12 13 **Abstract**

14 Particle formation rates are usually measured at sizes larger than the critical size where nucleation
15 occurs. Due to loss of particles during their growth to the detection threshold, the measured
16 formation rate is often substantially smaller than the nucleation rate. For this reason a correction
17 needs to be applied in order to determine the nucleation rate from the measured formation rate.
18 Analytical formulae for the correction factor are provided in the literature. However, these methods
19 were derived for atmospheric nucleation measurements and therefore need to be adjusted in order
20 to be applied to chamber nucleation studies. Here we propose an alternative, numerical method that
21 allows precise nucleation rates to be determined in arbitrary experimental environments. The
22 method requires knowledge of the particle size distribution above detection threshold, the particle
23 growth rate, and the particle loss rates as a function of particle size. The effect of self-coagulation,
24 i.e. cluster-cluster collisions, is taken into account in the method.

25 1. Introduction

26

27 Aerosol nucleation, or new particle formation (NPF), is an important phenomenon taking place
28 throughout the Earth's atmosphere (Kulmala et al., 2004). The key parameter of interest is the
29 nucleation rate, which is defined as the formation rate ($\text{cm}^{-3}\text{s}^{-1}$) of new particles at the critical size.
30 The critical size is the smallest size at which the growth rate of a particle is on average faster than its
31 evaporation rate. This size depends mainly on the concentrations and other properties of the
32 nucleating vapors, as well as on temperature. However, it is generally agreed that the critical size is
33 somewhere below 2 nm mobility diameter under atmospheric conditions (Kulmala et al., 2013). In
34 fact it can be as small as two molecules in the case of barrierless, kinetically-limited particle
35 formation, where the dimer is already stable against evaporation (McMurry, 1980; Kürten et al.,
36 2014).

37 Until recently the smallest mobility diameter that could be measured by a condensation particle
38 counter (CPC) was 2.5 to 3 nm – which is substantially larger than the critical size. However, the
39 detection limit of newly-developed CPCs is as small as 1.2 nm in particle mobility diameter (Sgro and
40 Fernández de la Mora, 2004; Iida et al., 2009; Vanhanen et al., 2011; Kuang et al., 2012a; Wimmer et
41 al., 2013). Nevertheless, despite this progress the most widely-used CPCs have detection thresholds
42 at 2.5 nm or above. Moreover, care is needed when interpreting data from the newly-developed
43 CPCs since they can be sensitive to the chemical composition of the particles (Kangasluoma et al.,
44 2014). Furthermore, CPC cut-off curves do not have the shape of a step function. Instead, detection
45 of particles below the cut-off size (usually defined as the size d_{50} , where 50% of the particles are
46 detected) is occurring to some extent and, if this includes clusters below the critical size, the accuracy
47 of the derived nucleation rates can be strongly affected. For this reason, under certain conditions, it
48 can still be more reliable to use a conventional CPC with a nominal cut-off around 3 nm for
49 determining NPF rates. On the other hand, in order to minimize the corrections, it is advantageous to
50 measure the formation rates as close as possible to the critical size.

51 Kerminen and Kulmala (2002) have derived an analytical formula for correcting experimental
52 particle formation rates to determine nucleation rates at a given critical size (abbreviated as the KK
53 method in the following). This method was developed for atmospheric nucleation measurements
54 and a similar formula was also used by the McMurry group (Weber et al., 1997; McMurry et al.,
55 2005). Several publications followed Kerminen and Kulmala (2002) to include additional effects, like a
56 better description of the coagulation sink from particle size distribution measurements (Lehtinen et
57 al., 2007), self-coagulation (Anttila et al., 2010), and a size-dependent growth rate (Korhonen et al.,
58 2014). In addition to atmospheric measurements, nucleation studies in aerosol chambers or flow
59 reactors have tremendously helped the understanding of aerosol nucleation. Such experiments

60 require an accurate method to derive the NPF rates. In this study the applicability of the previous
 61 methods to chamber experiments such as CLOUD (Cosmics Leaving OUtdoor Droplets) at CERN will
 62 be discussed (Kirkby et al., 2011; Almeida et al., 2013; Riccobono et al., 2014). Furthermore, we
 63 present here a new method that yields accurate results for any environment – be they chamber or
 64 atmospheric data – provided the particle size distribution above a certain threshold size is known, as
 65 well as the particle growth rate, and where all loss processes are quantified as a function of size. The
 66 new method is verified with the results from a numeric aerosol model.

67

68

69 2. Methods

70

71 2.1 Review of methods previously used for correcting the measured particle formation rate

72

73 Lack of suitable instrumentation for the measurement of the particle number density at diameters
 74 below ~3 nm required the application of a correction to derive the NPF rates close to the critical size
 75 (Weber et al., 1997; Kerminen and Kulmala, 2002). The corrections were derived for atmospheric
 76 particle measurements where the sink of the particles is usually dominated by the coagulation with
 77 larger pre-existing particles. In order to derive their analytical formulae Kerminen and Kulmala (2002)
 78 as well as Lehtinen et al. (2007) made the following assumptions:

- 79 1) the only important sink for new particles is their coagulation with larger pre-existing
 80 particles,
- 81 2) the new particles grow at a constant rate, and
- 82 3) the population of pre-existing particles remains unchanged during the new particle growth.

83 Finding an analytical expression for the relationship between the nucleation rate at a smaller size
 84 (d_{p1}) and a larger size (d_{p2}) requires taking into account the size-dependency of the coagulation
 85 coefficient. However, the coagulation coefficient does not follow an expression, which can be
 86 analytically integrated (Seinfeld and Pandis, 2006). Therefore, KK made the assumption that the
 87 coagulation coefficient decreases with particle size d_p to the second power, i.e.

$$88 K(d_p, d_j) \cdot d_p^2 = K(d_{p1}, d_j) \cdot d_{p1}^2, \quad (1)$$

89 where K is the coagulation coefficient and d_j is the diameter of pre-existing particles. This assumption
 90 leads to the following analytical expression, which connects the particle formation rates J at different
 91 sizes:

$$92 J(d_{p1}) = J(d_{p2}) \cdot \exp\left(\frac{CS(d_{p1})}{GR} \cdot d_{p1}^2 \cdot \left(\frac{1}{d_{p1}} - \frac{1}{d_{p2}}\right)\right), \quad (2)$$

