Abstract

Atmospheric mercury (Hg) measurements using the Tekran[®] analytical system from 5 high-elevation sites (1400–3200 m elevation), one in Asia and 4 in the western US, were compiled over multiple seasons and years, and these data were compared with the global model GEOS-Chem. Mercury data consisted of gaseous elemental Hg (GEM) and “reactive Hg” (RM) which is a combination of the gaseous oxidized (GOM) and particulate bound (< 2.5 μm) (PBM) fractions as measured by the Tekran[®] system. We used a subset of the observations by defining a “free tropospheric” (FT) dataset by screening using measured water vapor mixing ratios. The oxidation scheme used by the GEOS-Chem model was varied between the standard run with Br oxidation and an alternative run with OH-O₃ oxidation. We used this model-measurement comparison to help interpret the spatio-temporal trends in, and relationships among the Hg species and ancillary parameters and to better understand the sources and fate of atmospheric RM. The most salient feature of the data across sites, seen more in the summer relative to the spring, was that RM was negatively correlated with GEM and water vapor mixing ratios (WV) and positively correlated with ozone (O₃) both in the standard model and for most of the observations, indicating that RM was formed in dry upper altitude air from the photo-oxidation of GEM. Overall, however, the comparison between observed mercury species (GEM and RM) and those from the standard model showed a relatively weak relationship demonstrating the need to strengthen our understanding of fundamental chemistry and measurement artifacts. An improved correlation between the observations and the model was seen when the model was run with the OH-O₃ oxidation scheme instead of the Br oxidation scheme. This simulation produced higher concentrations of RM and lower concentrations of GEM, especially at the desert sites in northwestern Nevada, which raises the possibility that OH as an oxidant via the HgBr+OH pathway could be more important in the summer at desert sites, compared to the mountaintop sites at Storm Peak and Mount Bachelor.

Interactive Discussion

1 Introduction

Mercury (Hg) is a neurotoxin that persists in the environment and bioaccumulates in food chains. It is dispersed globally by long-range atmospheric transport (Schroeder and Munthe, 1998; Strode et al., 2008). Anthropogenic sources emit Hg to the atmosphere as gaseous elemental mercury (GEM) and divalent chemical compounds (Hg^{II}), whereas natural sources are thought to emit predominantly GEM (Pirrone et al., 2010). Oxidized atmospheric compounds (also termed Reactive Mercury = RM = Gaseous Oxidized Mercury (GOM) + Particulate Bound Mercury (PBM)) are typically measured as two operationally-defined forms. The first is adsorbed onto a KCl (potassium chloride)-coated denuder and the later collected on a quartz fiber filter and quartz chips (Landis et al., 2002). Gaseous oxidized Hg is water soluble and removed rapidly from the atmosphere in wet deposition (Lindberg and Straton, 1998), however it may be transported long distances in the free troposphere (Huang et al., 2012; Ambrose et al., 2012, Wright et al., 2013). Dry deposition is also thought to be an important sink for GOM and this has been demonstrated using surrogate surfaces. (cf. Gustin et al, 2012; Wright et al, 2013; Huang et al., 2013, Sather et al., 2013, Castro et al., 2013). The lifetime of PBM, limited by particle size, is typically less than 10 days (Schroeder and Munthe, 1998). Gaseous elemental Hg has lower water solubility and an atmospheric lifetime on the order of months to a year (Schroeder and Munthe, 1998). This form may also make a contribution to dry deposition of equivalent magnitude to GOM (Zhang et al., 2012). Gaseous elemental Hg atoms may be re-emitted depending on the surfaces on which they land (Gustin, 2011).

Most measurements of Hg forms made using the Tekran[®] system have found that GEM comprises 95–100 % of total Hg (Valente et al., 2007), a result of the long lifetime of GEM, and the rapid removal of GOM and PBM by wet and dry deposition. However, observations in the free troposphere (FT) from a mountain-top site have shown that the concentrations of GOM can be roughly equivalent to the concentrations of GEM during brief periods (Swartzendruber et al., 2006; Timonen et al., 2013). Observations

data to constrain the processes important for RM. In addition, we examined OH + O₃ chemistry in the model as an alternative to the standard model run that uses Br as the oxidant, and compared with the observations to reveal any clues about the likely oxidation mechanism for GEM.

