

1 **Reply to the editor's technical corrections**

2 We thank Jan Bottenheim for suggestions regarding technical corrections, which we take into account  
3 in the revised manuscript. Comments (in italics) are addressed below. Revised text, where neces-  
4 sary, is shown in blue, and is included in the final manuscript version for ACP. Line numbers refer to  
5 the final manuscript (version 2).

6  
7 *I like this paper, too bad it took such a long time to get it to its final stage. I was therefore going to  
8 recommend to publish as is to speed this up, but I feel a few corrections and possibly a minor revision  
9 are required so I go for publish subject to technical corrections.*

10 **Reply:** Thank you. We regret as well the delay due to field season commitments as explained to the  
11 editorial office.

12  
13 *To start with the need for minor revision: section 3.4 looks to me as quickly put together without  
14 proper editing. It is rather sloppily written and contains a couple of rather odd mistakes (see below).  
15 Maybe my personal bias but it also has one of the more interesting conclusions: something is missing  
16 in the NO<sub>x</sub> chemistry. The same conclusion is derived from different angles in the paper by Legrand  
17 et al, and the recently submitted manuscript by Savarino et al. I for one would emphasize this in  
18 the conclusion section but it is so far only mentioned as almost an afterthought. Specific points  
19 (numbering refers to the line number in the final manuscript (version 2):*

20 **Reply:** While we don't find any mistakes in section 3.4, we welcome suggestions to improve the  
21 wording (see below). We concur that the conclusions should contain a statement on that the oxida-  
22 tion chemistry at Dome C is not fully understood yet.

23 **Revised text in conclusions; Line 1026:** First-time observations of BrO at Dome C suggest that  
24 mixing ratios of BrO near the ground are low, certainly less than 5 pptv. Assuming steady-state the  
25 observed mixing ratios of BrO and RO<sub>2</sub> radicals are about a factor ten too low to explain the NO<sub>2</sub> : NO  
26 ratios measured in ambient air. A potential interference of HO<sub>2</sub>NO<sub>2</sub> with the NO<sub>2</sub> measurements ex-  
27 plains only a small part of this inconsistency. Hence, the large NO<sub>2</sub> : NO ratios observed at Dome C  
28 are either the result of an unknown measurement bias or of a yet unidentified mechanism in boundary  
29 layer oxidation chemistry, as similarly concluded in OPALE companion papers (e.g. Legrand et al.,  
30 2014; Kukui et al., 2014; Savarino et al., 2015).

31  
32 *194/325: talks about a 4m inlet, but this is never described or referred to (I presume it is more clearly  
33 indicated in Frey et al 2013). Please give more info.*

34 **Reply:** Not really. Sampling heights of 0.01, 1.0 and also that at 4m are indeed mentioned at the  
35 very beginning of the method section (Line 151), and results are listed in Table 1, but not specifically  
36 discussed in the text, as they did not yield more information over what has been reported in Frey et  
37 al. (2013).

38 **Revised text Line 509:** In the following we focus on measurements at 0.01 and 1.0m, but statistics  
39 from all three measurement heights are reported in Table 1 and 4m measurements were discussed  
40 for summer 2009–10 in Frey et al. (2013).

41  
42 *451: I find it odd to call NO<sub>3</sub>- concentrations in snow an "ancillary measurement", to me it seems to  
43 be a key measurement for this paper. I would make it as a separate subchapter, even if the current  
44 authors did not make the actual measurements*

45 **Reply:** Done.

46  
47 *454: "accuracy is larger than usual". I guess it is correct in the sense that accuracy is used here. But  
48 at first it gave me the wrong impression that the accuracy was "better" than before. Maybe change it  
49 into "the results are less accurate than before".*

50 **Reply:** Done.

51  
52 *671: section 3.4, as mentioned I recommend to edit the whole section. To me it gives a feeling of  
53 handwaiving with numbers.*

54 **Reply:** Done as shown below and in the revised manuscript.

55

56 683: "- the AMFs are incorrect" ?? How so?

57 **Revised text Line 683:** this shows that the vertical profile of BrO used to calculate AMFs, whereby  
58 all the BrO is in the boundary layer, must be incorrect.

59

60 694: "So, if... then..." My first comment would be "yes, but if not... then not..." To me there is very  
61 little indication whether the procedure makes sense. I do not suggest to come up with a better one,  
62 but formulate it more neutral like "based on the latter observation, we decided to divide the dome-C  
63 observations by a factor 3 to arrive at a first estimate of 2-3 pptv"

64 **Revised text Line 694:** Based on the similarity of relative changes of slant BrO with elevation an-  
65 gles to those of Halley in 2007, and the approximate ratio of the slant columns at Halley in 2007 to  
66 those at Dome C of 3, we decided to divide the Halley inversion results by a factor 3 to arrive at a first  
67 estimate for Dome C of 2-3 pptv.

68

69 698: "XO = BrO, ClO" Now here is a jump?! If you have ClO data then you better show them. But I  
70 suspect this is just a remnant from another manuscript.

71 **Reply:** In this expression XO may also be ClO, although not measured. Hence, it is omitted in the  
72 revised text.

73

74 703-706: again, not wrong, but certainly a rambling sentence.

75 **Revised text Line 194:** However, during the same period observations showed a median concentra-  
76 tion of  $9.9 \times 10^7$  molecule  $\text{cm}^{-3}$  or 5 pptv of  $[\text{RO}_2] + [\text{HO}_2]$  (Kukui et al., 2014) and approximately 3 pptv  
77 of BrO, yielding a total radical concentration [OX] of 11 pptv. Hence, [OX] deduced from measured  
78  $\text{NO}_2 : \text{NO}$  ratios exceeds available observations by a factor 10.3.

