22 Abstract

23 Diesel trucks are major contributors of nitrogen oxides (NO_x) and primary particulate 24 matter smaller than 2.5 μ m (PM_{2.5}) in transportation sector. However, there are more those to obstacles on existing estimation of diesel truck emissions compared with that of cars. 25 26 The obstacles include both inappropriate methodology and missing basic data in China. 27 According to our research, a large number of trucks are conducting long-distance inter-28 city or inter province transportation. Thus, the method, used by most of existing to estimate emissions inventories, based on local registration number is inappropriate. A road emission 29 30 intensity-based (REIB) approach is introduced in this research instead of registration 31 population based approach. To provide efficient data for the REIB approach, 1,060 32 questionnaire responses and approximately 1.7 million valid seconds of onboard GPS 33 monitoring data were collected in China.

34

35 The estimated NO_X and $PM_{2.5}$ emissions from diesel freight trucks in China were 5.0 36 (4.8 - 7.2) million ton_k and 0.20 (0.17 - 0.22) million ton_k respectively in 2011. The 37 provinces based emission inventory is also established using REIB approach. It was 38 found that the driving conditions on different types of road have significant impacts on 39 the emission levels of freight trucks. The largest differences among the emission factors 40 (in g/km) on different roads exceed 70% and 50% for NO_X and PM_{2.5}, respectively. A 41 region with more inter-city freeways or national roads tends to have more NO_X 42 emissions, while urban streets play a more important role in primary PM_{2.5} emissions 43 from freight trucks. Compared with inventory of Ministry of Environment, which 44 allocate emissions according to local truck registration number and neglect inter-region 45 long distance transport trips, the differences for NO_x and $PM_{2.5}$ are +28% and -57%

- 46 differences respectively. And the REIB approach matches better with traffic statistic
- 47 data on province level. Furthermore, the different driving conditions on the different
- 48 roads types are no longer overlooked with this approach.

51 **1 Introduction**

52 China has been facing severe air quality challenges in the past several years. Air 53 pollution in China not only endangers the health of billions of people but also creates a 54 substantial burden on the economy (Matus et al., 2012). The 2005 marginal welfare 55 impact to China, considering only ozone and particulate matter, was US\$112 billion 56 (1997 US\$) (Hammitt and Zhou, 2006). Vehicular emissions form one of the greatest 57 contributors to the air pollution in China, especially for NO_x and PM_{2.5}. According to 58 the Ministry of Environmental Protection (MEP), vehicular emissions contributed 27.4% 59 of the total NO_x emissions in 2012 (MEP, 2012a). Vehicle emissions also contribute 60 more than 30% of PM_{2.5} in Beijing, as announced by the Beijing government.

61

62 Preparing inventories is essential to the assessment and management of current atmospheric problems (Ohara et al., 2007; Streets et al., 2003; Beaton et al., 1995). 63 64 Among all the sources, the mobile source is one with the greatest uncertainty and 65 ambiguity (Cai and Xie, 2007; Wang et al., 2008a). Among all the vehicles, diesel 66 freight trucks contributed to a large portion of vehicular emissions. According to the 67 MEP, diesel vehicles, mainly consisting of freight trucks, contributed 70% of NO_X and 68 90% of PM in the total vehicular emissions in 2012 (MEP, 2013). Therefore, improving 69 current emission inventory and reducing the uncertainty is of great necessities.

70

Another major impediment to developing a new approach to estimate freight truck emissions is that most inventories were based on the local registration numbers, which means there is an assumption that trucks are running within the province or city where they registered (Zheng et al., 2013). However, according to this research, many trucks are conducting long-distance inter-city or inter-province transportation trips. Therefore,

a road-based estimate approach was introduced in this research instead of the former
local registration number based approach. This simulation addresses more on the freight
transportation system as a whole rather than a local emissions scale.

79

80 In summary, we attempt to identify and reduce the impact of the factors mentioned 81 above by adopting a road-based approach with collected activity level data including 82 both questionnaire answers and GPS records. In particular, this research serves to (i) 83 provide more accurate activity level data for freight trucks including mileage traveled 84 versus age, activity regions and driving conditions, (ii) identify the different emission 85 rates caused by different driving conditions on each type of road and (iii) provide a 86 national emissions inventory that considers the road freight system as whole instead of 87 separating it into different pieces according to the province divisions.

88

89 2 Data and Methodology

2.1 Data Source

The data source of this research primarily consists of two major parts: 1. Questionnaires that investigated the driving behavior of professional truck drivers, along with experiential data that related to their driving pattern. 2. Driving condition tests of trucks driving on different types of roads. Information about the questionnaires and GPS data, such as the sample numbers and location range, is shown in Table 1.