2 Methods

2.1 Site characteristics

Maps depicting the locations of the study sites are shown in Fig. S1 in the Supplement. Site characteristics and the date ranges of the model-observation comparisons are given in Table 1. Four sites in this study are located in the temperate latitudes of North America, in the intermountain west. Two of these sites are on mountain-tops: Mount Bachelor Observatory (MBO) and Storm Peak Laboratory (SPL). Two other sites are within the Basin and Range province of Nevada: Desert Research Institute near Reno (DRI) and Paradise Valley north of Winnemucca (NV02). The fifth site, Lulin Atmospheric Background Station (LABS) is a tropical mountaintop location on the island of Taiwan in East Asia. Details of all these sites have been discussed elsewhere (Sheu et al., 2010; Swartzendruber et al., 2008; Stamenkovic et al., 2008; Weiss-Penzias et al., 2009; Fain et al., 2009). The LABS site observed polluted air due to Asian outflow primarily in spring, fall and winter (Sheu et al., 2010) and biomass burning emissions from the Indochina Peninsula in the spring (Sheu et al., 2012). Likewise, Asian long-range transport of GEM has been observed at MBO and SPL in the spring (Jaffe et al., 2005; Obrist et al., 2008). The DRI and NV2 sites were operated by University of Nevada, Reno from 2005 to 2007 (Peterson et al. 2009) and during the summer of 2007 (Lyman and Gustin, 2008), respectively. All sites have reported enhanced concentrations of GOM during periods of dry air and low GEM.

2.2 Speciated Hg and ancillary measurements

At all sites GEM, GOM, and PBM were measured with the Tekran[®] 2537/1130/1135 automated CVAFS instrument. Details of the Hg measurements, along with O₃ and meteorology are described in detail elsewhere (Swartzendruber et al., 2006; Faïn et al., 2009; Peterson et al., 2009; Lyman and Gustin, 2008; Sheu et al., 2010). Briefly, air is drawn into an inlet with a 2.5 μm size cut impactor into a KCl-coated denuder which absorbs GOM (unknown efficiency), then through a quartz fiber filter and quartz chips which are hypothesized to collect PBM, and finally across alternating Au cartridges which adsorb GEM. Gaseous elemental Hg measurements are recorded every 5 min, while GOM and PBM are collected for 2 h and desorbed for 1 h, giving a measurement every 3 h.

GEM can be calibrated with a primary source, but currently there is no calibrant for GOM or PBM, a serious limitation to the accuracy of all data produced by the Tekran[®] system (Gustin and Jaffe, 2010; Jaffe et al., 2014). Furthermore, ambient ozone concentrations negatively interfere with the adsorption and retention of GOM on the denuder (Lyman et al., 2010). There is also recent evidence that GOM may be composed of various forms of Hg, including HgCl₂, HgBr₂, etc., and that the KCl-coated denuder may not collect all these forms with equivalent efficiency (Gustin et al., 2012, 2013; Huang et al., 2013). In addition to the denuder, some fraction of GOM may be collected on the quartz fiber filter in the particulate Hg instrument (Tekran[®]-1135) (Gustin et al., 2013), and for these reasons we present GOM + PBM=reactive Hg (RM) measurements in this paper. A recent inter-comparison between Tekran[®] and new Hg measurement methods was performed and it was found that the Tekran[®] RM measurements were systematically 2–3 times lower than Hg^{II} measured with other methods (Gustin et al., 2013; Huang et al., 2013). Thus, the Tekran[®] measurements reported in this paper, while representing the best available observations, must be treated with caution in light of these uncertainties, and are likely a lower bound to the actual concentrations of RM. However, despite these uncertainties, speciated Hg data from these

high-elevation sites might still be meaningful for comparing site-to-site variability and RM/GEM slopes.