93 where

$$CS(d_{p1}) = \sum_j K(d_{p1}, d_j) \cdot N_j \quad (3)$$

is the coagulation sink for the nucleated particles due to larger pre-existing particles N_j and GR is the particle growth rate (typically expressed in nm/h). However, depending on the ambient particle size spectrum, the power dependency from equation (1) can be weaker, e.g. Fig. 1 shows the calculated coagulation coefficient between nanometer-sized particles and particles of 100 nm in diameter (solid black line, upper panel). The power dependency follows rather a value of -1.5 than -2 (see equation (1)) and for smaller particles the magnitude of the slope becomes even smaller (colored lines in Fig. 1, upper panel). The indicated slopes are reported for the size range between $d_{p1} = 1.7$ nm and $d_{p2} = 3.2$ nm (mobility diameters) because these are used in the CLOUD experiment (Kirkby et al., 2011; Almeida et al., 2013; Riccobono et al., 2014) and also in the later sections. Note that the mobility diameter can be obtained by adding a constant value of 0.3 nm to the geometric diameter (Ku and Fernandez de la Mora, 2009).

Realizing that the power dependency from equation (1) depends on the conditions during a nucleation event, a follow-up publication by Lehtinen et al. (2007) deals with introducing the real power dependency derived from atmospheric size distribution measurements. This led to the following formulation for the size correction:

$$J(d_{p1}) = J(d_{p2}) \cdot \exp\left(\gamma \cdot d_{p1} \cdot \frac{CS(d_{p1})}{GR}\right), \quad (4)$$

with

$$\gamma = \frac{1}{s+1} \cdot \left[\left(\frac{d_{p2}}{d_{p1}} \right)^{s+1} - 1 \right], \quad (5)$$

where the parameter s is the slope of the coagulation coefficient with particle size.

Furthermore, recent findings from atmospheric growth rate measurements indicate that the GR can be a function of particle size (Kuang et al., 2012b; Kulmala et al., 2013). Therefore, Korhonen et al. (2014) have extended the analytical solution from equation (4) and (5) and included the effect of a size-dependent GR , which can either vary linearly with particle size or according to a power-law dependency. Another effect that can become important when the population of particles between d_{p1} and d_{p2} becomes large is self-coagulation. This effect has been considered recently by Anttila et al. (2010). While we will also deal with the effects of a size-dependent GR (section 3.1) and self-coagulation (section 3.3), we will first focus on the question in how far atmospheric nucleation and nucleation within a chamber experiment are comparable in terms of their loss processes in the next section.

124

125 **2.2 Relevant losses in chamber experiments**

126

127 The dominant particle loss mechanism for seedless chamber nucleation experiments is generally due
 128 to collisions with the walls of the vessel and possibly also due to dilution of the chamber gas. Large (3
 129 m) chambers such as CLOUD have wall loss rates (around 0.001 s^{-1} at 1 nm) similar to the loss rates
 130 onto pre-existing aerosols in a pristine atmospheric environment. We will address here to what
 131 extent these two environments are equivalent.

132 The wall loss rate in chamber experiments can be expressed by (Crump and Seinfeld, 1981;
 133 Metzger et al., 2010):

$$134 \quad k_w(d_p) = C \cdot \sqrt{D(d_p)}, \quad (6)$$

135 where $D(d_p)$ is the diffusivity of a particle with size d_p and C is an empirical factor that depends on the
 136 chamber dimensions and turbulent mixing. The diffusivity of a particle can be calculated from the
 137 Stokes-Einstein relationship according to (Hinds, 1999)

$$138 \quad D(d_p) = \frac{k_B \cdot T \cdot C_C}{3 \cdot \pi \cdot \eta \cdot d_p}, \quad (7)$$

139 which depends on the Boltzmann constant k_B , the temperature T , gas viscosity η and the
 140 Cunningham correction factor C_C . The latter is a function of the gas mean free path and the particle
 141 diameter. At small particle sizes the Cunningham correction factor is approximately proportional to
 142 d_p^{-1} , and so the wall loss rate can be approximated by

$$143 \quad k_w(d_p) = \frac{C'}{d_p}, \quad (8)$$

144 where C' is an empirically-determined constant. Fig. 1 shows the measured wall loss rate for the
 145 CLOUD chamber as a function of d_p (dashed curve, lower panel), where the value of C' is
 146 approximately 0.001 nm s^{-1} . The wall loss rate decreases as $\sim d_p^{-1}$, which is much weaker than the
 147 originally assumed power dependency of $\sim d_p^{-2}$ for loss to atmospheric particles (equation (1)).

148 In addition to wall loss another mechanism which affects the particle number density in a
 149 chamber experiment is dilution of the chamber gas. Instruments can take considerable amounts of
 150 the chamber gas and this gas needs to be replenished in order to maintain a constant pressure. The
 151 CLOUD chamber has a volume of 26.1 m^3 , while the instruments typically use 150 l/min. This leads to
 152 a dilution rate of $k_{dil} = 9.6 \times 10^{-5} \text{ s}^{-1}$, which is independent of particle size (see dash-dotted black line in
 153 the lower panel of Fig. 1).

154 Neglecting coagulation with larger pre-existing aerosols, which is well-justified in a seedless
 155 chamber experiment, the two main loss mechanisms wall loss and dilution can be used to derive an
 156 analytical solution for the NPF rate at a small size. This is achieved by replacing the coagulation loss
 157 term in equation (4) from Lehtinen et al. (2007) with $k_w(d_p)$ and k_{dil} :

$$158 \quad \frac{dJ(d_p)}{dd_p} = -\frac{\text{loss rate}}{GR} \cdot J(d_p) = -\frac{1}{GR} \cdot \left(\frac{C'}{d_p} + k_{dil} \right) \cdot J(d_p). \quad (9)$$

159 In this case integration yields:

160
$$J(d_{p1}) = J(d_{p2}) \cdot \exp\left(\frac{1}{GR} \cdot \left(C' \cdot \ln\left(\frac{d_{p2}}{d_{p1}}\right) + k_{dil} \cdot (d_{p2} - d_{p1})\right)\right). \quad (10)$$

161 The identical result would follow from equations (4) and (5) by taking the limit for $s \rightarrow -1$ to take into
 162 account wall loss, and by taking $s = 0$ for loss due to dilution, respectively.