79

80 715: "9.6 (3.3)". What does the (3.3) refer to? Maybe you mean when 100% of HO2NO2 is interfer-  
81 ing? The earlier text makes a case that 25% is the likely factor based on temperature and lifetime  
82 in the CLD cell, so why suddenly bringing in the possibility that it should be 100%? Be consistent  
83 please.

84 **Reply:** Omitted in the revised text.

85

86 717: "(not measured)" ? no kidding. This is mentioned far too often, just refer to earlier text where  
87 this is discussed, including the likely factor of 25%.

88 **Reply:** Done.

89

90 1026-1030: conclusion on BrO: firstly saying that "the data suggest 2-3 pptv" is too strong for my taste  
91 (these things have a habit of being requoted in future papers and start a life of their own). I would  
92 be more comfortable with not quoting numbers but referring to the actual text that it is "probably low,  
93 certainly less than 5 pptv".

94 **Reply:** We would accept "the data suggest that the mixing ratio of BrO near the ground is low, cer-  
95 tainly less than 5 pptv", but "probably" is not appropriate.

96 **Revised text Lines 1026-30:** the data suggest that the mixing ratio of BrO near the ground is low,  
97 certainly less than 5 pptv.

98

99 1026-1030: Furthermore the text with referring to the Theys et al and Salawich et al papers fits more  
100 properly in chapter 3.4. And once again, this harping on the potential HO2NO2 interference.... I have  
101 not tried to determine how often the potential HO2NO2 interference is referred to, but it sure seems  
102 to be invoked frequently. I recommend to skim to manuscript for it and cull the text. After all you talk  
103 about a missing measurement that in the end appears not even to be so important anyway.

104 **Reply:** The text citing work by Theys et al and Salawich et al is moved to section 3.4. and references  
105 to a potential HO2NO2 interference are kept to a minimum.

106

Abstract. Mixing ratios of the atmospheric nitrogen oxides NO and NO<sub>2</sub> were measured as part of the OPALE (Oxidant Production in Antarctic Lands & Export) campaign at Dome C, East Antarctica (75.1° S, 123.3° E, 3233 m), during December 2011 to January 2012. Profiles of NO<sub>x</sub> mixing ratios of the lower 100 m of the atmosphere confirm that, in contrast to South Pole, air chemistry at Dome C is strongly influenced by large diurnal cycles in solar irradiance and a sudden collapse of the atmospheric boundary layer in the early evening. Depth profiles of mixing ratios in firn air suggest that the upper snowpack at Dome C holds a significant reservoir of photolytically produced NO<sub>2</sub> and is a sink of gas phase ozone (O<sub>3</sub>). First-time observations of BrO at Dome C suggest ~~2–3~~ show that mixing ratios of BrO near the ground are low, certainly less than 5 pptv, with higher levels in the free troposphere. Assuming steady-state, observed mixing ratios of BrO and RO<sub>2</sub> radicals are too low to explain the large NO<sub>2</sub>:NO ratios found in ambient air. ~~A possible interference by pernitric acid (–) may explain part of this inconsistency, possibly indicating the existence of an unknown process contributing to the atmospheric chemistry of reactive nitrogen above the Antarctic Plateau.~~ During 2011–2012 NO<sub>x</sub> mixing ratios and flux were larger than in 2009–2010 consistent with also larger surface O<sub>3</sub> mixing ratios resulting from increased net O<sub>3</sub> production. Large

NO<sub>x</sub> mixing ratios at Dome C arise from a combination of continuous sun light, shallow mixing height and significant NO<sub>x</sub> emissions by surface snow ( $F_{\text{NO}_x}$ ). During 23 December 2011–12 January 2012 median  $F_{\text{NO}_x}$  was twice that during the same period in 2009–2010 due to significantly larger atmospheric turbulence and a slightly stronger snowpack source. A tripling of  $F_{\text{NO}_x}$  in December 2011 was largely due to changes in snow pack source strength caused primarily by changes in NO<sub>3</sub><sup>-</sup> concentrations in the snow skin layer, and only to a secondary order by decrease of total column O<sub>3</sub> and associated increase in NO<sub>3</sub><sup>-</sup> photolysis rates. A source of uncertainty in model estimates of  $F_{\text{NO}_x}$  is the quantum yield of ~~nitrate~~ NO<sub>3</sub><sup>-</sup> photolysis in natural snow, which may change over time as the snow ages.

## 1 Introduction

The nitrogen oxides NO and NO<sub>2</sub> (NO<sub>x</sub> = NO + NO<sub>2</sub>) play a key role in the polar troposphere in determining its oxidation capacity, defined here as the sum of O<sub>3</sub>, HO<sub>x</sub> radicals, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). The influence is achieved via photolysis of NO<sub>2</sub>, the only source for in situ production of tropospheric O<sub>3</sub>, through shifting HO<sub>x</sub> radical partitioning towards the hydroxyl radical (OH) via the reaction NO + HO<sub>2</sub> → NO<sub>2</sub> + OH, and finally through reactions with peroxyradicals NO + HO<sub>2</sub> (or RO<sub>2</sub>) which compete with the formation of peroxides (H<sub>2</sub>O<sub>2</sub> and ROOH).