2.3 GEOS-Chem model

The standard model runs used version 9-01-01 of the GEOS-Chem (GC) Hg coupled atmosphere-ocean-land model (www.geos-chem.org), described in detail elsewhere (Amos et al., 2012). Briefly, the simulation was conducted for 2004–2009 with GEOS-5 assimilated meteorological and surface data from the NASA Global Modeling and Assimilation Office (GMAO) at the $2^\circ \times 2.5^\circ$ resolution. The GEOS-Chem simulation transports 2 Hg tracers in the atmosphere: Hg and Hg^{II}. Mercury redox chemistry followed Holmes et al. (2010), with oxidation of Hg by Br atoms and photoreduction of Hg^{II} in liquid cloud droplets. Oxidation of Hg by OH and O₃ is an alternative to oxidation by Br in GEOS-Chem (Holmes et al., 2010). The likelihood that OH-O₃ oxidation would proceed in the atmosphere has been questioned (Hynes et al., 2009; Goodsite et al., 2004). However, given the large uncertainties surrounding the oxidation of GEM, we include model runs with OH-O₃ oxidation mechanism as a model test to shed light on potential shortcomings of the Br mechanism. Anthropogenic emissions are from GEIA 2005 inventory (Pacyna et al., 2010). Model output is taken from pressure levels consistent with each site, and mean modeled values, on seasonal, daily, 12 h, and 3 h timescales, were compared with observations. Ancillary model output data (O₃, WV, and T) were generated from the v9-01-01 full chemistry simulation. GEOS-Chem has been extensively evaluated against Mercury Deposition Network wet deposition observations (Amos et al., 2012; Holmes et al., 2010; Selin and Jacob, 2008) as well as surface land-based sites, ship cruises, and plane flight data of GEM and seawater concentrations (Selin et al., 2008; Holmes et al. 2010; Soerensen et al., 2010; Amos et al., 2012).

2.4 FT subset of data based on water vapor measurements

The global chemical transport model used here cannot resolve local effects that sometimes influenced the measurements at each site. The model is sampling in the free troposphere (FT) but each site has time periods where the air is from the boundary layer (BL) influenced by surface Hg sources and sinks. In order to compare the Hg observed and modeled data more directly, the observations were filtered using a WV cutoff: only data were considered (termed “FT”) when WV < 75th percentile based on seasonal data sets (Table S1 in the Supplement). The seasonal months were: March–May = spring, June–August = summer, September–November = fall, and December–February = winter. This cutoff removed from the data set, for example, time periods when GEM concentration were > 6 ng m⁻³ at one site in Nevada (NV02). By removing the outliers, the interspecies correlation statistics were more comparable with the model. Applying a more stringent WV cutoff, such as < 50th percentile, would select data with even less influence from the BL, but would have less statistical power due to small numbers of observations. Thus, the 75th percentile WV cutoff was chosen for all sites. Water vapor screens have been used previously based on the empirically-derived equations described in Bolton (1980):

$$WV \left(\text{g kg}^{-1} \right) = \left[\text{RH} \cdot (6.22) \frac{0.01 \cdot e^{\left(77.345 + 0.00577 T_{\text{amb}} - \frac{7235}{T_{\text{amb}}} \right)}}{T_{\text{amb}}^{8.2}} \right] \left(P^{-1} \right)$$

where RH is relative humidity, T_{amb} is the ambient temperature in Kelvin, and P is the barometric pressure in hPa (Weiss-Penzias et al., 2006, 2009; Ambrose et al., 2011; Faïn et al., 2009; Sheu et al., 2010). Since barometric pressure data were not available for each site, a constant P was assumed for each site, based on the elevation of each site, which adds < 1 % error to the WV calculation.

