2012; Johansson and Janson, 1993), so our values may be reasonable. In any case, model calculations where we relax our oxidant-neutrality assumption (Sect. 2.4) and allow 100% loss of NO_3 have shown that even though NO_3 levels are reduced dramatically, the effect on SIE-SOA is moderate, about 30%.

540 The SOA formation from the NO_3 reaction is difficult to assess, but if the ambient MeSA levels are indeed often at a level higher than 100 ppt it is worthwhile to study the MeSA - NO_3 yield in more detail. Moreover, recent data indicate very efficient SOA formation from NO_3 reactions of e.g. pool emitted MT (Fry et al., 2009, 2011).

3.4 Regional bark lice infestation - Case 3

545 The very large episodic C_{17} -BVOC emissions in Baden-Württemberg, simulated in Case 3, lead to a large production of SIE-SOA in the infested region. For the two-month infestation period the average modelled SIE-SOA contribution to $PM_{2.5}$ is larger than $3 \mu\text{g m}^{-3}$ in BW and above $0.5 \mu\text{g m}^{-3}$ in all of southern Germany. For BW the modelled regional background $PM_{2.5}$ concentration is more than twice that in the reference case without SIE, as shown in Fig. 8. Since Case 3 assumes a wide-spread, 550 severe infestation of spruce trees in BW, it could be considered a “worst-case” scenario for lice infestation in BW (or best-case for the honey-production) but it should be pointed out that bark lice may infect other tree species as well and that infestations are likely to occur simultaneously in other regions of Europe. The very high modelled impact of this scenario also indicates that even a much more limited degree of infestation could lead to substantially enhanced OA concentrations. The 555 emissions of C_{17} -BVOC from insect infested vegetation is thus a field worth further investigation.

4 Conclusions

A large number of different biotic stressors exist in the environment and many plants are obviously infested by at least some stress-inducing organisms as shown in ICP Forests, 2011 (chap. 2, Fig. 2-4 and 2-5). The inspections of European forests suggest that totally non-infested plants are not likely 560 to be common and thus some stress is the normal state of vegetation. New laboratory data indicate that stress induced emissions (SIE) from trees common in Central and Northern Europe may be of great importance for SOA formation under current conditions. SIE are difficult to assess but the emission factors for the different SIE compounds included in this study (sesquiterpenes, SQT; methyl salicylate, MeSA; unsaturated linear C_{17} -BVOC) have been inferred from plant chamber 565 SOA experiments.

In this study we estimated the degree of stress from forest damage observations in Europe and forest honey production data from beekeepers in south west Germany. Combining these estimates with the plant chamber experiment based stress induced emission factors we constructed different SIE scenarios, and implemented SIE-SOA formation in the EMEP MSC-W model, in order to get a 570 first model estimate of the potential impact of SIE in Europe north of Lat. 45°N .

The implementation of SIE in the model resulted in less bias and better correlation coefficients, for particulate organic carbon at a forest site in Finland, compared to the standard model simulation with only constitutive biogenic emissions. However, based on these results alone, we cannot draw the conclusion that this is proof of the importance of SIE, since any increase in BVOC emissions, 575 or BSOA yields from “unstressed” BVOC, would have essentially identical effects on total organic aerosol concentrations: we cannot distinguish SIE induced SOA from SOA from unstressed vegetation with higher emission rates. On the other hand we also cannot distinguish between much higher abundance of SIE-SOA already at present and overestimated SOA from constitutive emissions. Fur-

ther, the fate of the SIE in the atmosphere is uncertain, as shown by the sensitivity tests of the MeSA
580 chemistry and deposition, and the modelling of SOA is still so fraught with difficulty that we cannot use model-measurement discrepancy for total OA concentrations to establish the likely level of SIE-SOA.