96

A series of questions related to driving pattern, fuel consumption, route selection,transport range, etc. were included in the questionnaires. All the investigated drivers

99 are professional freight truck drivers. Because most of the freight truck drivers are not 100 highly educated, all the questionnaires were conducted by college students, and a 101 detailed explanation was required to make sure that the drivers understood the question 102 correctly. To ensure the quality of the answers, related questions that validate each other 103 are designed to wipe out careless or wrong answers. A total of 1,060 samples from 16 104 provinces were investigated. Therefore, it is a large sample study according to the 105 theory of statistics (Box et al., 2005). Previous studies on driver behavior in China also 106 conducted questionnaire investigations. For example, 520 samples, which were targeted 107 all at automobile drivers and not limited to trucks, were studied in 2002 to understand 108 the behavior of drivers (Xie and Parker, 2002). Another 87 completed samples were 109 used to make comparisons between China and Hong Kong in 2009 (Chan et al., 2009). 110 Questionnaires are also used on truck drivers in Australia (N=433), Germany 111 (N=10,101), Brazil (N=4,878) and New Zealand (1,065) for different purposes 112 (Sullman et al., 2002;Lajunen et al., 2004;Moreno et al., 2006;Moreno et al., 2004). 113 Compared with other sample sizes of domestic and foreign studies on truck drivers, the 114 number of samples in this study is adequate to describe the average level of freight truck 115 activities.

116

117 Trucks are classified into four types according to weight in this research, following the 118 rule made by National Statistics Bureau (CATARC, 2012): Mini Trucks (MiniT) with 119 weights less than 1.8 t, light duty trucks (LDT) with weights of 1.8–6 t, middle duty 120 trucks (MDT) with weights of 6–14 t and heavy duty trucks (HDT) with weights greater 121 than 14 ton. The classification is used on getting-vehicle stock from national statistic, 122 questionnaires investigation and data analysis in this study. Because the MiniT 123 population only consists of a very small proportion of the total truck fleet,

approximately 0.98% of the total freight truck stock in 2011, and the differences
between MiniT and LDT are not significant, MiniTs and LDTs are grouped together in
the calculation of emission factors.

127

128 Because the normal method to testing driving patterns focuses on driving in cities, this 129 method can hardly be applied to freight trucks; a freight truck has significant operation 130 differences with that of a private passenger car (Holguin-Veras et al., 2006;Kamakat é 131 and Schipper, 2009). Freight trucks in China generally travel inter-cities and do not stop 132 for extended time periods, except for a small portion that run inside cities for short 133 distance freight transit or other special public service (like garbage collection or road 134 sprinkler) (Hine et al., 1995). To obtain the real time driving patterns of freight trucks, 135 a Global Positioning System (GPS) receiver and speed sensor were used. For many 136 years, GPS has been used to monitor the driving conditions of vehicles in many 137 emission related studies (Ochieng et al., 2003;Rakha et al., 2004;Canagaratna et al., 138 2004). A multifunction Columbus GPS data logger V-990 produced by GPSWebShop 139 (Canada) Incorporation was used in this research. The GPS data logger is set to 140 automatically turn on/off when the engine of the investigated truck is turned on/off. 141 Therefore, the data was collected every second when the engine of the truck under 142 investigation is running. We were allowed to do this because a sensor was put into GPS 143 to capture the voltage change of cigarette-lighter.

144

The investigated trucks were all driven by professional truck drivers during the tested time period. The GPS data logger was required to be used for at least one week to record the full driving pattern of the freight trucks. All drivers maintained their business as usual during the test time period. In total, 1,728,622 valid seconds from 16 trucks with

149 different load capacities and functions were tested. All of the tested data were classified 150 into five different types according to the road type they were on. The road type is identified by Google Map. The roads are divided into 5 classifications: urban roads, 151 152 rural/town road, provincial roads, national roads and inter-city freeways. Typical speed 153 tracks and routes of each type of the tested roads are shown in Figure 1. To present the 154 speed distribution in a same scale, only the first 4,000 seconds of speed are shown in Figure 1. For urban road, there are only 3,989 seconds of data, and it represents the 155 longest single trip in urban area that was monitored in this research. 156

157

2.2 Emission Rates and Emission Factors

Vehicle-specific power (VSP) is a concept that is designed to describe the working
conditions, such as aerodynamic drag, acceleration, rolling resistance and hill climbing,
of a vehicle and is used in the evaluation of vehicle emissions (Jimenez-Palacios, 1998).
VSP is now widely used in emission factor modeling, such as in the IVE and MOVES
models. For the VSP calculation, the equation for heavy duty diesel trucks (HDDTs)
from the MOVES model was applied in this study (Eq. 1).

165
$$VSP = \frac{A}{m} \cdot v + \frac{B}{m} \cdot v^2 + \frac{C}{m} \cdot v^3 + a \cdot v + gv \cdot \sin\theta \qquad \text{Eq.1}$$

166 where m is the vehicle weight, tons; v is the instantaneous vehicle speed, $m \cdot s^{-1}$; a is 167 the instantaneous vehicle acceleration, $m \cdot s^{-2}$; θ is the road grade, radians; A is the 168 rolling resistance coefficient, $kW \cdot s \cdot m^{-1}$; B is the rotational resistance coefficient, 169 $kW \cdot s^2 \cdot m^{-2}$; and C is the aerodynamic drag coefficient, $kW \cdot s^3 \cdot m^{-3}$. The road-load 170 coefficients (i.e., A, B and C) by each major category are shown in Table 2. The 171 coefficients were estimated according to the typical weight type used in Motor Vehicle 172 Emission Simulator (MOVES) model (Koupal et al., 2004).