Interactive Discussion

was enhanced when the conditions at LABS were drier and more conducive to long-range transport. The FT data showed higher mean RM at every site and season with notable increases of 40 %, 20 %, and 15 % for MBO summer, SPL summer, and DRI summer compared to unfiltered RM mean concentrations. This suggests that air from the FT at these sites was generally enhanced in RM and depleted in GEM, reflecting the photochemical loss of GEM and longer lifetime of RM in the FT.

Measured O₃ concentrations were 15–20 % higher during the spring compared to the summer at the North American mountain top sites (MBO, SPL), which is different from the RM seasonal maximum in summer (Table S1 in the Supplement). The desert sites located in Nevada showed WV mixing ratios equivalent to, or below those at the mountaintop sites during the summer.

3.2 Standard model-measurement comparison

The standard model showed the highest mean GEM concentration among all sites at LABS (2.10 ng m⁻³) during the spring (Fig. 1), which was in close agreement with the observations (2.20 ng m⁻³) (Table S1 in the Supplement). At all sites, the direction of the seasonal trend in GEM in the standard model agreed with the observations (spring > summer), with the difference at MBO during the spring GEM (+11 %) seen in both the standard model and observations. However, the standard model tended to over-predict GEM concentrations by about 10 % across all sites (Table S1 in the Supplement), with the greatest difference in the summer at DRI (+32 %).

Modeled RM concentrations also varied by about a factor of 7 between sites (similar variance seen in the observations), with the highest concentrations predicted for MBO and SPL in the spring and summer, and the lowest predicted for LABS in the summer (Fig. 1, Table S1 in the Supplement). However, in terms of absolute difference in RM concentrations, the model over-predicted the observations by a factor of 2.5 overall.

The linear relationships between RM and other measured species (GEM, O₃, and WV) were determined both for the observations and the standard model. The slopes between observed RM vs. GEM daily concentrations were negative at all sites during

**Use of a global model

the summer, and the standard model reproduced this RM/GEM trend at all sites (except for LABS) (Figs. 2, 3, Table S2 in the Supplement). Positive slopes were observed between observed RM and O_3 at all sites (significant at MBO, NV02, and SPL) during the summer, and this trend was duplicated by the standard model (significant at all sites). Negative slopes between RM and WV were also observed (significant at all sites except SPL) and modeled (significant at all sites) for data from the summer. Negative correlations of RM with GEM and WV and positive correlations of RM with O_3 both in the observations and the standard are consistent with RM being formed in the free troposphere (where WV was low and O_3 was high) from the photo-oxidation of GEM (resulting in low GEM).

In contrast to the summer time period, however, there was a greater lack of agreement between the model and observations for the spring data in Fig. 2 and Table S2 in the Supplement. The slopes of interspecies correlations of observed RM with GEM were about a factor of 2 less negative during the spring compared to the summer at MBO and SPL (Fig. 2). At LABS, the spring RM/GEM ratio was a factor of 4 less negative compared to the summertime ratio, and at DRI the RM/GEM ratio was positive (Fig. 2). Modeled RM/GEM ratios did not show the same seasonal trend, but instead were similar across spring and summer (~ -275 for MBO, ~ -150 for DRI and $\sim -350 \text{ pg ng}^{-1}$ for SPL). For RM : O_3 the observed ratios were positive and the observed RM : WV ratios were negative at all sites during the summer, but during the spring, these ratios did not show a consistent pattern (e.g. the observed positive correlation between RM and WV during the spring at MBO) (Fig. 2). One or more of the following conditions could account for the seasonal change in the model-observation comparison: (1) a seasonal change in transport of RM from regions other than the free troposphere that was not simulated in the model, (2) unknown oxidation mechanisms that are not included in the model (Timonen et al., 2013), and (3) a seasonal change in chemical forms of RM that were more poorly detected by the analytical system.