Atmospheric mixing ratios of NO<sub>x</sub> in the atmospheric boundary layer of coastal Antarctica are small, with average NO<sub>x</sub> values in summer not exceeding 30 pptv (Bauguitte et al., 2012). The build up of large mixing ratios is prevented by gas-phase formation of halogen nitrates (e.g. BrNO<sub>3</sub>, INO<sub>3</sub>) followed by their heterogeneous loss (Bauguitte et al., 2012). Conversely, mixing ratios of NO<sub>x</sub> on the East Antarctic Plateau are unusually large, similar to those from the mid-latitudes (Davis et al., 2008; Slusher et al., 2010; Frey et al., 2013). Such large mixing ratios of NO<sub>x</sub> were found to arise from a combination of several factors: continuous sunlight, location at the bottom of a large air drainage basin, low temperatures leading to low primary production rates of HO<sub>x</sub> radicals, significant emissions of NO<sub>x</sub> from surface snow, and a shallow boundary layer (Davis et al., 2008; Frey et al., 2013, and refs. therein).

Snow emissions of NO<sub>x</sub>, observed at several polar locations (e.g. Jones et al., 2001; Honrath et al., 2000b), are driven by UV-photolysis of nitrate (NO<sub>3</sub><sup>-</sup>) in snow (Honrath et al., 2000b; Simpson et al., 2002) and are now considered to be an essential component of air-snow cycling of oxidised nitrogen species above the polar ice sheets (Davis et al., 2008; Frey et al., 2009b) and likely also above mid-latitude snow packs (Honrath et al., 2000a; Fisher et al., 2005). Atmospheric dynamics, i.e. vertical mixing strength and mixing height, can explain some of the observed temporal variability and site-specific chemical composition of the lower troposphere at South Pole and Summit, Greenland (Neff et al., 2008; Van Dam et al., 2013). Recently, the very strong diurnal cycle of mixing ratios of NO<sub>x</sub> observed at Dome C, East Antarctic Plateau, during summer was shown to result from the interplay between boundary layer mixing and emissions from the photochemical snow source; during calm periods a minimum of NO<sub>x</sub> mixing ratios occurred around local noon and a maximum in the early evening coinciding with the development and collapse of a convective boundary layer (Frey et al., 2013). A key parameter of the physical atmospheric processes at play is the turbulent diffusivity of the atmosphere, which controls the mixing height,  $h_z$ , of the atmospheric bound-

ary layer and contributes to the magnitude of the flux of trace chemical species emitted by the snow (e.g. Frey et al., 2013).

The impact of NO<sub>x</sub> emissions from snow on the oxidation capacity of the lower troposphere in summer can be significant. For example, NO<sub>x</sub> snow emissions can result in net O<sub>3</sub> production as observed in the interior of Antarctica (Crawford et al., 2001; Legrand et al., 2009; Slusher et al., 2010) as well as unusually large mixing ratios of hydroxyl radicals as detected at South Pole (Davis et al., 2008, and refs. therein). Furthermore, in Antarctica the gas phase production of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), the only major atmospheric oxidant preserved in ice cores, is sensitive to NO released by the surface snowpack (e.g. Frey et al., 2005, 2009a). A steady-state analysis of ratios of NO<sub>2</sub> : NO at Dome C suggested that mixing ratios of peroxy radicals (not measured at the time) are possibly larger at Dome C than any previous observations in air above polar snow (Frey et al., 2013). The quantitative understanding of emissions of NO<sub>x</sub> from snow remains incomplete, but it is a research priority to be able to parameterise global models to assess for example global impacts of chemical air-snow exchange on tropospheric O<sub>3</sub> (e.g. Zlatko et al., 2013). Emissions of NO<sub>x</sub> from snow at Dome C are among the largest observed above either polar ice sheet, but are typically underestimated by models, especially at large solar zenith angles (Frey et al., 2013).

The study presented here was part of the comprehensive atmospheric chemistry campaign OPALE (Oxidant Production and its Export from Antarctic Lands) in East Antarctica (Preunkert et al., 2012) and provided the opportunity to measure NO<sub>x</sub> mixing ratios and flux during a second summer season, after a previous campaign in 2009–2010 (Frey et al., 2013). The study objectives were firstly to extend the existing data set with mixing ratio profiles of the lower atmosphere and the firn air (interstitial air) column of the upper snow pack. Secondly, to investigate if observed NO<sub>2</sub> : NO ratios are consistent with measurements of hydroxyl and halogen radicals. And thirdly, to analyse the main drivers of the atmospheric NO<sub>x</sub> emission flux from snow.

## 2 Methods

The measurement campaign of 50 days took place at Dome C (75.1° S, 123.3° E, 3233 m) from 23 November 2011 to 12 January 2012. Similar to the 2009–2010 campaign atmospheric sampling was performed from an electrically heated lab shelter (Weatherhaven tent) located in the designated clean-air sector 0.7 km upwind (South) of Concordia station (Frey et al., 2013, Fig.1a). All times are given as local time (LT), equivalent to

UTC + 8 h, and during the study period the sun always remained above the horizon.