Engine stress (ES), which includes 25-second historical VSP data, was introduced by emission models such as International Vehicle Emission (IVE) model to represent how early running conditions impact current emissions. ES is calculated in following equation (Eq.2) from the IVE model (CE-CERT et al., 2008):

178
$$ES=RPMIndex+(0.08 ton \cdot kW^{-1}) \times Pr eaveragePower$$
 Eq.2

179 where PreaveragePower is the average VSP during -5 s to -25 s, $kW \cdot ton^{-1}$; RPMIndex 180 is the Velocity_{t=0} / *SpeedDivider*, unitless; and the minimum RPMIndex is 0.9. The

181 detailed SpeedDivider is shown in Supplementary Information Table S1.

182

183 Operating mode bins are identified according to the VSP and ES. Data from multiple 184 researches was used to obtain the representative emission rates in this research since no 185 study provides sufficient data of emission rates for all types of trucks. Emission rates of each bin from Liu's study (Liu et al. 2009) were used to generate curves of emission 186 versus bins, what we called bin-emission curves. Emission factors of different vehicle 187 188 classes from Wang et al. (2012) and Zhang et al. (2013) were used to amend the bin-189 emission curves, moving the curves up or down without changing the relative 190 relationship among bins. The outcome representative emission rates of each bin are 191 shown in Supplementary Information, Figure S1. With GPS monitoring data from 192 tested trucks in this research, distance-specific emission factors can be calculated with 193 the following equation (Eq.3):

194
$$EF_{i,j} = \frac{1000 \cdot \sum_{t} ER_{i,j,t}}{\sum_{t} v_{i,j,t}}$$
 Eq.3

where EF is the distance-specific emission factor, $g \cdot km^{-1}$; ER is the second-bysecond emission rate, $g \cdot s^{-1}$; and v is the velocity. The subscripts i, j and t represent road type, type of tested truck and time, respectively.

198

2.3

Setting up the Regional Emission Inventory

199 Top-down approaches are widely used in estimating anthropogenic emissions for a 200 relatively large geographic range. According to the annual vehicle population numbers 201 from the China's Automotive Industrial Statistics Yearbook (CATARC, 2012) and the 202 survival curve from a former study (Hao et al., 2011), details about the existing vehicle 203 population, such as the portion of trucks at different ages and weight, can be calculated. 204 Following the Yearbook, the trucks were divided into 4 types according to their GVW 205 (shown in Table 2). In addition, the annual VKT (vehicle kilometer traveled) of trucks 206 at different ages is acquired from the investigation. Combining the fleet information 207 and the VKT data together yields the total activity level number.

208

209 In this research, a new road emission intensity based (REIB) approach was introduced 210 to calculate the regional emission inventory of diesel trucks. Instead of relying on local 211 registration numbers, the road emission intensity served as the base of the REIB 212 approach. The basic assumption for REIB is that for freight trucks, the driving 213 conditions and truck flow were similar on the same type of road in different regions. 214 The emission intensity of different types of road was calculated according to the activity 215 distribution obtained from this research. Then, the emissions in each grid cell or 216 province could be calculated according to the length of different types of road. Unlike 217 former approaches that assumed that trucks ran limitedly in the region where they are 218 registered, the REIB approach examines the road freight transportation as a whole nationwide system. The REIB approach is a better fit, given the fact that a large portion
of trucks run across provinces. In the GPS monitoring conducted in this research, the
longest single trip traveled across 8 provinces. The local registration based approach
introduced great inaccuracy by overlooking the cross region trips of freight trucks.

223

Different types of truck were investigated to determine their traveling information. The drivers were asked to estimate the distance portion that they drive on different types of roads. In this study, the roads are classified into freeway, national roads, provincial roads, rural roads, urban roads and other special roads such as those within factories and ports. Then, the emission density of different types of roads was calculated according to following equation (Eq.4):

230
$$\rho_{i} = \frac{\sum_{j,k} \overline{VKT}_{j,k} \cdot NV_{current_year-k,j} \cdot SR_{j,k} \cdot EF_{i,j,k} \cdot DP_{i,j}}{L_{i}} \qquad Eq.4$$

where ρ_i is the emission density of i type road, $g \cdot km^{-1} \cdot year^{-1}$; $\overline{VKT}_{j,k}$ is the 231 average VKT per vehicle, $\text{km} \cdot \text{year}^{-1}$; $NV_{current_year-k,j}$ is the new vehicle population 232 of type j k years ago; $SR_{j,k}$ is the survival rate of a k-year-old type j vehicle, The data 233 234 came from a nationwide vehicle survival pattern research conducted by Hao el al. (2011). And the survival curves are shown in SI, Figure S2; $DP_{i,j}$ is the distance 235 portion for type j truck running on type i road; and L_{i} is the total length of type i road 236 in China, km. The subscript k refers to the age of a vehicle. The remaining variables 237 238 are the same as described above.

With the emission density number, the national emissions inventory can be calculated according to the spatial distribution of different types of road. In this research, multidimensions of inventories have been created to present the spatial distribution of freight truck emissions.