Having stated this, we want to point out that if our assumptions regarding the magnitude of the SIE are overall about right, it is possible that, at least for some periods, the SIE including MeSA
585 could be more important for organic aerosol production than the constitutive emissions of BVOC. SIE of SQT have a lower BSOA-forming potential but still the SIE-SOA production from SQT may become fairly substantial in the future in much of Central, Northern and Eastern Europe. The emissions of unsaturated C₁₇-BVOC from insect infested vegetation, although episodic and regional, could have a large impact on SOA formation. If the climate changes relatively rapidly (on the time
590 scale of the life-span of individual trees), established vegetation may have problems adapting to the new conditions, which could make the trees more vulnerable to different stressors; this can lead to increased SIE in the future.

Measurements using real plant emissions have shown that SIE can have higher potential to form SOA mass than constitutive emissions. On laboratory scale SIE can dominate SOA formation, as is
595 also reflected by the model calculations. But up-scaling of laboratory results is complicated because the contribution of SIE to biogenic emissions in the air over large areas is uncertain. We constructed plausible scenarios, for Central and Northern Europe, by using independent data on European forest systems. This approach is only a first step and may lead to over- or underestimations of the importance of SIE-SOA. However, without consideration of SIE-SOA modeling scenarios will remain
600 unrealistic. A limitation of the present study is that the stress-induced emissions and SIE-SOA yields are based on data for a limited number of tree species and stressors (Mentel et al., 2013).

The uncertainties encountered in our approach point to the need to quantify SIE directly in the field. The agreement of the model predicted MeSA level with observations by Karl et al. (2008) encourage such initiatives. Our findings suggest that the SIE and SIE-SOA are potentially important
605 at least in large parts of Europe and that there is need for additional efforts in further investigations.

Fig. 1: Fraction (%) of damaged trees (>25% defoliation) in different European forest ecosystems. The top two bars refer to the main forest types investigated in the present study. (Figure adapted from ICP Forests, Fischer et al., 2012, used with permission.)