163 In conclusion, the KK method and also the follow-up versions should only be applied to chamber
 164 nucleation experiments after applying the necessary adjustments. Equation (10) provides a useful
 165 analytical formula, when coagulation can be neglected. The data from Fig. 1 gives a guideline about
 166 the relative importance of the different loss mechanisms for the CLOUD chamber. The wall loss rate
 167 for the relevant sizes between 1.4 and 2.9 nm is on the order of 10^{-3} s^{-1} . Depending on particle size
 168 the coagulation coefficient is in the range 10^{-9} to $10^{-8} \text{ cm}^3 \text{ s}^{-1}$, which indicates that particle number
 169 densities between 10^5 and 10^6 cm^{-3} are required in order to reach similar effects for coagulation and
 170 wall loss. At this point it is also worth mentioning that all the expressions derived so far are based on
 171 the assumption that nucleation and particle growth is driven by the condensation of monomers
 172 (Lehtinen et al., 2007) and that cluster-cluster collisions are unimportant. The effect of cluster-cluster
 173 collisions will be discussed in section 2.4.

174 The important conclusion that follows from the comparison of equations (2), (4) and (10) is that
 175 experiments and atmospheric environments with similar sink rates cannot be directly compared
 176 before corrections are applied, because not only the magnitude of the sink is important but also the
 177 dependency of the loss rate as function of particle size. Despite the practicability of equation (10) a
 178 new method is required, which additionally takes into account coagulation as well as self-
 179 coagulation.

180

181 **2.3 New method to derive the nucleation rate from the experimental formation rate**

182

183 We will assume that the size distribution above a certain threshold size (d_{p2}) is known, and
 184 furthermore that the size between two adjacent bins differs by one molecule only. For the following
 185 discussion it is useful to add m to all bin indices, although the original size distribution contains n size
 186 bins ranging from 1 to n . In this case the size d_{p2} corresponds to the bin with the index $m+1$ (Fig. 2).

187 The formation rate of particles at and above d_{p2} can then be calculated from:

188
$$J_{\geq m+1} = \frac{dN_{\geq m+1}}{dt} + \sum_{i=m+1}^{n+m} (k_{w,i} \cdot N_i) + k_{dil} \cdot N_{\geq m+1} + \sum_{i=m+1}^{n+m} \left(\sum_{j=i}^{n+m} \delta_{i,j} \cdot K_{i,j} \cdot N_j \cdot N_i \right). \quad (11)$$

189 where double-counting of collisions between particles in the same size bin is avoided by the factor
 190 (Seinfeld and Pandis, 2006):

191
$$\delta_{i,j} = \begin{cases} 0.5 & \text{if } i = j \\ 1 & \text{if } i \neq j \end{cases}. \quad (12)$$

192 The first term on the RHS takes into account non steady-state conditions, by the time derivative of
 193 the total particle number density (sum of the particle concentrations from bin $m+1$ to $n+m$). The
 194 remaining three terms on the RHS describe the loss processes of neutral particles in a chamber
 195 experiment: wall loss, loss due to dilution of the chamber gas (independent of particle size) and
 196 coagulation loss between particles of all size bins. Note that the index i runs from $m+1$ to $n+m$ and
 197 the index j from i to $n+m$. In this way, the collisions between the bins i and j are not counted twice.
 198 Since we are looking at formation rates larger than a certain size, collision products will remain in the
 199 size range under consideration and therefore loss due to coagulation between bins i and j has to be
 200 taken into account only once. The formation rate at d_{p2} can also be calculated from

$$201 \quad J_{\geq m+1} = J_{\geq m+2} + \frac{dN_{m+1}}{dt} + (k_{w,m+1} + k_{dil} + \sum_{j=m+1}^{n+m} \delta_{m+1,j} \cdot K_{m+1,j} \cdot N_j) \cdot N_{m+1}. \quad (13)$$

202 This equation allows calculating the formation rate at a smaller size from the NPF rate at the next
 203 larger size. Here the time derivative of N_{m+1} refers to the concentration of particles in the size bin
 204 $m+1$, whereas in equation (11) it refers to all particles at and above index $m+1$.

205 In order to calculate the formation rate d_{p1} let us now introduce $x+1$ new size bins, which extends
 206 the size distribution towards the smaller sizes (Fig. 2). Also Kerminen et al. (2004) introduced extra
 207 size bins in order to increase the accuracy of their analytical formula, which connects the nucleation
 208 rate and a formation rate at a larger size similar to equation (2). Extending the size distribution
 209 towards smaller sizes requires calculation of the number concentration N_m in the first new bin.
 210 However, equation (13) does not allow this directly, therefore additional information is required. This
 211 information can be taken from the growth rate of the particles. According to Lehtinen et al. (2007)
 212 the formation rate and the growth rate (GR) are connected by the following equation:

$$213 \quad J_{m+1} = GR_m \cdot \frac{N_m}{d_{p,m+1} - d_{p,m}}. \quad (14)$$

214 This relationship was used to describe the flux of particles due to collisions with monomers. In such a
 215 case particles can grow only from one size bin to the next larger bin without “jumping” into an even
 216 larger bin due to cluster-cluster collisions. However, for the moment we will assume that equation
 217 (14) is valid also for the case where cluster-cluster collisions are relevant if appropriate definitions for
 218 the growth rate and NPF rate are being used and we will justify this assumption later in section 2.4.
 219 Using the formation rate and growth rate relationship the particle number concentration can be
 220 calculated for the first new size bin (N_m) by the following relationship:

$$221 \quad N_m = \frac{d_{p,m+1} - d_{p,m}}{GR_m} \cdot \left(J_{\geq m+2} + \frac{dN_{m+1}}{dt} + (k_{w,m+1} + k_{dil} + \sum_{j=m+1}^{n+m} \delta_{m+1,j} \cdot K_{m+1,j} \cdot N_j) \cdot N_{m+1} \right). \quad (15)$$

222 In the limiting case where particle formation and growth is dominated by the addition of monomers
 223 this method is accurate at steady-state provided that knowledge about the growth rate is available
 224 initially.