244

245 **3 Results and Discussion**

246

3.1 Activity Level of Freight Trucks

247 Freight trucks with different ages were investigated in this research. According to a 248 former study, the total distance that a passenger car traveled has a quadratic relationship 249 versus its age (Liu et al., 2008). This relationship means that as the passenger car ages, 250 the mileage traveled per year decreases. According to the investigated samples in this 251 study, the average total kilometers that a truck traveled also follow the similar pattern 252 (shown in Figure 2). With an R-square value of 0.9651, the empirical quadratic equation 253 is adequate to describe the average activity level. The standard error in this research is 254 relatively high compared with passenger car, revealing large variation among the trucks 255 of the same age. This significant variation is caused by the diversity of functions of different trucks, which makes the investigation in truck activity a tough task. However, 256 257 the investigation result is the only data available now to understand the characteristics 258 of trucks at different ages. Moreover, unlike former research that used average mileage 259 traveled for the entire fleet (Huo et al., 2012b;Fu et al., 2001), these results here 260 represent the aging effect of trucks, which is that the annual mileage decreases as the 261 truck grows older. By neglecting the annual mileage reduction as trucks age, the impact 262 of old trucks may be exaggerated because they do not actually run as much as newer trucks. Therefore, this investigation will help to identify the contribution of trucks underdifferent ages more accurately.

265

Moreover, mileage correction factors by vehicle type was introduced to identify the differences between each type of truck, as shown in Table 2. The correction factors were the ratio of the average kilometers travelled of a certain type of truck versus the entire truck fleet. From the value of correction factors we can see that as GVW grows, the average kilometers travelled increase.

271

272 Both the mileage traveled and emission rates for trucks at different ages are different. 273 Therefore, it is required to have the detailed age composition of truck fleet in the target 274 year. The fleet composition and the total mileage traveled in 2011 by vehicle age are 275 shown in Figure 3 (a) and (b). The total diesel truck population in 2011 reached 193.3 276 million, of which 53% came online during 2009-2011 and therefore meet the China 3 277 tailpipe emissions standard. Chinese government adopted vehicle emission standards 278 following emission standards in Europe since 1999. The emission level 1 to 3 in China 279 are equivalent to Euro 1 to 3 standard respectively, while China 0 means no emission 280 control was applied. The limits of NO_x and PM based on China vehicle emission 281 standards are shown in SI, Table S2. Truck population in China experienced a 282 tremendously growth during 2009-2011, according to the data from National Statistical 283 Bureau of China. In 2009, there was 0.98 million more new trucks came into the market 284 compared with 2008, which was equivalent to 8.7% of the total truck stock in 2008. 285 And most of the 2009-2011 trucks survived in the 2011 market. Therefore, there was 286 an obvious excess of trucks from 2009-2011 in the 2011 market compared with 287 previous years. Different from the vehicle population, the total mileage contributed by

288 the China 3 trucks reaches 60% because new trucks are more frequently used. A total 289 of 1.47 trillion kilometers were conducted by diesel freight trucks in 2011. The large 290 portion of new vehicles in both population number and mileage traveled indicates that 291 the application of stricter emissions standards has great significance because China is 292 experiencing a booming in its truck population. However, the application of the China 293 4 emissions standard on diesel vehicles has been delayed because oil companies in 294 China were unable to supply diesel that met the standard (Zhang et al., 2012). 295 Considering the booming increase of new diesel trucks and the large share of them in 296 the total mileage traveled, the impact of the delay of upgrading the emissions standard 297 would be highly significant.

298

299 One of the challenges in mapping the emissions of freight trucks is that it is hard to 300 identify where the trucks are running. The problem is more challenging with trucks 301 rather than other types of automotive because trucks are not limited to their registration 302 region as cars are nor do they have fixed routes as buses do. In the questionnaires 303 conducted in this research, the professional truck drivers estimated the length 304 proportions they drive on different types of road. The length proportions of roads that 305 trucks run on is summarized into different groups according to their GVW, as in Figure 306 4. As Figure 4 shows, we determined that different types of trucks tend to have different 307 running patterns. It is obvious that heavier trucks are more likely to run on the high 308 speed freeways; heavy duty trucks are generally employed for long distance 309 transportation because it is more economical than lighter carriers. For long distance 310 transportation, high speed freeways are the primary options for the drivers. On the 311 contrary, inside an urban area, mini trucks and light duty trucks are more common given 312 their flexibility and also possible constrictions on heavy duty trucks. This result is used

to estimate the truck flow and fleet composition and to assign total kilometers traveled for each type of truck. The mileage and fleet information on each type of road are inputs for the calculation of emission intensity. The differences of fleet compositions between the different types of road have long been overlooked in past inventory work.

317

318

8 **3.2** Different Driving Characters on Different Types of Roads

Trucks with different weights usually serve different purposes. This consequently leads to different driving patterns of the different types of trucks. According to the research results, the annual mileage traveled and average speed have significant differences among the different types of trucks.