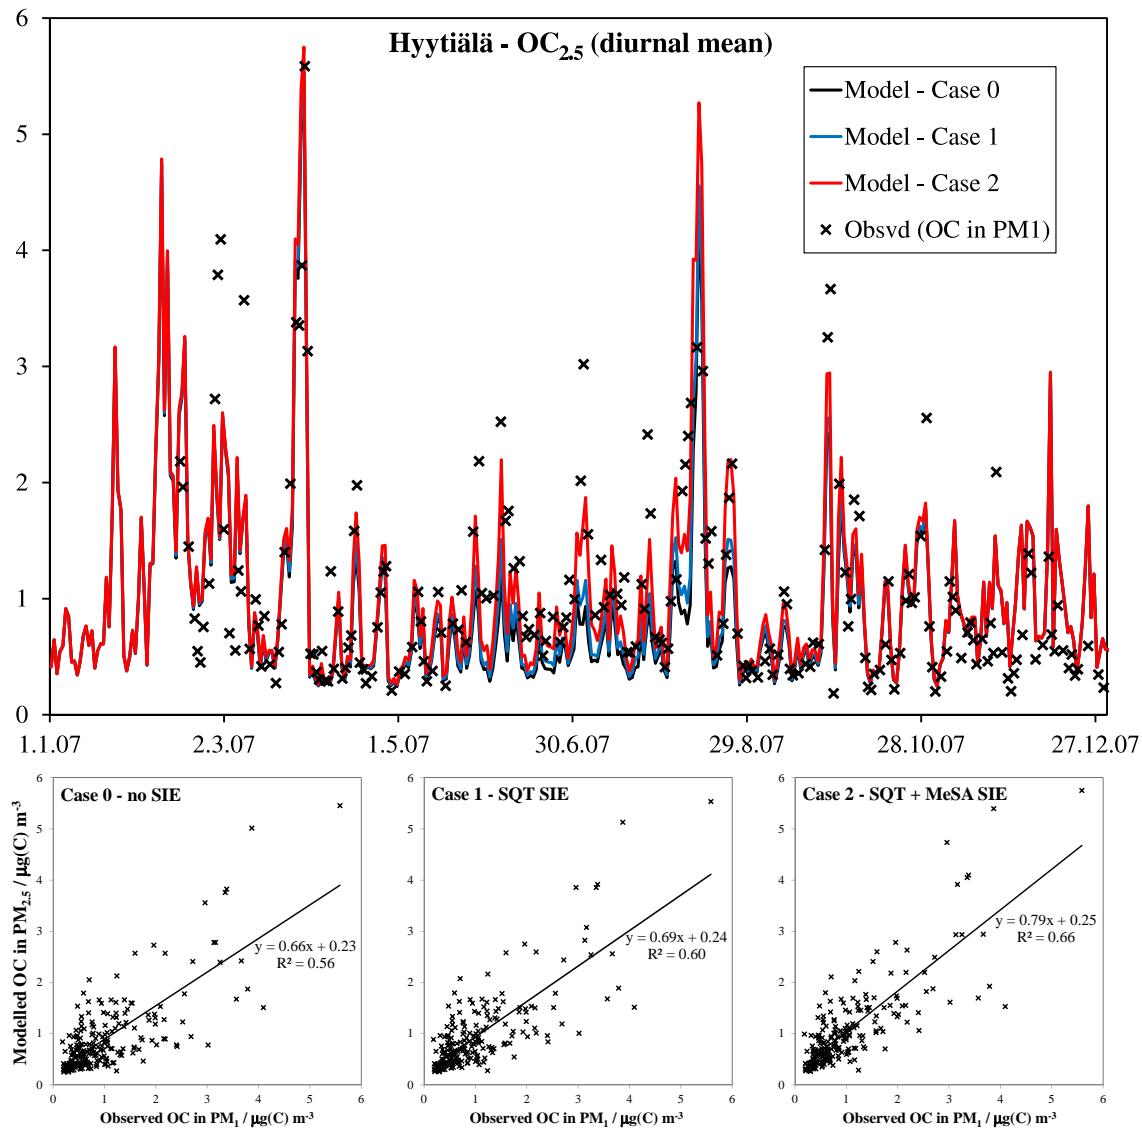

Fig. 2: Modelled diurnal mean Organic Carbon in PM_{2.5} (OC_{2.5}) at Hyytiälä (Finland) for 2007 compared to measured OC in PM₁ (Aurela et al., 2011). Results from three different model simulations (see Sect. 2.5) are shown in the top panel: Case 0 (black line) - Reference scenario, without explicit stress induced emissions (SIE); Case 1 (blue) - Current situation scenario with SIE of sesquiterpenes (SQT); Case 2 (red) - Current situation scenario with SIE of SQT and methyl salicylate. The lower panels show the model-measurement scatter plots for the three cases. Unit: μg(C)m⁻³.