225 When applying the method the particle growth rate GR_m is required for calculating the first
226 unknown concentration. Strictly, the growth rate is not known at the index m (because the known
227 size distribution starts at index $m+1$ by definition, see Fig. 2) but can only be calculated at the next
228 larger index using equation (14) by adjusting all indices to the next larger bin. According to equation
229 (15), the GR would need to be updated in every reconstruction step. Nevertheless, we have found
230 from numerical simulation (see later sections) that the method is numerically more stable if a
231 constant GR at index $m+1$ is used for all iterative steps. However, if accurate knowledge about a size-
232 dependent GR is available it can easily be implemented in the method.

233 In equation (15) all quantities are known except the value of N_m (if GR_m is approximated by GR_{m+1}).
234 Once N_m is found the formation rate J_m can be calculated and the process can be repeated with the
235 next smaller size bin (index $m-1$). In this way the complete particle spectrum above d_{p1} (containing
236 now $n+x+1$ size bins) can be recreated until the final formation rate J_{dp1} (at index x) is calculated. The
237 underlying assumption is that growth above this size is purely kinetic (no evaporation), which is likely
238 a good assumption for most chemical systems and the atmospheric data (e.g. Chen et al., 2012). A
239 similar approximation has been made by Nieminen et al. (2010) when deriving an analytical formula
240 for calculating growth rates where the vapor pressure of the condensing species has been set to
241 zero. However, in future studies one could examine the effect of evaporation at sizes larger than the
242 critical diameter on the method and attempt to implement it in a similar fashion as Olenius et al.
243 (2014) in their study about the effect of monomer collisions on the growth rates.

244 In order to test the relative importance of self-coagulation on the magnitude of the formation
245 rate correction it is also possible to take into account only particles at and above $m+1$ in all
246 reconstruction steps in the last term on the RHS of equation (15). We will discuss in section 3.3 under
247 which circumstances this can be done without sacrificing too much accuracy.

248

249 **2.4 Relationship between particle formation rate and growth rate including cluster-cluster** 250 **collisions**

251

252 In a recent publication Olenius et al. (2014) have investigated the relationship between J and GR as
253 well as different methods for deriving the GR due to monomer collisions. The method introduced
254 here should also be applied to conditions where new particle formation is proceeding at the kinetic
255 limit, i.e. where all cluster evaporation rates are zero. Under such conditions the cluster
256 concentrations are quite high in comparison to the monomer concentration, e.g. the dimer
257 concentration can be ~20% of the monomer concentration (McMurry, 1980; Chen et al., 2012;
258 Kürten et al., 2014). In this case, the particle formation as well as the particle growth cannot be
259 described by monomer collisions only and cluster-cluster collisions have to be taken into account.

260 Therefore, equation (14) might not be valid anymore. In the following we will investigate if the
 261 relationship from equation (14) can still be used. Taking into account cluster collisions the particle
 262 growth rate for particles in the size bin m can be defined as

$$263 \quad GR_m = \sum_{i=1}^{m-1} \left((d_{p,m}^3 + d_{p,i}^3)^{1/3} - d_{p,m} \right) \cdot K_{i,m} \cdot N_i. \quad (16)$$

264 Equation (16) indicates that the clusters in the size bin m can grow by collisions with all smaller
 265 clusters. We will assume that a particle in size bin m contains m monomers with a mass u and density
 266 ρ :

$$267 \quad d_{p,m} = \left(\frac{6 \cdot m \cdot u}{\pi \cdot \rho} \right)^{1/3} = d_{p,mono} \cdot m^{1/3}, \quad (17)$$

268 where $d_{p,mono}$ is the diameter of the monomer. Multiplication of the growth rate from equation (16)
 269 with $N_m / (d_{p,m+1} - d_{p,m})$ and using the Taylor expansion

$$270 \quad \left((m+i)^{1/3} - m^{1/3} \right) = m^{1/3} \cdot \left(\left(1 + \frac{i}{m} \right)^{1/3} - 1 \right) \approx \frac{i}{3 \cdot m^{2/3}} \quad (18)$$

271 leads to the following expression:

$$272 \quad GR_m \cdot \frac{N_m}{d_{p,m+1} - d_{p,m}} = \sum_{i=1}^{m-1} i \cdot K_{i,m} \cdot N_i \cdot N_m. \quad (19)$$

273 The particle formation rate $J_{\geq m+1}$ can be defined as

$$274 \quad J_{\geq m+1} = 0.5 \cdot \sum_{i+j \geq m+1} \delta_{ij} \cdot K_{i,j} \cdot N_i \cdot N_j, \quad (20)$$

275 where i and j have to be smaller than $m+1$. From this definition it follows that equation (19) cannot
 276 be cast into the form of equation (20) because the equation involving the growth rate only considers
 277 collisions where one collision partner always belongs to the size bin m . Instead, equation (20)
 278 involves collisions where none of the collision partners is fixed to one size bin in the summation.
 279 Therefore, we were not able to find an analytical solution in terms of bringing equation (19) and (20)
 280 into agreement. However, we can argue qualitatively that the two equations are approximately
 281 yielding the same results for certain conditions.

282 The accurate definition of $J_{\geq m+1}$ (equation (20)) is visualized schematically in Fig. 3a, whereas
 283 equation (19) is indicated in Fig. 3b. For the monomer there is only one possibility for contributing to
 284 $J_{\geq m+1}$ in both cases. However, the dimer can contribute to $J_{\geq m+1}$ due to collisions with particles in bin m
 285 and bin $m-1$. The approximation (equation (19)) does take into account only collisions between
 286 dimers and particles in bin m . However, the dimer collision is taken twice and the second collision
 287 can therefore compensate for the collision between dimers and particles in bin $m-1$ from equation
 288 (20). For the trimer the situation is similar, in the accurate case the trimer has three possibilities (i.e.
 289 three different collisions) to contribute to $J_{\geq m+1}$. The approximation (equation (19)) is taking into
 290 account only one collision but it is multiplied by a factor of three. This mechanism is the same for the
 291 collisions involving larger clusters. Therefore, we can conclude that

$$292 \quad GR_m \cdot \frac{N_m}{d_{p,m+1} - d_{p,m}} \approx J_{\geq m+1} \quad (21)$$

293 applies also for conditions where cluster-cluster collisions become important (note the ‘≥’ sign on the
 294 RHS). The requirement is that the cluster concentrations do not change strongly in the region around
 295 bin m and that the contribution of clusters to new particle formation and growth becomes negligible
 296 at some index smaller than m . Under what circumstances the relationship from equation (21) is valid
 297 needs to be studied in more detail in the future. However, the benefit of the method from section
 298 2.3 is that even if the relationship from equation (21) introduces inaccuracies these are very likely
 299 small because its effects should cancel out. GR_{m+1} for equation (15) is calculated from the relationship
 300 in equation (21) and the same relationship is used to calculate N_m in equation (15). Therefore, we
 301 expect the error due to this approximation to be small and the numerical simulations shown in the
 302 following sections support this assumption.