323

324 Generally, heavier trucks ran at higher speeds and traveled greater mileage than lighter 325 trucks. This behavior is due to the varying main function of trucks with different load 326 capacities. Heavier trucks are usually used for long-distance transportation to reduce 327 average cost, which means heavier trucks operate more on high-speed roads. Lighter 328 trucks run more on urban roads given their flexibility. The differences in the time 329 portions from running on each type of road by the different levels of trucks are shown 330 in Figure 4. These differences will lead to different driving patterns for the different 331 types of trucks. As shown in Figure 1, the speed records on selected routes for each 332 type of road were quite different from each other. For the tested route on the G93 333 Freeway, the average speed was maintained at approximately 70 km/h, and the stop 334 times (when the speed reaches zero) were rare. It indicated that the traffic flow on the 335 G93 Freeway during the tested time was very fluent. For the tested routes on the G309 336 National Road and S343 Provincial Road, the speed hardly exceeded 70 km/h, and the 337 stops and sudden drops in speed were more frequent than on the G93 Freeway. 338 Although the speed distributions on the G309 and S434 looked similar, the speed on 339 the S434 obviously fluctuated more frequently than that on the G309. This revealed that 340 the driving conditions on these two roads were similar, while traffic flow on the G309 341 was more fluent. For the urban road in Changsha City, Hunan, it was difficult for the 342 truck to reach 40 km/h during the tested time. Stops were much more frequent than on 343 former roads potentially due to traffic lights and traffic jams within the city. As for the 344 country road between two villages in Shandong, the driving conditions were the worst 345 among all the roads. The maximum speed during the tested time period was 40 km/h, 346 and 85.5% of time the speed stayed below 20 km/h. In summary, as what we can see 347 from the selected examples of the different types of roads, the driving conditions were 348 distinctly different.

349

350 To demonstrate that the differences were not special cases, a statistical summary was 351 made to see whether significant differences could be found in the large amount of data 352 that we collected. The velocity and acceleration distributions for the total monitored 353 data on urban roads (226,290 valid seconds) and freeways (583,922 valid seconds) are 354 shown in Figure 5 as selected examples to illustrate the differences between the running 355 conditions on these two types of roads. (Monitoring data on other roads are shown in 356 Supplementary Information Figure S3-5.)Velocity and acceleration are divided into 357 several bins, and the frequency of each bin is calculated. Velocity is divided into 30 bins from 0 - 30 m/s, and acceleration is divided into 7 bins from -1.5 to 2 m/s². 358

359

360 The results show two obvious different running conditions on the urban roads and inter-361 city freeway. The average speed and the maximum speed on the urban road are much

362 lower than that on the inter-city freeways. Additionally, the urban road has much greater 363 low-speed-running and idling time. If the high peak of the low-speed zone is removed, 364 the speed distribution on the urban road is relatively flat with the range from 5 m/s to 365 20 m/s. On the other hand, the situation on the inter-city freeway is quite different. 366 There are two peaks on the inter-city freeway: a smaller peak in the lower speed zone 367 and a larger peak in the high speed zone. The percentage of the middle speed is very 368 low. From the results, it shows that the difference is still significant considering all the 369 collected data from different roads and trucks. Because both velocity and acceleration 370 will affect the vehicle specific power and engine stress, different velocity and 371 acceleration distributions will lead to different emission results. Without considering 372 the differences in emission factors caused by the different driving conditions, 373 uncertainties and inaccuracy were introduced to former vehicular emissions inventory 374 research. In the upcoming section, the differences in emission factors on the different 375 roads will be discussed.

376

377 3.3 Emission Differences Caused by Different Driving Cycles on Each Type 378 of Road

379 As discussed in the previous section, different driving cycles on the different types of 380 road lead to different emission factors for the different roads. The IVE model is a widely 381 accepted tool to estimate vehicle emissions, and former research in China has already 382 localized the IVE model so that it applies to the Chinese vehicles. The IVE model uses 383 velocity and VSP as two inputs and classifies the driving conditions into different bins. 384 For each bin, a measured typical emission factor is used to represent the average 385 emission level. The distribution of bins on each type of road is shown in Figure S6, and 386 the emission factors that are derived for each type of the road using the IVE model are 17

shown in Table 2. As introduced in section 2.2, on-board measurement data in China
was used to calculate the average emission factor on the different types of road with
real time monitoring GPS data. The results are shown in Figure 6.

390

391 From the results, it can be concluded that different running conditions on different types 392 of road lead to significant differences in the emission factors. Generally, rural or town 393 areas tend to have the worst conditions for diesel freight trucks. In almost all the cases, 394 the emission factors for both NO_x and PM_{2.5} on rural or town roads are the largest 395 among the 5 types of roads. This is mainly due to the long idling time without shutting 396 down the engine on the rural or town roads while loading or unloading. Generally, the highest emission factor is 73.5% and 51.2% higher than the lowest one for NO_x and 397 398 PM_{2.5}, respectively. These significant differences will lead to equivalent scaling errors 399 in the total emissions of freight trucks. Generally, the emission factors tested on urban 400 roads where the driving conditions are relatively worse, leading to a higher emission 401 factor.. However, inter-city national, provincial road and freeway are also important 402 places where many freight trucks run, especially those with heavier gross vehicle 403 weights. This means the former study has over-estimated the emissions from freight 404 trucks, because when running on inter-city roads or freeways, trucks have a lower 405 emission factor due to better running conditions.