## 150 2.1 NO<sub>x</sub> concentration measurements and uncertainties 205

Three 20 m-long intake lines (Fluoroline 4200 high purity PFA, I.D. 4.0 mm) were attached to a mast located at 15 m from the lab shelter into the prevailing wind to continuously sample air at 0.01, 1.00 and 4.00 m above 155 the natural snow pack. The intake lines were away from the influence of the drifted snow around the lab shelter. On 9 January 2012 vertical profiles of the lower atmosphere were sampled by attaching a 100 m-long intake 160 line to a helium-filled weather balloon, which was then manually raised and lowered. During selected time periods firn air was sampled, to depths 5–100 cm, by means of a custom built probe. The probe consisted of a tube (10 cm diameter) which was lowered vertically into a pre- 165 cored hole to the chosen snow depth, passing through a disc (1 m diameter) resting on the snow surface. The disk had a lip of 10 cm protruding into the snow. The lip and disk minimised preferential pumping of ambient air along the tube walls. The air intake was mounted 170 so that only air from the bottom and sides could enter, using small horizontal holes at 0–10 cm above the open bottom end of the vertical tube. All probe components were made from UV-transparent plastic (Plexiglas Sunactive GS 2458). Furthermore, 2 × 3 m sheets of UV- 175 opaque (Acrylite OP-3) and UV-transparent (Acrylite OP-4) plexiglass, mounted on aluminium frames at 1 m above the snow surface, were used to deduce the effect of UV radiation on the mixing ratio of NO<sub>x</sub> in the interstitial air and avoid at the same time any temperature 180 effect altering the snow surface. 235

To measure NO<sub>x</sub> the same 2-channel chemiluminescence detector (CLD) and experimental set up as during the 2009–2010 campaign were used (Frey et al., 2013, Fig. 1b). Channel one of the CLD measured atmospheric 185 mixing ratios of NO whereas the other channel determined the sum of the mixing ratios of NO and NO originating from the quantitative photolytic conversion of NO<sub>2</sub>. The difference between the two channels was used to calculate atmospheric mixing ratios of NO<sub>2</sub>. The 190 three sample inlets were connected inside the lab shelter to a valve box, which automatically switched the CLD between sampling heights on a 90 s duty cycle. As described below, the 10-minute average concentration difference  $\Delta\text{NO}_x$  between the 0.01 and 1.0 m inlets is used 195 to estimate flux. Therefore, 10-minute mean  $\Delta\text{NO}_x$  values are calculated on average from two sets of two subsequent 90 s intervals, separated by a 90 s interval during which the 4.0 m inlet was measured. Baseline count rates were determined by adding excess O<sub>3</sub> to sample 200 air in a pre-chamber so that all electronically excited

NO<sub>2</sub> has returned to ground state when reaching the reaction chamber. The baseline was measured for 60 s every 13.5 min alternating between all three inlets. The NO sensitivity of the CLDs was determined every 14 h by standard addition to the sample air matrix of a 1 ppm NO/NO<sub>2</sub> mixture (UK National Physics Laboratory traceable BOC certified), which is further diluted to 4 ppbv of NO. During standard runs also the conversion efficiency (CE) of the photolytic converter was determined by addition of a known mole fraction of NO<sub>2</sub>. This was achieved by gas phase titration of the NO/NO<sub>2</sub> mixture to NO<sub>2</sub> by O<sub>3</sub> generated from a pen-ray lamp, and monitoring the un-titrated NO mole fraction. The instrument artefact originating from NO<sub>x</sub> producing surface reactions in inlets and reaction cells was determined by overflowing the instrument inlet with scrubbed ambient air supplied by a pure air generator (Eco-Physics PAG003). The artefact was measured every 14 h, offset by 7 h to the calibration runs. [The CLD performance, e.g. sensitivity, random error and precision, was similar to that during 2009–10 \(Frey et al., 2013, Table 1\).](#)

The mean wind direction during the measurement period was from S (176°) with an average speed of 4.0 m s<sup>-1</sup> (Fig. 1b). During 2.5% of the time winds came from the direction of Concordia station, i.e. the 355–15° sector (Frey et al., 2013, Fig. 1a), potentially carrying polluted air from the station power generator to the measurement site. For example, during Period III, winds rotated 4 times through northerly directions (Fig. 1b). Pollution spikes in the raw 1-s data typically exceeded 10 ppbv of NO<sub>x</sub> and were effectively removed before computing the 1-min averages by applying a moving 1-min standard deviation ( $\sigma$ ) filter. Observations were rejected when 1- $\sigma$  of NO and NO<sub>2</sub> mixing ratios within a 1-min window exceeded 24 and 90 pptv, respectively.

The CLD employed also converts nitrous acid (HONO) to NO in the photolytic converter and thus HONO sampled by the CLD is an interferent, as discussed previously (Frey et al., 2013). Average mixing ratios of HONO at 1 m above the snowpack measured with the LOPAP (Long Path Absorption Photometer) technique were  $\sim 35$  pptv (Legrand et al., 2014). The corresponding downward correction for NO<sub>2</sub> at 1 m above the snowpack is  $\sim 5\%$ . However the LOPAP technique may overestimate the mixing ratio of HONO owing to an interference by pernitric acid (HO<sub>2</sub>NO<sub>2</sub>) (Legrand et al., 2014). True corrections of NO<sub>2</sub> inferred from modelled HONO mixing ratios (Legrand et al., 2014) are more likely to be on the order of  $< 1.5\%$ . Due to the uncertainty in absolute mixing ratios of HONO, no correction of NO<sub>x</sub> values for the HONO interference was applied.