303

304 2.5 Kinetic model for testing the universal method

305

306 A numerical model has been developed recently for the CLOUD chamber to simulate the formation
 307 and growth of uncharged sulfuric acid-dimethylamine particles (Kürten et al., 2014). The model
 308 assumes that particles grow from monomers by condensation and coagulation. Due to the
 309 arguments presented by Kürten et al. (2014), it has been concluded that $H_2SO_4 \cdot ((CH_3)_2NH)$ clusters
 310 (abbreviated as SA•DMA) constitute the basic “monomer” for the formation of particles in a system
 311 of sulfuric acid (SA) and dimethylamine (DMA). Assuming unit sticking efficiency and zero
 312 evaporation rate, good agreement is found between the model and the experimentally-measured
 313 neutral clusters.

314 The kinetic model is based on McMurry (1980). The time-dependent balance equation for the
 315 monomer concentration N_1 is

$$316 \frac{dN_1}{dt} = P_1 - (k_{1,w} + k_{dil} + \sum_{j=1}^N K_{1,j} \cdot N_j) \cdot N_1 \quad (22)$$

317 and, for all larger clusters ($k \geq 2$),

$$318 \frac{dN_k}{dt} = \frac{1}{2} \cdot \sum_{i+j=k} K_{i,j} \cdot N_i \cdot N_j - (k_{w,k} + k_{dil} + \sum_{j=1}^N K_{k,j} \cdot N_j) \cdot N_k. \quad (23)$$

319 Here, P_1 is the production rate of the monomers, k_w is the wall loss rate, k_{dil} the dilution rate, and K
 320 the coagulation coefficient.

321 The original model calculated concentrations of clusters ranging from dimer up to clusters of
 322 several thousand molecules. Each size bin was represented by a single cluster with a fixed number of
 323 molecules (or SA•DMA clusters, which are each treated as one molecule). The maximum particle size
 324 that can be reached with reasonable computation time is a few nm, which is too small for the current
 325 study. Therefore we incremented the size by one molecule for the first 100 bins (linear bins), and by
 326 a constant geometrical factor for the next 100 bins (geometric bins, see e.g. Landgrebe and Pratsinis

327 (1990) or Lovejoy et al. (2004)). By this method, a size of ~ 30 nm can be reached using a geometrical
328 factor of 1.023, which is suitable for the present study. The sizes of d_{p1} and d_{p2} do, however, fall into
329 the size range of the linear bins.

330 In addition to the kinetic modeling we have also introduced evaporation rates for the dimer and
331 the trimer (evaporation rates not included in equations (22) and (23) for simplicity). These
332 simulations are used to investigate situations where nucleation and particle growth is dominated by
333 the addition of monomers because if the evaporation rates for the smallest clusters are sufficiently
334 high their concentrations become very small and will therefore not contribute significantly to NPF
335 and growth. Although not directly relevant for the sulfuric acid-dimethylamine system we have
336 calculated the dimer and trimer evaporation rates at 223.15, 248.15 and 278.15 K at 38% RH from
337 the data presented by Hanson and Lovejoy (2006). Their thermodynamic data was derived for the
338 binary system of sulfuric acid and water. However, the calculated formation rates are not meant to
339 be representative for binary nucleation but only serve to demonstrate the effect of going from purely
340 kinetic nucleation to nucleation with a relatively large barrier (278 K data). Kinetic nucleation will
341 include collisions with monomers and also show a significant effect from clusters, whereas the new
342 particle formation at 278 K will be dominated by monomer collisions. The other two temperatures
343 show the transition from purely kinetic nucleation to nucleation dominated by monomer additions.

344 Particle formation rates that have been calculated from the model serve as the reference
345 formation rates to which the reconstructed formation rates can be compared to. We have
346 implemented two separate procedures to calculate the NPF rates, where the first one is following the
347 approach based on equation (11) by taking into account all loss processes, while the second one
348 follows the production of particles from two smaller clusters (equation (20)). The two methods yield
349 exactly the same result, which is a good verification of the model in this respect.

350

351

352 **3. Discussion**

353

354 Figure 4 shows the result of the kinetic model simulation for a monomer (molecular weight of 143
355 g/mol and density of 1.47 g/cm^3) production rate of $8.8 \times 10^4 \text{ cm}^{-3} \text{ s}^{-1}$, after $1.5 \times 10^4 \text{ s}$. Integration of
356 equations (22) and (23) yields the displayed size distribution (grey sticks). Although the particles
357 continue to grow, the populations at smaller sizes (below about 10 nm) are close to steady-state.
358 Since the total particle number concentration is dominated by these smaller particles, time-
359 dependency can be neglected in the following, but will be revisited in section 3.2. The size
360 distribution (grey sticks in Fig. 4) is obtained after normalizing the concentrations by the number of
361 molecules per bin.

362 The new universal method to derive a particle formation rate at a smaller size d_{p1} has been
 363 applied to the data shown in Fig. 4. A threshold size $d_{p2} = 3.2$ nm (corresponding to 2.9 nm geometric
 364 diameter) has been chosen. Starting with the size distribution for particles equal to or larger than 2.9
 365 nm, 71 new bins were introduced to reach the size d_{p1} at 1.7 nm (1.4 nm geometric diameter). The
 366 red line shows the recreated size distribution obtained by this method. A constant growth rate of
 367 3.81 nm/hr was chosen, corresponding to the value given by a numeric model calculation for a
 368 particle in the size bin $m+1$. As can be seen, the reconstruction works well for the first few size bins
 369 and then starts to deviate somewhat from the correct values. This occurs since the GR is not exactly
 370 constant with size, and slightly increases when approaching d_{p1} (see section 3.1).