406

407

3.4 Emission Inventory of Freight Trucks

408 According to this research, the total NO_X from freight trucks in 2011 was 5,000,000 409 ton. The primary $PM_{2.5}$ emissions from diesel trucks in 2011 were 200,000 tons.

411 Figure 7 shows the NO_x and $PM_{2.5}$ emissions from trucks of different ages in the 2011 412 fleet. For both NO_x and PM_{2.5}, heavy duty trucks accounted for over 70% of the total emissions despite only counting for 26% of the total population. Hence, focus should 413 414 be placed on controlling the emissions from heavy duty trucks. If the age of trucks is 415 considered, the trucks that went into the market during 2009-2011 accounted for 40% 416 of the total population and 60% of the total mileage traveled due to the mushrooming 417 sales and the greater activity of new vehicles. This means the tightening of the 418 emissions standard for new vehicles plays a critical role in the vehicular emissions 419 control section. Moreover, the Yellow Label Vehicle, which means the pre-China 3 420 emissions standard diesel vehicles, has a more significant contribution to primary PM_{2.5} 421 emissions than NO_x.

422

423 Figure 8 shows the emissions distribution calculated according to the emission intensity of the different types of roads in the eastern part of China, where the major emissions 424 425 occurred, with a resolution of 0.5×0.5 degrees per cell. Unlike approaches that are based 426 on the local registration numbers of trucks, the approach applied in this research relies 427 on the assumption that the traffic volume of freight trucks on each type of road remains 428 similar. This approach views the freight transport in the nation as a whole system. From 429 the emissions map and the emission intensity comparison, the freeways and national 430 roads, where most of the freight transportation in China is conducted, have large 431 emission intensities and emission impacts on their surroundings.

432

From Figure 8, freight transportation has the strongest impact in locations where the
economy is well developed and the population has high density. The Beijing-TianjinHebei (Jing-Jin-Ji) district, Yangzi River Delta and Pearl River Delta, the three biggest

436 economic circles in China, are also the regions with highest emission density. From another perspective, 12 out of the 13 key control regions listed in the 12th Five Year 437 Plan (FYP) of Air Pollution Control in China have relatively high emission densities, 438 439 as shown in Figure 8 (MEP et al., 2012). (The remaining key region, Urumqi and its 440 surroundings in the Xinjiang province, which is not shown in the East China map, is 441 also a hot spot of freight emission.) Therefore, the significance of controlling emission 442 from diesel freight trucks is greater considering the high impact on the air quality and 443 human health in the key regions.

444

445 Figure 9 shows more detailed emissions inventories of diesel freight trucks in the three biggest economic circles, Jing-Jin-Ji, Yangzi River Delta and Pearl River Delta, with a 446 447 resolution of 0.1×0.1 degrees per cell. The emission map indicated that cities with 448 developed road networks and their surroundings suffered the most from the emissions 449 of freight trucks. The distributions in the three districts were not the same. Pearl River 450 Delta had the highest density of emissions. The high emissions area is close to 451 Guangzhou and Shenzhen, the core cities in PRD. Meanwhile in Yangzi River Delta, 452 the emissions are much more dispersive due to the large numbers of cities with high 453 economic growth and well developed road networks. From the differences in the 454 emission distribution, we can conclude that emissions from freight trucks in PRD are more aggregate. Therefore, controlling dies eight truck emissions in YRD would be 455 456 more challenging because more cities are needed to be involved in the control strategy.

458 **3.5** Comparisons with Other Studies

459 NO_x emission from this research is 28% higher than the MEP's estimation of 3,900,000 460 ton NO_x emissions from trucks in 2011 (MEP, 2012b). And according to the MEP, the 461 total PM_{2.5} emissions from the truck fleet were 460,000 ton in 2011 (MEP, 2012a), 462 which is 130% higher than estimation in this research. The differences come from 463 method, basic data and major assumptions.

464

465 Briefly, MEP estimated vehicle emission on the basis of local vehicle stock, activity 466 level and emission factors. The truck classification is the same with our study, 467 according to gross vehicle weight and the national emission standards. For each group, 468 the emission equals the product of local registration number, kilometer travelled per 469 vehicle and emission factor. Adding up emissions of each group is the total emission. 470 The emission factor that MEP used is based on the national emission standard. Detailed 471 information of emission standards in China is shown in SI, Table S2. However, no 472 further input data related to vehicle kilometer travelled was provided in this inventory.

473

The difference on_NO_x emissions was mainly caused by emission factors used in these two studies. In our study, the emission factor of China 3 trucks was not improved compared with China 2 (Wu et al., 2012; Liu et al., 2009). Thus, compared with MEP inventory and other inventory based on low NOx emission rate, our NO_x emission is much higher.