The thermal decomposition of HO<sub>2</sub>NO<sub>2</sub> in the sample lines or photolytic converter of the CLD could also cause a positive bias of NO<sub>x</sub>. Spike tests showed that the sample air residence time in the total volume of in-

lets and CLD is  $\sim 4$  s (Frey et al., 2013). At a sample flow rate of  $5.0 \text{ STP} - \text{L min}^{-1}$  the residence time in the combined volume of photolytic converter and CLD reaction cell is estimated to be  $< 2$  s. Atmospheric lifetimes of  $\text{HO}_2\text{NO}_2$ ,  $\tau_{\text{HO}_2\text{NO}_2}$ , with respect to thermal decomposition to  $\text{HO}_2 + \text{NO}_2$  were calculated at mean ambient pressure (645 mb) using rate coefficients after Jacobson (1999).  $\tau_{\text{HO}_2\text{NO}_2}$  decreases from 8.6 h at mean ambient temperature assumed in the sample intake lines ( $-30^\circ\text{C}$ ) to 7 s at the maximum observed temperature in the photolytic converter ( $30^\circ\text{C}$ ). Therefore,  $\text{NO}_2$  production from  $\text{HO}_2\text{NO}_2$  thermal decomposition is negligible in the sample intake lines, but approximately 25% of all  $\text{HO}_2\text{NO}_2$  present may be converted to  $\text{NO}_2$  in the photolytic converter. A recent airborne campaign above the East Antarctic Plateau showed mean summertime atmospheric mixing ratios of  $\text{HO}_2\text{NO}_2$  between 0 and 50 m of 65 pptv with maxima about twice as large (Slusher et al., 2010).  $\text{HO}_2\text{NO}_2$  present at these values could potentially produce 16–32 pptv of  $\text{NO}_2$  in the photolytic converter equivalent to 8–16% of the average  $\text{NO}_2$  mixing ratio measured at 1 m. On 5 January 2012 we attempted to test for the presence of  $\text{HO}_2\text{NO}_2$  by passing ambient air through a 50 m intake heated to  $50^\circ\text{C}$  before it entered the CLD. However, during the tests no significant change in  $\text{NO}_2$  was detected.

The presence of strong gradients in mixing ratios of HONO inferred by Legrand et al. (2014) can potentially lead to an overestimate of the  $\text{NO}_x$  concentration differences between 0.01 and 1.0 m used below to derive the vertical  $\text{NO}_x$  flux. During the OPALE campaign the atmospheric life time of  $\text{NO}_x$ ,  $\tau_{\text{NO}_x}$ , ranged between 3 h (12:00 LT) and 7 h (00:00 LT), whereas that of HONO,  $\tau_{\text{HONO}}$ , ranged between 4.5 min (12:00 LT) and 24 min (00:00 LT) (Legrand et al., 2014). The life time of HONO is comparable to the typical transport times of  $\sim 10$  min between the surface and 1 m at Dome C in summer (Frey et al., 2013). Hence, HONO: $\text{NO}_x$  ratios as well as corresponding corrections required for  $\text{NO}_2$  are not constant with height above the snow surface. No gradients of HONO mixing ratios were measured but modelled values were 18.8 and 10.2 pptv at noon, and 15.3 and 12 pptv at midnight, at 0.1 and 1.0 m, respectively (Legrand et al., 2014). Corresponding corrections of mean  $\text{NO}_2$  mixing ratios for HONO are 1.3–1.5% with a maximum difference of 0.2% between 0.1 and 1.0 m. Thus, at Dome C a strong gradient in the mixing ratios of HONO was a negligible effect on the mixing ratios of  $\text{NO}_x$  measured at 0.1 and 1.0 m and thus a negligible effect on the estimated  $\text{NO}_x$  flux.

## 2.2 $\text{NO}_x$ flux estimates

The turbulent flux of  $\text{NO}_x$ ,  $F_{\text{NO}_x}$ , was estimated using the integrated flux gradient method (e.g. Lenschow,

1995) and mixing ratios of  $\text{NO}_x$  measured at 0.01 and 1.0 m.  $F_{\text{NO}_x}$  in the surface layer is parameterised according to the Monin–Obukhov similarity theory (MOST) whose predictions of flux-profile relationships at Halley, an Antarctic coastal site of the same latitude as Dome C, agree well with observations (Anderson and Neff, 2008, and references therein):

$$F_{\text{NO}_x} = -\frac{\kappa u_* z}{\Phi_h\left(\frac{z}{L}\right)} \frac{\partial c}{\partial z} \quad (1)$$

with the von Karman constant  $\kappa$  (set to 0.40), friction velocity  $u_*$ , measurement height  $z$ , concentration gradient  $\partial c/\partial z$ , and  $\Phi_h\left(\frac{z}{L}\right)$  an empirically determined stability function for heat with  $L$  as the Monin–Obukhov length. Assuming constant flux across the layer between the two measurement heights  $z_1$  and  $z_2$  allows the integration to be solved and yields:

$$F_{\text{NO}_x} = -\frac{\int_{c_1}^{c_2} \kappa u_* \partial c}{\int_{z_1}^{z_2} \Phi_h\left(\frac{z}{L}\right) \frac{\partial z}{z}} = -\frac{\kappa u_* [c(z_2) - c(z_1)]}{\int_{z_1}^{z_2} \Phi_h\left(\frac{z}{L}\right) \frac{\partial z}{z}} \quad (2)$$

Stability functions  $\Phi_h$  used are given in Frey et al. (2013), while their integrated forms can be found in Jacobson (1999). Friction velocity  $u_*$  and  $L$  were computed from the three-dimensional wind components ( $u$ ,  $v$ ,  $w$ ) and temperature measured at 25 Hz by a sonic anemometer (Metek USA-1) mounted next to the uppermost  $\text{NO}_x$  intake line, at 4 m above the snow surface. Processing of raw [sonic](#) data in 10 min blocks included temperature cross-wind correction and a double coordinate rotation to force mean  $w$  to zero (Kaimal and Finnigan, 1994; Van Dijk et al., 2006). Equation (2) implies that a positive flux is in upward direction, equivalent to snow pack emissions and a negative flux is in downward direction, equivalent to deposition.