371

372 **3.1 Size-dependent growth rate**

373

374 The growth rate, which is used for the reconstruction is calculated from

$$375 \quad GR_{m+1} = J_{\geq m+2} \cdot \frac{d_{p,m+2} - d_{p,m+1}}{N_{m+1}}. \quad (24)$$

376 Our studies with the kinetic model indicate that GR is only weakly-dependent on particle size in the
 377 range between critical size and detection threshold. In the example shown in Fig. 4 there is less than
 378 20% variation. However, the model does not include the effects of evaporation or of a spectrum of
 379 condensable vapors with different volatilities. Therefore care has to be taken when applying size
 380 corrections to atmospheric particle formation rates. The GR should ideally be measured over a wide
 381 range of diameters (Kulmala et al., 2013). In this case analytical solutions for the KK method can be
 382 found for certain size-dependent GR s (Korhonen et al., 2014). These considerations underscore the
 383 importance of directly measuring the particle GR in the sub-3 nm size range, as well as at larger sizes.
 384 With this information the effect of particle evaporation can be separated from the uncertainties due
 385 to size-dependent particle GR . In the absence of such measurements, a detailed error analysis is
 386 required to bracket the range of GR uncertainty and its impact on the derived nucleation rates.

387 A comparison between the accurate solution for the NPF rates and the ones from the
 388 reconstruction method as a function of particle size is shown in Fig. 5. The accurate solution from the
 389 kinetic model is shown by the green solid line, while the results from the reconstruction method are
 390 indicated by the red triangles. Due to the slight size-dependency of the growth rate (it increases
 391 slightly with decreasing size) the reconstructed NPF rates are somewhat higher than the accurately
 392 calculated values. The maximum deviation occurs at the smallest size and reaches ~17% in this
 393 example. Given the fact that the formation rate $J(d_{p1})$ is more than a factor of 12 higher than $J(d_{p2})$
 394 this is a rather small deviation.

395

396 **3.2 Time evolution in a simulated chamber nucleation experiment**

397

398 Using a kinetic model simulation, we show in Fig. 6 an example of the time-dependent formation
399 rates J for the particle sizes d_{p1} (1.4 nm geometric diameter; solid green line) and d_{p2} (2.9 nm
400 geometric diameter; solid blue line). In addition, the rate of change of particle concentration dN/dt
401 (dashed lines) above the size thresholds d_{p1} and d_{p2} are shown. The formation rates J are directly
402 obtained from the model using equation (11) and the size distribution. Interestingly, the formation
403 rates overshoot before they reach an almost constant value. This overshoot is explained by the
404 absence of larger particles at the beginning of the experiment. Therefore the loss rate is smaller at
405 the beginning, which allows for faster formation rates. Once the larger particles start to form, the
406 loss rate increases until eventually there are only small changes in particle concentrations and
407 formation rates. This overshoot can be quite large and, in this example, reaches almost a factor of
408 three for the maximum J compared with its steady-state value.

409 Using the size distribution as a function of time for particle sizes equal to or larger than d_{p2} (not
410 shown), as well as the growth rates GR_{m+1} (not shown) and the time derivative of the total number
411 concentration of particles dN_{m+1}/dt , the size-corrected formation rate J_{dp1} can be derived by the
412 method described in section 2.3 (red solid line). The derived formation rate agrees closely with the
413 accurate solution from the kinetic model (green solid line) for conditions close to steady-state.
414 However, when evaluating J at d_{p1} from the formation rate at d_{p2} and time t one needs to consider
415 that the particles that appear at d_{p2} were passing the size d_{p1} at an earlier time t' . This time can be
416 approximated by

$$417 \quad t' = t - \frac{d_{p2} - d_{p1}}{GR_{m+1}(t)} \quad (25)$$

418 if the time-dependency of the GR is considered. Displaying the reconstructed formation rate $J(d_{p1})$
419 against the corrected time axis yields the dash-dotted red line, which shows a very similar time-
420 dependency as the accurate $J(d_{p1})$. The over-estimation (difference between the red and green lines
421 in Fig. 6) is due to the size-dependency of the growth rate (see previous section). An accurate
422 determination of $J(d_{p1})$ can only be obtained after the particles have formed at and above d_{p2} .

423

424 **3.3 Formation rates as function of the sulfuric monomer concentration**

425

426 **Kinetic limit.** In the preceding section, the universal method has only been tested for one sulfuric
427 acid monomer concentration. Variation of the monomer production rate P_1 in equation (22) will
428 result in different sulfuric acid concentrations. The resulting size distributions (N), growth rates (GR)
429 and rates of change of particle concentration (dN/dt) as a function of particle size can be used to test
430 the reconstruction method. Fig. 7 shows the results for 8×10^5 to 2×10^7 cm^{-3} sulfuric acid
431 concentration (lines denoted with 'kinetic limit'). The accurate solution for d_{p2} is shown by the blue

432 solid line, while $J(d_{p1})$ is shown by the green solid line. Using a constant GR , corresponding to its value
433 at d_{p2} , the reconstruction method yields the results shown by the red solid line. For the high
434 nucleation rates (above several hundred) the accuracy is quite good. For the lower formation rates,
435 the required corrections are quite large because the growth between 1.4 and 2.9 nm is slow and
436 therefore losses are high. The effect of the size-dependent growth rate has therefore a relatively
437 large impact on the reconstructed NPF rates. The curved shape of the formation rates displayed
438 against the sulfuric acid concentration on a log-log plot is due to the fact that losses are much more
439 relevant when particle growth is slow (see Ehrhart and Curtius, 2013).

440 In practice, GR will always be subject to measurement uncertainties. In order to test the
441 sensitivity of the method, the constant GR was multiplied by a factor of 1.5 and 0.9, respectively. The
442 faster GR leads to an under-estimation in the reconstructed $J(d_{p1})$, while the smaller GR leads to an
443 over-estimation. The variation in the GR is indicated by the light red bands in Fig. 7. It can be seen
444 that the reconstructed $J(d_{p1})$ is highly sensitive to GR , especially when the particle growth is slow. In
445 this example a GR under-estimation of only 10% can lead to a substantial over-estimation of $J(d_{p1})$
446 due to the exponential dependence on GR . Therefore, accurate growth rate measurements are
447 essential to reliably reconstruct the particle formation rate at a smaller size.