479

480 Compared with MEP results, the $PM_{2.5}$ emissions calculated in this research are 481 significantly lower. A major reason for this lower result is that we included the

482 decreasing trend of mileage traveled by trucks per year in this calculation. In China, 483 overloading was common for commercial trucks. This accelerated the deterioration of 484 trucks, which means older trucks had to run less due to deteriorated performance and 485 more frequent repair and maintenance. The decrease of VKT was proved by our 486 questionnaire investigation. If the mileages variation with age were omitted, the 487 calculated PM_{2.5} emissions would increase 50%, exceeding 300,000 ton. However, the VKT variation is not such a large problem for NO_x because the NO_x emission factor 488 489 did not improve from old trucks to new trucks.

490

491 The provincial level NO_x and $PM_{2.5}$ emissions from road freight transportation are 492 shown in Figure 10 (a) and (b), respectively, ranking from the highest to the lowest. For both NO_x and PM_{2.5}, Shandong and Guangdong, where most of the freight 493 494 transportation in China is conducted, take the leading positions in freight truck 495 emissions. The NO_x and PM_{2.5} emissions in these two provinces exceeded 600,000 ton 496 and 25,000 ton, respectively. Provincial emissions from MEP inventory are also shown 497 in Figure 10. The provincial differences between the outcome of REIB approach and 498 MEP inventories are obvious. The greatest differences are 220% and -72% for NOx 499 and PM2.5 respectively (REIB compared with MEP inventory). Not only the emission 500 scales are different, discrepancies also exist in the rankings of provinces. The 501 differences come from both different basic data and different methods. To avoid 502 influence from input data, we re-calculated provincial VKT using our method and the 503 traditional approach. Here traditional approach means calculating total VKT based on 504 local registration data and average mileage travelled. The differences between the 505 provincial proportions of VKT are shown in Figure 11. Taking Shanghai as an example, 506 REIB method has 39.9% lower VKT compared with the traditional method. In the

507 report published by MEP (2012a), the largest contributor of both NO_x and PM_{2.5} in 508 China during 2011 was Hebei province. However, Shandong contributed the most road 509 freight emissions in 2011 according to this research. This difference was caused by the 510 methodology on which the inventory was based. As discussed earlier, the registration 511 number based approaches have a significant bias because trucks are not limited to the province where they are registered. Therefore, a province with the largest registration 512 513 number of trucks might not have the most freight transportation. According to the China 514 Statistics Bureau, Shandong has the greatest cargo volume and cargo turnover volume 515 in the road transportation sector (Bureau, 2012). These data verified our assumption 516 from a different perspective. Therefore, the former approach would be inaccurate 517 without considering that the real range of truck activities might be different from the 518 place where they are registered. There is an assumption of REIB approach that the same 519 type of roads have equal congestion in different provinces. This is a limitation of our 520 study and the limitation is mainly because the limited data amount. This limitation 521 could be avoided if future GPS data could be sufficient to characterize driving 522 conditions in each province, which means that the REIB approach is still suitable for 523 future mass data analysis. Now, we can still trust the results because the differences 524 within the same types of roads is much insignificant compared with that among 525 different types.

526

527

3.6 Uncertainty Analysis

Monte Carlo simulation is used to quantify the uncertainty in both NO_x and primary
PM_{2.5} emissions from diesel freight trucks. Monte Carlo methods are widely used in
identifying uncertainties in emission inventories (Hammersley and Handscomb,
1964;Sawyer et al., 2000;Wang et al., 2008b). The simulation is based on activity data

532 and emission factors variety distribution. The statistical distributions of the annual 533 kilometers travelled and stock are determined according to Zhang et al. (2013). And the 534 uncertainty of mileage distribution was estimated according to our questionnaire results. 535 For uncertainties of emission factors, we used the standard errors in the emission 536 measurements to represent the uncertainties (Wang et al. 2012; Zhang et al, 2013). 537 Considering that the activity level data are estimated based upon survey since it is not 538 available through official channels, there is inevitable systematic bias in the estimation 539 (Zheng et al., 2009). The uncertainties of the input parameters are listed in Table 3. The 540 distribution of the inputs follows normal distribution. The trials of the simulation were 541 set to 100,000 times.

542

543 The overall uncertainties in this inventory are estimated at -24.1% to 44.7% for NO_x 544 emissions and -16.3% to 31.3% for primary PM_{2.5} emissions. The uncertainty is 545 significant compared with other types of anthropogenic emissions because the 546 uncertainties in both activity level and emission factor of mobile sources are more 547 significant than other types of sources. The greatest uncertainties in the simulation are 548 the uncertainties of emission factors of freight trucks. The uncertainties were significant 549 during the test procedure. The emission data from the on-board measurement of diesel freight truck emissions has significant variances, which even reached 100% in some 550 551 cases (Huo et al., 2012a). In this research, comprehensive research into the activity 552 levels of freight trucks was conducted to minimize the uncertainties in activity level. 553 The new REIB approach also reduced the uncertainties in the distribution of freight 554 truck activity. Further improvements can be achieved by more accurate measurements 555 on emission factors.