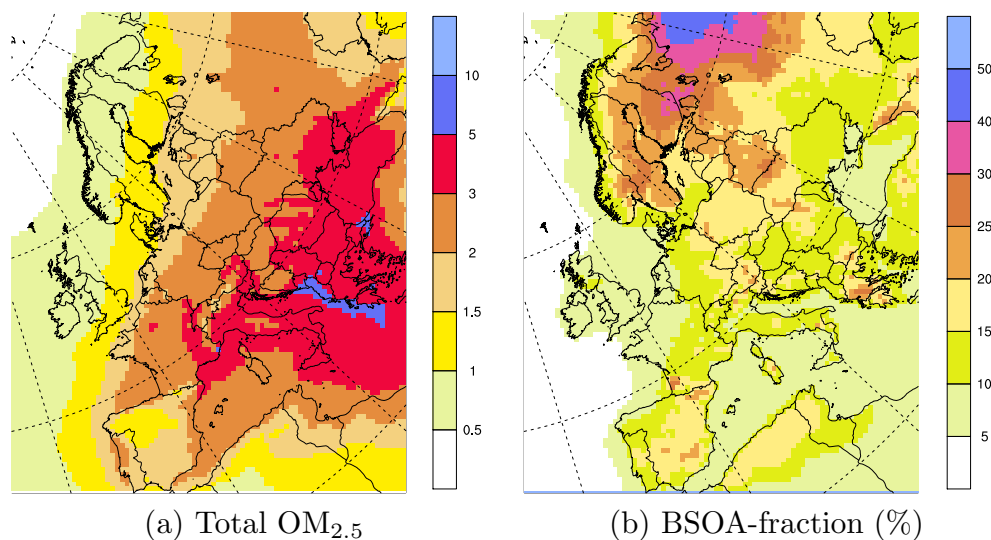

Fig. 3: Model calculated 6-month mean (Apr-Sep) concentrations of (a) total Organic Matter in $PM_{2.5}$ ($OM_{2.5}$) [Unit: $\mu\text{g m}^{-3}$] and (b) Fraction of biogenic secondary organic aerosol (BSOA) [% of total $OM_{2.5}$] for the reference scenario without explicit biotic stress emissions (Case 0).

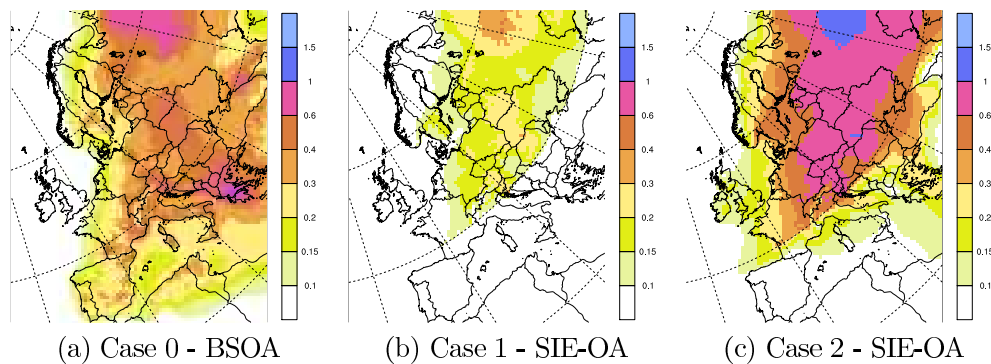

Fig. 4: Model calculated 6-month mean (Apr-Sep) concentrations of BSOA and biotic stress induced OA (SIE-OA); (a) BSOA in Case 0 (reference case without explicit stress induced emissions), (b) SIE-OA in Case 1 (biotic stress with sesquiterpene (SQT) emissions), (c) SIE-OA in Case 2 (biotic stress with emissions of SQT and methyl salicylate). Unit: $\mu\text{g m}^{-3}$.

Fig. 5: Potential increase of $OM_{2.5}$ (6-month mean, Apr-Sep) from increased biotic stress induced emissions (SIE) in two “maximum” impact scenarios, compared to the corresponding current-situation model calculated concentrations. The concentration-difference fields illustrate potential effects of a changed climate that the Northern/Central European forests have not had time to adapt to; (a) Difference in $OM_{2.5}$ between Case 1F and Case 1 (SIE with only SQT), (b) Case 2F - Case 2 (SIE of both SQT and methyl salicylate). Unit: $\mu\text{g m}^{-3}$. Note: Different colour scales.

Fig. 6: Modelled diurnal variation (average for the period March-October) of methyl salicylate (MeSA) at Hyytiälä (Finland), using the Case 2 scenario for biotic stress induced emissions. Comparison of model runs with four different assumptions regarding deposition losses and NO₃-reactivity of MeSA (g). Black curve: only OH-reaction, no deposition of MeSA; dark blue: OH-reaction, dry deposition of MeSA with the same deposition velocity as acetaldehyde; light blue: OH-reaction, wet and dry deposition of MeSA with the same treatment as formaldehyde; red: NO₃-reaction ($k=5.4 \times 10^{-13} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$), OH-reaction, dry deposition as acetaldehyde. The modelled concentration of NO₃ is also shown (orange curve, right axis). Unit: ppt(v).