448 In order to test the effect of self-coagulation, coagulation has only been taken into account to
449 occur with particles at and above d_{p2} (dashed black lines). As long as the formation rate is close to
450 $\sim 100 \text{ cm}^{-3} \text{ s}^{-1}$ at d_{p1} , the effect of neglecting self-coagulation is quite small. For larger formation rates
451 the deviation progressively increases because self-coagulation loss becomes competitive and
452 eventually dominant compared to wall loss, dilution and coagulation with larger particles. However,
453 these numbers are relevant for the CLOUD chamber experiment and are not necessarily applicable to
454 other chambers with other wall loss and dilution characteristics. Performing the corrections twice –
455 once by including self-coagulation and a second time by neglecting it – over a range of formation
456 rates can help to find the formation rate at which self-coagulation becomes important in other
457 chambers. The advantage of neglecting coagulation is that the reconstruction is computationally
458 much less demanding. One major difference between most experiments and the example
459 calculations shown in Fig. 7 is that nucleation is generally not proceeding at the kinetic limit, even
460 though this is the case for nucleation of sulfuric acid and dimethylamine (Kürten et al., 2014). In
461 order to evaluate the method for NPF which is not proceeding at the kinetic limit we have also
462 simulated NPF with non-zero dimer and trimer evaporation rates.

463 **223 K.** The dimer evaporation rate has been set to 2.9 s^{-1} and the trimer evaporation rate to 0.024 s^{-1}
464 (corresponding to conditions in the binary system at 223.15 K and 38% RH, see Hanson and Lovejoy,
465 2006). At these relatively low evaporation rates the effect of cluster-cluster collisions is still
466 pronounced, which can be seen for the high sulfuric acid concentrations where a relatively large

467 difference between $J(d_{p2})$ and $J(d_{p1})$ can be seen. This difference is due to the strong effect of self-
468 coagulation which leads to high loss rates. Although the GR is increasing with higher sulfuric acid
469 concentration, self-coagulation increases as well because the cluster concentrations increase.
470 Therefore, the two opposing effects cancel out, which leads to a rather constant factor between
471 $J(d_{p2})$ and $J(d_{p1})$. The maximum deviation between the reconstructed and the accurate J reaches a
472 factor of 4 at the lowest sulfuric acid concentration of $2 \times 10^6 \text{ cm}^{-3}$. As the growth rate becomes higher
473 and the corrections smaller with increasing sulfuric acid concentration the effect of the size-
474 dependent GR becomes less relevant and the accuracy increases.

475 **248 K.** Evaporation rates of 181 s^{-1} and 3.1 s^{-1} for the dimer and the trimer were used, respectively
476 (Hanson and Lovejoy, 2006). Because of these relatively high evaporation rates, particle formation
477 and growth is dominated by collisions with monomers. The growth rates are quite high and self-
478 coagulation can be neglected for most conditions (monomer concentration below $\sim 1 \times 10^8 \text{ cm}^{-3}$),
479 therefore the correction factors are lower than for the previous two conditions discussed. The
480 maximum error due to the size-dependent GR is a factor of 2 at $5 \times 10^6 \text{ cm}^{-3}$ of sulfuric acid.

481 **278 K.** When evaporation rates of 10060 s^{-1} and 360 s^{-1} for the dimer and the trimer are used,
482 respectively, conditions can be simulated where monomer collisions are by far the dominant process
483 for nucleation and growth due to very low cluster concentrations. In this case quite high sulfuric acid
484 monomer concentrations are required to yield substantial NPF. At these conditions the GR s are very
485 high (up to $\sim 100 \text{ nm/hr}$) and self-coagulation is irrelevant. Therefore, the correction factor between
486 $J(d_{p2})$ and $J(d_{p1})$ approaches a value of 1. Only at the low sulfuric acid monomer concentrations a
487 significant correction is necessary.

488

489

490 **4. Conclusions**

491

492 The Kerminen and Kulmala (2002) method and its refinements presented in subsequent publications
493 (Lehtinen et al., 2007; Anttila et al., 2010; Korhonen et al., 2014) is widely used in atmospheric and
494 chamber experiments to derive nucleation rates from experimentally-measured formation rates at
495 larger particle sizes. However, it has not been designed to be applied to chamber nucleation
496 experiments where self-coagulation can be important.

497 We have therefore presented a new method that yields representative results in any general
498 environment, provided certain quantities are known. The new method requires knowledge of the
499 particle size spectrum above the detection threshold, the particle growth rate, and all loss processes
500 as a function of particle size. With this information the size spectrum and the formation rate can be
501 reconstructed in a step-wise process to a smaller size, where the nucleation rate is determined. The

502 method can give accurate results and, furthermore, takes into account self-coagulation among
503 newly-formed particles, which can be an important effect, recognized previously by Anttila et al.
504 (2010). Additionally, if the size-dependent growth rate is available from measurements, it can be
505 readily incorporated during the reconstruction of the size distribution.

506 The proposed new method allows extrapolation of the particle formation rate measured at one
507 threshold size (d_{p2}) to a second, smaller size (d_{p1}). In this way, a precise quantitative comparison can
508 be made between formation rates measured simultaneously by several counters operating in the 1
509 to 3 nm threshold range and, where differences emerge, a deeper understanding of fundamental
510 quantities such as cluster critical sizes, growth rates and evaporation rates can be obtained.

511 One general issue with all methods, which are extrapolating formation rates towards smaller
512 sizes, arises from the uncertainty in the growth rate. In most cases no measurement of the *GR* will be
513 available down to the very small size since also the particle number concentrations are not available
514 (otherwise no extrapolation of the formation rate would be necessary). A small size-dependency of
515 the *GR* that is not taken into account can therefore lead to a big uncertainty. In addition, the critical
516 size of the nucleating particles is generally not known. Ideally, one would choose d_{p1} to correspond
517 with the critical size. However, since this is not possible a reasonable solution to this issue is to
518 choose a size for d_{p1} , which is safely at or above the critical size to avoid extending the size
519 distribution into the subcritical size regime. For this reason the CLOUD experiment has reported
520 particle formation rates at a size of 1.7 nm in mobility diameter rather than nucleation rates (Kirkby
521 et al., 2011).

522 Further studies using the new method will focus on the effect of using larger size bins and its
523 application to experimental data measured with condensation particle counters (CPCs) and scanning
524 mobility particle sizer (SMPS) systems.