3.3 Case study of free tropospheric transport

This study also compared observed and modeled data on 12 h time resolution during a period of subsiding air across western North America (see weather maps and back trajectories shown in Supplement) when observed RM concentrations were elevated. This event occurred during the week of 20–25 June 2007, when 12 h maximum concentrations of the RM reached 26, 250, and 100 pg m^{-3} at MBO, DRI, and NV02, respectively (Fig. 4a, f, i). These maximum values were observed at the 3 sites sequentially in time along a west–east transect from central Oregon to northern Nevada. Maximum RM concentrations occurred at MBO during the night when downslope flow was observed, and maximum RM concentrations at DR and NV02 occurred during the day when convective mixing was at its maximum.

Observed 12 h mean GEM concentrations associated with the RM maxima were 1.0, 1.2, and 1.0 ng m^{-3} at MBO, DRI, and NV02, respectively (Fig. 4b, e, h), all significantly lower than the seasonal means of GEM at each site. The diurnal pattern in GEM can be seen in Fig. 4e and 4h for DRI and NV02, with higher concentrations during the night (12:00 UTC) and lower concentrations during the day (0:00 UTC) due to accumulation in the boundary layer and local geologic emission of GEM.

Observed O_3 concentrations were elevated (> 50 ppb) at DRI and NV02 (Fig. 4d, g) during the RM peak of the event, but at MBO the O_3 concentration was far below seasonal mean (23 ppb) (Fig. 4a), as previously noted by Timonen et al. (2013). However, the O_3 concentrations at MBO rebounded to nearly 50 ppb just after the RM peak, coinciding with the minimum in WV on 22 June 2007 and perhaps lack of mixing with marine boundary layer air.

Observed water vapor concentrations at DRI and NV02 (Fig. 4d, g) were equivalent to, or lower than WV observed at MBO (Fig. 4a), corresponding to minimum relative humidity values of 17%, 6%, and 3%, at MBO, DRI, and NV02 respectively. This indicates the very dry conditions in the desert and may have contributed to the longer

Interactive Discussion

lifetime of RM in the atmosphere and also perhaps the better collection efficiency of the analytical system.

The RM/GEM mean ratio calculated using the data including the maximum and minimum concentrations during the events followed both a longitudinal and elevation trend.

At the western-most and highest elevation site, MBO, the RM/GEM event ratio was $-1020 \pm 209 \text{ pg ng}^{-1}$, compared with $-568 \pm 60 \text{ pg ng}^{-1}$ at DRI and $-173 \pm 33 \text{ pg ng}^{-1}$ at NV02, which was the eastern-most and lowest elevation site. The nearness of the RM/GEM ratio to -1000 at MBO suggests approximate “mass conservation” between RM and GEM. Slopes less negative than -1000 can indicate some combination of loss of RM due to deposition, air mass mixing with varying total Hg concentrations, and varying air chemistries producing different forms of RM that have different collection efficiencies by the KCl-denuder (Huang et al., 2013).

Model output from two simulations is also shown for this time: the standard Hg-model with Br-oxidation and the OH-O₃ model with the oxidation scheme involving OH and O₃ (Fig. 4b, c, e, f, h, i). At MBO the model simulation with the OH-O₃ chemistry provided a closer match in timing of peak RM concentrations (within 12 h) compared to the Br simulation (RM peak was 2 days later) (Fig. 4c). The simulated RM/GEM slopes for the MBO event were -850 pg ng^{-1} and -750 pg ng^{-1} for the Br and OH-O₃ simulations, respectively. Both model runs matched the timing of the RM peak at DRI within 12 h (Fig. 4f) and NV02 within 24 h (Fig. 4i). The model predicted O₃ concentrations that were within about 5 % of the observations at DRI and NV02 (Fig. 4d, g), but at MBO the model over-predicted O₃ and under-predicted WV (Fig. 4a).