Fig. 7: Modelled diurnal variation (average for the period March-October) of SIE-SOA at Hyytiälä using the Case 2 scenario for biotic stress induced emissions, with different assumptions regarding MeSA deposition losses, NO₃-reactivity and SOA-yield. Black curve: only OH-reaction, no deposition of MeSA; dark blue: OH-reaction, dry deposition of MeSA with the same deposition velocity as acetaldehyde; light blue: OH-reaction, wet and dry deposition of MeSA with the same treatment as formaldehyde; red: OH-reaction, NO₃-reaction ($k=5.4 \times 10^{-13} \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$), no SOA from MeSA+NO₃-reaction, dry deposition as acetaldehyde; pink: OH-reaction, NO₃-reaction with 22% SOA-yield, dry deposition as acetaldehyde. Unit: $\mu\text{g m}^{-3}$.

Fig. 8: Model calculated regional background $PM_{2.5}$ concentration (2-month-mean for June-July). (a) Total model $PM_{2.5}$ without explicit biotic stress emissions (Case 0) [$\mu\text{g m}^{-3}$]; (b) Additional $PM_{2.5}$ due to organic aerosol formation caused by biotic stress induced emissions in Case 3 (infestation of Spruce in Baden-Württemberg by *Cinara Pilicornis*) [$\mu\text{g m}^{-3}$]; (c) Relative increase in modelled regional background $PM_{2.5}$ [in %] due to the simulated infestation.

Table 1: Biotic stress induced emissions (SIE) of sesquiterpenes (SQT), methyl salicylate (MeSA) and unsaturated C_{17} -BVOC (C_{17}) in the different model scenarios. The SIE are expressed as fractions of the daytime model emissions of monoterpenes (MT)

Scenario (notes, exp.)	Area	SQT/MT	MeSA/MT	C_{17} /MT
Case 0 (a)	everywhere	0.05(e)	-	-
Case 1 (b)	Lat > 60°N	0.24	-	-
	45°N < Lat ≤ 60°N	0.48	-	-
	Lat ≤ 45°N	0.05	-	-
Case 2 (c)	Lat > 60°N	0.49	0.35	-
	45°N < Lat ≤ 60°N	0.98	0.70	-
	Lat ≤ 45°N	0.05	-	-
Case 1F (b)	Lat > 60°N	1.2	-	-
	45°N < Lat ≤ 60°N	1.6	-	-
	Lat ≤ 45°N	0.05	-	-
Case 2F (c)	Lat > 60°N	2.45	1.75	-
	45°N < Lat ≤ 60°N	3.27	2.33	-
	Lat ≤ 45°N	0.05	-	-
Case 3 (d)	June-July, Lat: 47.8°N - 49.8°N, Lon: 8.0°E - 10.2°E	0.38	-	6.8
	Elsewhere (and rest of year)	0.05	-	-

Notes: The model scenarios are based on the following JPAC chamber experiments (a) Mentel et al. (2009); (b) Exp. 2 in Mentel et al. (2013); (c) Exp. 1 in Mentel et al. (2013); (d) Exp. 3 in Mentel et al. (2013). (e) SQT emissions from unstressed plants are set to 5% of the MT emissions.

Acknowledgements. This work was funded by the Swedish Clean Air Research Programme (SCARP), EU projects ECLAIRE (project no: 282910), PEGASOS (no: 265148), as well as EMEP under UNECE. The work is also a contribution to the Swedish Climate Modelling project MERGE and the Climate change and Environmental Objectives (CLEO) research programme.

610 We would like to thank ICP Forests and the beekeepers of Baden-Württemberg for helpful comments and for allowing the use of material from their reports and webpages.

Thanks also to Sanna Saarikoski for providing the observational OC data from Hyytiälä.