The application of MOST requires the following conditions to be met: (a) flux is constant between measurement heights  $z_1$  and  $z_2$ , (b) the lower inlet height  $z_1$  is well above the aerodynamic roughness length of the surface, (c) the upper inlet height  $z_2$  is within the surface layer, i.e. below 10% of the boundary layer height  $h_z$  (Stull, 1988), and (d)  $z_1$  and  $z_2$  are far enough apart to allow for detection of a significant concentration difference  $[c(z_2) - c(z_1)]$ .

Condition (a) is met in the surface layer if the chemical lifetime  $\tau_{chem}$  of  $\text{NO}_x$  is much longer than the turbulent transport time scale  $\tau_{trans}$ . Based on observed OH and  $\text{HO}_2$  the  $\tau_{chem}$  for  $\text{NO}_x$  is estimated to be 3 h at 1200 LT and 7 h at 0000 LT during OPALE (Legrand et al., 2014). Estimating  $\tau_{trans}$  following the approach described previously (Frey et al., 2013, Eq. 6 and 7) yields 0.6, 1.7 and 2.5 min during the day (0900–1700 LT), the typical time of BL collapse (1700–1900 LT) and during the night (1900–0900 LT), respectively. Thus,

$\tau_{chem}$  exceeds  $\tau_{trans}$  by at least a factor 100, confirm-  
 ing that vertical mixing always dominates over the gas  
 phase photochemical sink and flux can be assumed con-  
 stant between the two inlets. Condition (b) is met as  
 discussed in Frey et al. (2013). For (c) the upper inlet  
 height of 1 m is compared to estimates of mixing height,  
 $h_z$  from the MAR model (Gallée et al., 2015). The MAR  
 model has been validated previously over the Antarctic  
 Plateau, focusing on Dome C, during winter (Gallée and  
 Gorodetskaya, 2010) and now also during summer (Gal-  
 lée et al., 2015). Calculated flux values of  $\text{NO}_x$  were re-  
 moved when  $h_z < 10$  m resulting in the removal of 22 %  
 (773 values) of all available 10 min flux averages. Flux es-  
 timates are removed specifically during the evening and  
 night, when the BL is shallow. Hence, fluxes during night  
 time are less well constrained, but nevertheless support  
 a significant diurnal cycle (Frey et al., 2013, Fig. 6b,g  
 and Fig. 9). For (d) 10 min averages of  $[c(z_2) - c(z_1)]$  not  
 significantly different from zero, i.e. smaller than their  
 respective  $1-\sigma$  standard error, were not included in the  
 calculation of the flux of  $\text{NO}_x$ . The  $1-\sigma$  standard error  
 in  $[c(z_2) - c(z_1)]$  was determined by error propagation  
 of the  $1-\sigma$  standard error of  $\text{NO}_x$  mixing ratios. A total  
 of 8 % (303 values) of all available 10 min flux averages  
 were not significantly different from zero and thus re-  
 moved.

In summary, the restrictions imposed by MOST and  
 $\text{NO}_x$  measurement uncertainty justify placing inlets at  
 0.01 and 1.0 m and lead to the removal of 30 % (1076  
 values) of all available flux estimates. The total uncer-  
 tainty of the 10 min  $\text{NO}_x$  flux values due to random  
 error in  $[c(z_2) - c(z_1)]$  (31 %),  $u_*$  (3 % after Bauguitte  
 et al., 2012) and measurement height (error in  $\ln(z_2/z_1)$   
 of  $\sim 7$  %) amounts to 32 %.

### 2.3 Analysis of $\text{NO}_3^-$ concentrations in snow

During this study  $\text{NO}_3^-$  concentrations in snow were  
 measured every 2–3 days in the surface skin layer,  
 i.e. in the top 0.5 cm of the snowpack, as well as  
 in shallow snow pits within the clean-air sector. Snow  
 $\text{NO}_3^-$  concentrations were determined using clean  
 sampling procedures and a continuous flow analysis  
 technique (e.g. Frey et al., 2009b). Samples were stored  
 together with the additional snow samples discussed  
 in Berhanu et al. (2014) and then analysed for  $\text{NO}_3^-$   
 in batches by the same operator. The precision is  
 5% based on replicate standard measurements. Due  
 to a systematic shift in the  $\text{NO}_3^-$  standard response  
 in between individual batch runs due to a calibration  
 issue (Berhanu et al., 2014) results are less accurate  
 than before. The overall accuracy including systematic  
 errors in calibration and collection of just the top few  
 mm of snow is of the order of 20%, and is therefore

comparable to the spatial variability of  $\text{NO}_3^-$  in surface  
 snow at Dome C (France et al., 2011). For the discussion  
 below it should be borne in mind that temporal changes  
 of  $\text{NO}_3^-$  concentrations observed in surface snow are  
 $>50\%$  (Fig. 7b) and therefore significantly larger than  
 the measurement accuracy.