3.4 Testing model oxidation

The RM and GEM observations were compared with Hg model simulations using two different oxidation schemes: Br and OH-O₃, the reactions of which are listed in Holmes et al. (2010) and Selin et al. (2008), respectively. Bromine reaction kinetics are more widely accepted than the OH-O₃ kinetic pathway, but there are still large uncertainties and present instruments cannot directly confirm RM chemistry, and therefore, the

Interactive Discussion

oxidation mechanism in the atmosphere. Thus, we ran GEOS-Chem with the OH-O₃ kinetics to see where the Br mechanism might be deficient. Daily mean RM and GEM concentrations from the observations at MBO and DRI and the two model runs are shown in Fig. 5. Note that the standard and OH-O₃ models provide similar RM concentrations but different GEM concentrations. RM concentrations are controlled by deposition and GEM oxidation, and because of the different patterns of oxidants between the OH/O₃ chemistry and Br chemistry, there are different patterns of wet deposition. Reactive Hg concentrations are similar in the two models perhaps due to a compensating effect from wet deposition, whereas GEM is not wet deposited, so its concentrations are reflecting chemistry only and are relatively different between model types.

The correlations across the time series in Fig. 5 between observations and each model run for RM and GEM for the two sites, are shown in Fig. 6. For GEM, the OH-O₃ model more closely matched the observations (steeper slope) compared to the Br model, especially for the data from DRI (Fig. 6). For RM the OH-O₃ model also produced steeper slopes and larger R^2 values compared to the Br model, most notably at DRI. Simulated RM concentrations from the Br model were notably smaller than the observed ones during the summer at DRI. This is significant because RM is probably already a lower bound on real ambient concentrations due to inefficiencies associated with the collection method.

Figure 7 shows monthly mean RM/GEM ratios in the observations plotted against monthly mean RM/GEM ratios in the model using the Br-oxidation scheme (left panel) and the OH-O₃ oxidation scheme (right panel). Excluding LABS, both the observations and the model agree that the higher RM/GEM ratios occurred in the summer months, and lower RM/GEM ratios occurred in the spring and fall. This is consistent with greater photochemical conversion of GEM and greater loss via dry deposition during the spring (Sigler et al., 2009). Modeled RM/GEM using either oxidation scheme was on average 2.8 ± 2.6 higher than the mean observed RM/GEM, a factor roughly in line with the estimate of collection inefficiency of the KCl-denuder (Gustin et al., 2013). Interestingly, however, the RM/GEM ratios using the Br-oxidation scheme fall into two patterns: data

Interactive Discussion

collection efficiency of the method. The variability of seasonal mean observed RM concentrations across sites was about a factor of 7 with the highest concentrations seen at DRI and at MBO in the summer and the lowest at LABS in the summer. The standard model also simulated mean RM concentrations that varied by about a factor of 7 across sites, but these concentrations were offset positively from the observations by a mean factor of 2.5 across all sites. However, the model offset was not equivalent at all sites, with mean observed RM concentrations across 3 consecutive summers at DRI being slightly higher than RM concentrations from the standard model (76 vs. 72 pg m^{-3}). This is in contrast to the mean summer RM concentrations at MBO from the observation and the model being 64 and 135 pg m^{-3} , respectively. When the model was run with the OH-O₃ oxidation scheme instead of the Br oxidation scheme, it was found that mean concentrations of RM were higher and GEM were lower, especially at the desert sites DRI and NV02, producing better correlations between measured/modeled RM and GEM compared to the model with the Br-oxidation scheme. This indicates that OH as an oxidant via the HgBr+OH pathway could be more important in the summer at desert sites, compared to the mountaintop sites at MBO and SPL, and suggests that there is not one single global oxidant for GEM and hence multiple forms of RM in the atmosphere.

Table 1. Information on the five sites that are compared in this study* (listed from west to east).