689
690

691 **Fig. 1.** Coagulation coefficient, K , as function of particle size, d_p (upper panel). Coagulation
 692 coefficients are calculated between two particles where one particle has a constant size (indicated in
 693 the legend of the figure) and the second particle diameter varies between 1 and 10 nm. The wall loss
 694 rate for the CLOUD chamber as function of particle size is shown by the dashed curve (lower panel),
 695 whereas the dilution rate is indicated by the dash-dotted line. Slopes of the curves are indicated for
 696 the range between d_{p1} (1.4 nm, i.e. 1.7 nm in mobility diameter) and d_{p2} (2.9 nm, i.e. 3.2 nm in
 697 mobility diameter).

698

699

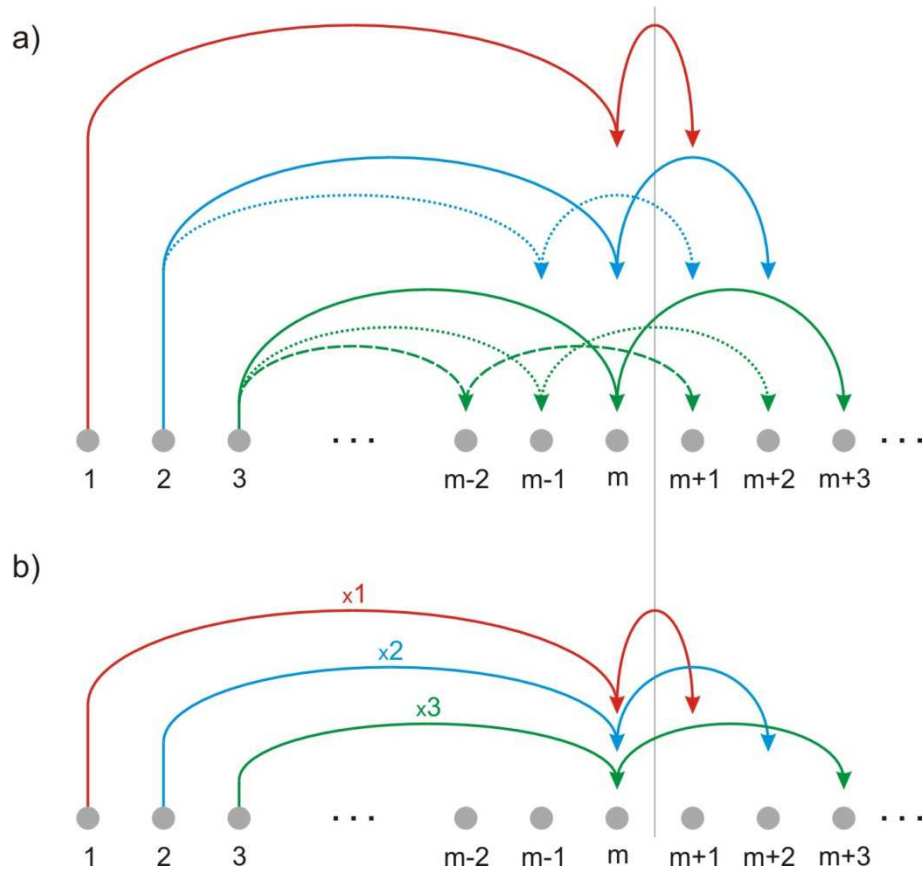

700 **Fig. 2.** The original size distribution above the cut-off size d_{p2} (size bin $m+1$) is shown in light gray. The

701 loss rate of particles and the rate of change of the particle concentration in this size range must be

702 compensated by the formation rate due to smaller particles growing into the measured size range.

703 This knowledge can be incrementally extended to bins at smaller sizes in a step-wise process, finally

704 reaching the smaller size, d_{p1} (size bin x).

705
706

707 **Fig. 3.** (a) Particle formation rate $J_{\geq m+1}$ due to collisions of monomers and clusters. (b) Approximation
708 of the particle formation rate including the growth rate definition according to equation (19). See
709 text for details.

710
711

712 **Fig. 4.** Modeled and reconstructed particle size distribution for kinetic nucleation. The model uses
 713 different definitions for the first 100 size bins (up to ~ 3.1 nm) and the last 100 size bins ($> \sim 3.1$ nm).
 714 In the first 100 size bins, the number of molecules in the particles increases by one between each
 715 bin, whereas in the next 100 bins the particle diameter is increased by a constant factor between
 716 each bin. Normalizing the concentration by the number of molecules per bin leads to the shown size
 717 distribution (grey sticks). The reconstructed size distribution using the new method described here is
 718 shown by the red solid line, starting from the particle distribution above 2.9 nm.

719

720

721 **Fig. 5.** Formation rates as function of particle size for kinetic nucleation. Formation rates simulated
 722 with the kinetic model are shown by the green line. Reconstructed particle formation rates starting
 723 at $d_{p2} = 2.9$ nm and ending at $d_{p1} = 1.4$ nm using a constant GR (taken at d_{p2}) are shown by the red
 724 triangles.

725

726

727 **Fig. 6.** Particle formation rates J ($\text{cm}^{-3}\text{s}^{-1}$, solid lines) and change in particle concentration dN/dt ($\text{cm}^{-3}\text{s}^{-1}$, dashed lines) shown for two different sizes, $d_{p1} = 1.4$ nm (green lines) and $d_{p2} = 2.9$ nm (blue lines). The data are from a kinetic model calculation. The reconstructed $J(d_{p1})$ is shown by the red solid line. Using a time correction, the reconstructed $J(d_{p1})$ are shifted to earlier times (dash-dotted red line).

730

731

732
733

734 **Fig. 7.** Formation rates as function of the sulfuric acid monomer concentration. The solid blue curves
 735 show the formation rates at d_{p2} calculated from the model. The simulated formation rates $J(d_{p1})$ from
 736 the model are indicated by the green lines. The reconstructed formation rates at d_{p1} are shown by
 737 the red lines. Varying the constant GR by a factor of 1.5 and 0.9, respectively results in the error band
 738 shown in light red. Neglecting self-coagulation yields the dashed black line. A complete set of all
 739 curves is shown for four different scenarios (kinetic limit, '223K', '248K', and '278K'). See text for
 740 details.