### 2.4 MAX-DOAS observations

Scattered sunlight was observed by a ground-based UV-  
 visible spectrometer, in order to retrieve bromine ox-  
 ide (BrO) column amounts. The instrument was con-  
 tained in a small temperature-controlled box, which was  
 mounted onto a tripod at 1 m above the snow surface.  
 An external gearbox and motor scanned the box in el-  
 evation (so-called Multiple Axis). Spectra were anal-  
 ysed by Differential Optical Absorption Spectroscopy  
 (DOAS), the combination being known as the MAX-  
 DOAS technique. See Roscoe et al. (2014) for more de-  
 tails of apparatus and analysis. Briefly, the observed  
 spectrum contains Fraunhofer lines from the Sun's at-  
 mosphere, which interfere with absorption lines in the  
 Earth's atmosphere and are removed by dividing by  
 a reference spectrum. The amounts of absorbers in  
 the Earth's atmosphere are found by fitting laboratory  
 cross-sections to the ratio of observed to reference spec-  
 tra, after applying a high-pass filter in wavelength (the  
 DOAS technique).

In our case the spectral fit was from 341 to 356 nm,  
 and the interfering gases  $\text{O}_3$ ,  $\text{O}_4$  (oxygen dimer) and  
 $\text{NO}_2$  were included with BrO. The analysis was done  
 with two reference spectra, one from near the start of  
 the campaign in December, the other following the ad-  
 dition of a snow excluder in January, necessary because  
 it also contained a blue glass filter with very different  
 spectral shape. The analysis was restricted to cloud-free  
 days or part-days. In MAX-DOAS geometry, the strato-  
 spheric light path is almost identical in low-elevation  
 and zenith views, so stratospheric absorption is removed  
 by subtracting simultaneous zenith amounts from low-  
 elevation slant amounts, important for BrO as there is  
 much in the stratosphere.

To find the vertical amounts of BrO radicals the  
 MAX-DOAS measurements were evaluated as follows:  
 we divided by the ratio of the slant path length to the  
 vertical (the Air Mass Factor, AMF), calculated by ra-  
 diative transfer code (Mayer and Kylling, 2005), assum-  
 ing all the BrO was in the lowest 200 m.

### 2.5 Ancillary measurements and data

Other co-located atmospheric measurements included  
 mixing ratios of OH radicals and the sum of peroxy  
 radicals ( $\text{RO}_2$ ) at 3 m using chemical ionisation mass  
 spectrometry (Kukui et al., 2014) and mixing ratios of

O<sub>3</sub> at 1 m with a UV absorption monitor (Thermo Elec-<sup>510</sup>tron Corporation model 49I, Franklin, Massachusetts). Photolysis rate coefficients,  $J$ , were determined based on actinic flux,  $I$ , measured at  $\sim 3.50$  m above the snow surface using a Met-Con  $2\pi$  spectral radiometer equipped with a CCD detector and a spectral range<sup>515</sup> from 285 to 700 nm (further details in Kukui et al., 2014). Total column O<sub>3</sub> above Dome C was taken from ground based SAOZ (Système d'Analyse par Observation Zenitale) observations ([http://saoz.obs.uvsq.fr/SAOZ\\_consol\\_v2.html](http://saoz.obs.uvsq.fr/SAOZ_consol_v2.html)). Standard meteorology was<sup>520</sup> available from an automatic weather station (AWS) at 0.5 km distance and included air temperature (Vaisala PT100 DTS12 at 1.6 m), relative humidity (at 1.6 m), wind speed and direction (Vaisala WAA 15A at 3.3 m).<sup>475</sup> The mixing height  $h_z$  of the atmospheric boundary layer<sup>525</sup> was calculated from simulations with the MAR model as the height where the turbulent kinetic energy decreases below 5% of the value of the lowest layer of the model<sup>480</sup> (Gallée et al., 2015).

~~During this study concentrations in snow were<sup>530</sup> measured every 2–3 days in the surface skin layer, i.e. in the top 0.5 of the snowpack, as well as in shallow snow pits within the clean-air sector. Snow concentrations were determined using clean sampling procedures and a continuous flow analysis technique (e.g. Frey et al., 2009b). Samples were stored together with the additional snow samples discussed in Berhanu et al. (2014) and then analysed for in<sup>485</sup> batches by the same operator. The precision is 5%<sup>535</sup> based on replicate standard measurements. Due to a systematic shift in the standard response in between individual batch runs due to a calibration issue (Berhanu et al., 2014) the accuracy is larger than usual. The overall accuracy including systematic errors in<sup>495</sup> calibration and collection of just the top few mm of snow is of the order of 20%, and is therefore comparable to the spatial variability of in surface snow at Dome C (France et al., 2011). For the discussion below it should be borne in mind that temporal changes of<sup>500</sup> concentrations observed in surface snow are >50% (Fig. 7b) and therefore significantly larger than the measurement accuracy.~~

## 2.6 Modelling NO<sub>3</sub><sup>-</sup> photolysis<sup>550</sup>

The flux of NO<sub>2</sub>,  $F_{\text{NO}_2}$ , from the snowpack owing to<sup>505</sup> photolysis of the NO<sub>3</sub><sup>-</sup> anion in the snowpack can be estimated as the depth-integrated photolysis rate of NO<sub>3</sub><sup>-</sup><sup>555</sup>

$$F_{\text{NO}_2} = \int_{z=0\text{ m}}^{z=1\text{ m}} [\text{NO}_3^-]_z J_z(\text{NO}_3^-) dz \quad (3)$$