556

557 4 Conclusions

558 We presented a REIB approach to estimate NO_x and $PM_{2.5}$ emissions in China, 2011.

559 The estimated emissions inventory may be used to forecast and evaluate the impact of

560 road freight transportation on air quality in China. Unlike approaches that are based on 561 the local registration numbers of trucks, the REIB approach views the freight system as 562 a whole nationwide system. The activity of freight trucks is distributed according to the 563 development and infrastructure of the local road system. The REIB approach is feasible 564 in the freight transportation sector, because in many cases, freight trucks conduct long-565 distance trips across several provinces, neglecting where they are registered. The 566 distribution of emissions among the different provinces has significant differences compared with the former research that was based on local registration numbers. 567 568 However, the REIB approach would be less efficient when applied to the passenger car 569 sector because private cars tend to have a more local range of activity.

570

571 According to the GPS monitoring results, the driving conditions on the different types 572 of road are different for trucks. These differences would lead to significant variances in 573 emission factors. According to the simulation results by the IVE model that were 574 interpolated with local on-board test data in China, the differences between the emission 575 factors from different types of trucks of same emissions standard could reach as high 576 as 70% and 50% for NO_X and PM_{2.5}, respectively. Uncertainties in emission factors are 577 the major drivers of the total uncertainty in the emissions inventory of diesel freight 578 trucks. The improvements of emission factors on the different roads reduce the 579 uncertainty and inaccuracy of diesel freight truck emissions.

580

In 2011, the diesel truck fleet emitted 5.0 (4.8 - 7.2) million ton NO_X and 0.20 (0.17 - 0.22) million ton primary PM_{2.5} in China. According to our research, the failure of reducing NO_X emission of the China 3 diesel trucks is the main reason of high NO_X emissions in total. And the challenge of NO_X reduction will last for many years until

585 all the existed trucks were replaced by new trucks with after-treatment system. 586 Moreover, places, with the highest diesel freight truck emission density are the regions that have most severe air quality problem. In addition, 12 out of the 13 key air quality 587 control areas listed in the 12th FYP of Air Pollution Control in Key Regions have high 588 densities of truck emissions. Therefore, controlling diesel truck emissions plays a 589 590 critical role in the air quality control plan in China. According to our emission 591 distribution in 2011 of the fleet by vehicle age, promoting more stringent emission 592 standard on new trucks is more efficient than eliminating the old Yellow Label Trucks. 593 However, the fact is that the Chinese government postponed the application of the 594 China 4 diesel truck emissions standard nationwide several times in the past few years.

595

596 Our research also indicates the uncertainties in freight truck emissions are 597 approximately from -24.1% to + 44.7% for NO_x and from -16.3% to + 31.3% for PM_{2.5}. 598 The uncertainties mainly come from the uncertainties in the emission factors from on-599 board measurements. Via improvements in specifying the emission factors to road type 600 levels, this research reduced the uncertainties in freight truck inventories.

Table 2 Summary of Road-load Coefficient Values for Calculating VSP of Each Truck Category

720

722 Note: With reference to the MOVES model, those vehicle types and coefficients are estimated

723 according to the typical gross vehicle weight (GVW) (Koupal et al., 2004). The classification of

truck type is explained in section 2.1.

Annual	Emission Factor		Mileage
Kilometer	NO _X	PM _{2.5}	Distribution
Traveled			
15%	-41% to +79%	-31% to +58%	5%
	Kilometer Traveled 15%	AnnualEnrissionKilometerNOxTraveled15%-41% to +79%	Kilometer NO_X $PM_{2.5}$ Traveled15%-41% to +79%-31% to +58%

726 Table 3 Uncertainties Scales of Inputs

Figure 2 Accumulated Traveled Distance of Trucks under Different Ages (The boxes show the 1st

Figure 3 Age and Total Mileage Traveled Distribution of the Diesel Truck Fleet in 2011, China: a)

737 Vehicle Population; b) Total Mileage

740 Figure 4 Proportion of Running time on Different Types of Roads

747 Figure 5 Velocity and Acceleration Distribution on Each Type of Roads: a) Urban Roads b) Inter-

748 city Freeway

Figure 6 Emission Factors on Different Roads a) NOx Emission Factors; b) PM2.5 Emission Factors

755 Figure 7 Emissions from Diesel Truck Fleet in 2011, China a) NOx Emission; b) PM2.5 Emission

Figure 8 Maps of NO_x and PM_{2.5} Emissions from Freight Trucks in the Eastern Part of China 2011: a)
NO_x Emission; b) PM_{2.5} Emission. (Key Control Areas in 12th Five Year Plan of Air Pollution Control:
1. Jing-Jin-Ji; 2. Yangzi River Delta; 3. Pearl River Delta; 4. central part of Liaoning Province; 5.
Shangdong Province; 6. Wuhan City and its surroundings; 7. Changsha-Zhuzhou-Changde; 8. Chengdu
and Chongqing; 9. west side of the Taiwan Strait; 10. central and north part of Shanxi Province; 11.
Guanzhong region in Shaanxi; 12 Gan-Ning region is Gansu and Ningxia)

Figure 9 Maps of NO_x and PM_{2.5} Emissions from Freight Trucks in East Part of China 2011

Ranks; b) PM_{2.5} Emissions Ranks. (*Ranking according to emission scales in this research).

Figure 11. Provincial VKT Proportions in REIB Approach and Traditional Approach.