Site	Site Abbrev.	Latitude	Longitude	Physical Setting	Elevation (m)	Periods of Measurement/Model Comparison
Mt. Front Lulin, Taiwan	LABS	23.51	120.92	Ridgetop summit, scrub forest	2862	3–31 Mar, 30 Jun–23 Jul, 31 Aug–10 Sep, 30 Nov–31 Dec 2008
Mt. Bachelor, Oregon, USA	MBO	43.98	–121.69	Summit of dormant volcano, rock, ice	2763	25 Apr–30 Jun 2006 17 Apr–17 Jul 2007 13 Mar–7 Jun 2008 1–20 May 2009
Reno, Nevada, USA	DRI	39.57	–119.8	Foothills, 5 km N of Reno, desert scrub	1497	1 Jan 2005–21 Aug 2007
Paradise Valley, Nevada, USA	NV02	41.5	–117.5	Valley within basin and range, sagebrush, cultivated alfalfa	1388	13 Jun–21 Aug 2007
Storm Peak, Colorado, USA	SPL	40.46	–106.74	Ridgetop summit, alpine	3200	29 Apr–1 Jul 2008

* Details of all these sites have been discussed elsewhere (Weiss-Penzias et al., 2006 (MBO), Fain et al. (2009) (SPL); Peterson et al. (2009) (DRI); Lyman and Gustin (2008) (NV02); Sheu et al. (2010) (LABS))

Use of a global model to understand speciated atmospheric mercury observations

P. Weiss-Penzias et al.

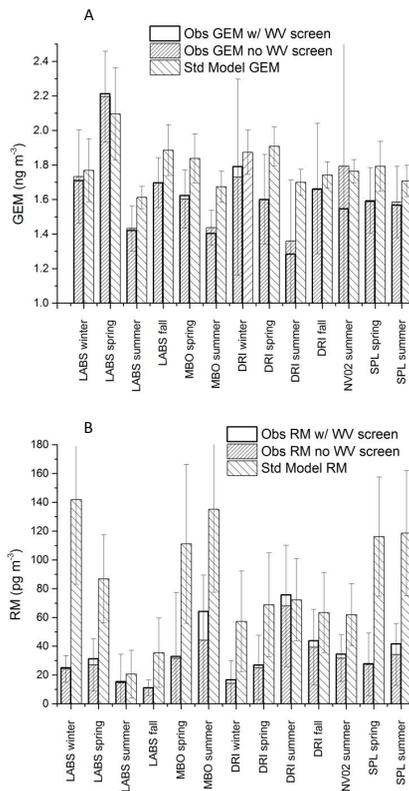

Figure 1. Means and standard deviations of observed and standard-modeled **(A)** GEM and **(B)** RM for each site by season. The WW screened data are plotted in the same column as the unscreened data.

Use of a global model to understand speciated atmospheric mercury observations

P. Weiss-Penzias et al.

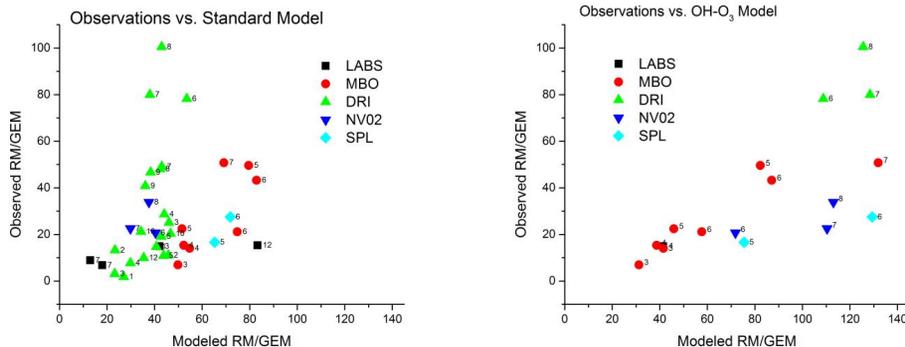

Figure 7. Plots of monthly mean RM/GEM from the observations vs. monthly mean RM/GEM in the standard model (left panel) and vs. monthly mean RM/GEM in the OH–O₃ model (right panel). The units are pg ng^{-1} . The month is indicated by the labels on each data point. The single data point from LABS is obscured by two data MBO points in the right panel. Fewer data were modeled using the OH–O₃ oxidation scheme so some months are missing.