where  $J_z(\text{NO}_3^-)$  is the photolysis rate coefficient of reaction  $\text{NO}_3^- + h\nu \rightarrow \text{NO}_2 + \text{O}^-$  at depth,  $z$ , in the snowpack.  $[\text{NO}_3^-]_z$  is the amount of NO<sub>3</sub><sup>-</sup> per unit volume of snow at depth,  $z$ , in the snowpack.  $J_z(\text{NO}_3^-)$  is calculated as described in France et al. (2010) using a radiative transfer model, TUV-snow (Lee-Taylor and Madronich, 2002), to calculate irradiances within the snowpack as a function of depth. The optical properties and detailed description of the Dome C snowpack are reported in France et al. (2011). Values of depth-integrated flux were calculated as a function of solar zenith angle and scaled by values of  $J(\text{NO}_3^-)$  measured by the Met-Con  $2\pi$  spectral radiometer described above to account for changing sky conditions. Scaling by a measured value of  $J(\text{NO}_3^-)$  is more accurate than previous efforts of scaling with a broad band UV instrument (e.g. France et al., 2011). The quantum yield and the absorption spectrum for NO<sub>3</sub><sup>-</sup> photolysis in snow were taken from Chu and Anastasio (2003). For the discussion below it should be borne in mind that the calculated  $F_{\text{NO}_2}$  is a potential emission flux assuming that NO<sub>2</sub> is vented immediately after release from the snow grain to the air above the snow pack without undergoing any secondary reactions.

## 3 Results and discussion

### 3.1 NO<sub>x</sub> observations in ambient and firn air

In summer 2011–2012 atmospheric mixing ratios of NO<sub>x</sub> with strong diurnal variability were observed (Fig. 1c), similar to the 2009–2010 season, and showed maximum median levels in firn air of  $\sim 3837$  pptv, which rapidly decreased to 319 pptv at 0.01 m and 213 pptv at 1.0 m (Table 1). In the following we focus on measurements at 0.01 and 1.0 m, but statistics from all three measurement heights are reported in Table 1 and 4 m measurements were discussed for summer 2009–10 in Frey et al. (2013).

As seen previously at Dome C and other locations, NO<sub>x</sub> mixing ratios were weakly but significantly anti-correlated with wind speed (at 1.0 m  $R = -0.37$ ,  $p < 0.001$ ), especially when only the time period of the daily collapse of the convective boundary layer, i.e. 1700–1900 LT, was considered ( $R = -0.45$ ,  $p < 0.001$ ), and their diurnal cycle was dampened during storms (Fig. 1b–c).

The two main differences between summer 2011–2012 and summer 2009–2010 are a strong intra-seasonal variability and larger atmospheric mixing ratios. A significant increase of NO<sub>x</sub> mixing ratios at 1.0 m from low values in Period I. (23–30 November 2011) occurred in two steps: a small rise in Period II. (1–8 December 2011), followed by a strong increase of daily averages from 300 to 1200 pptv at the beginning of Period III. (9–11–9–22 December 2011) (Fig. 1c). After that NO<sub>x</sub> mixing ra-

tios gradually dropped over 10 days (Period III.–IV.) to median concentrations of  $\sim 120$  pptv, slightly lower than 615 observed in late November (Fig. 1c, Table 2). During Period III. (~~9–22 December 2011~~) the median concentration of  $\text{NO}_x$  at 1.0 m was 451 pptv, about 2.5 times 565 that during the same time period in 2009, but similar thereafter (Fig. 1c, Table 2). 620

The  $\text{NO}_x$  fluxes,  $F_{\text{NO}_x}$ , between 0.01 and 1.0 m were mostly emissions from the snow surface, with a median 570 of  $1.6 \times 10^{13}$  molecule  $\text{m}^{-2} \text{s}^{-1}$ . Median values of  $F_{\text{NO}_x}$  at midnight and at noon were 0.4 and  $2.9 \times 10^{13}$  molecule  $\text{m}^{-2} \text{s}^{-1}$ , respectively (Table 1). During 625 Period III.  $F_{\text{NO}_x}$  showed an increase by a factor 3, approximately around the same time when atmospheric mixing ratios of  $\text{NO}_x$  increased (Fig. 1d, Table 2). The median flux of  $\text{NO}_x$  during ~~9–22 December 2011~~ Period III. reached  $3.1 \times 10^{13}$  molecule  $\text{m}^{-2} \text{s}^{-1}$ , almost 5 times 630 the season median from 2009–2010. During ~~23 December to 12 January~~ (Period IV. (23 December 2011–12 January 2012)) the median flux of  $\text{NO}_x$  in 2011–2012 was about twice that observed in 2009–2010 (Table 2). Potential causes of significant variability in mixing ra- 635 tios and flux on seasonal time scales are discussed in Sect. 3.5.

### 585 3.2 The lower atmosphere–firn air profile

On 9 January 2012 a total of 12 vertical atmospheric 640 profiles of  $\text{NO}_x$  mixing ratios were measured between 11:30 and 23:30 LT. The lower 100 m of the atmosphere appear well mixed throughout the afternoon, with modelled mixing heights  $h_z$  of 200–550 m and observed tur- 645 bulent diffusion coefficients of heat  $K_h$  of  $\sim 0.1 \text{ m}^2 \text{ s}^{-1}$  (Fig. 2). However, in the late afternoon  $K_h$  values decreased gradually over a few hours to reach in the evening levels half those during the day thereby giving 590 evidence of strongly reduced vertical mixing. Furthermore, around 18:30 LT modelled  $h_z$  values decreased within minutes from 550 to  $< 15$  m height (Fig. 2a) illustrating the collapse of the convective boundary layer typically observed at Dome C in the early evening during 600 summer (King et al., 2006). At Dome C rapid cooling of the surface in the evening results in a strong shallow surface inversion (e.g. Frey et al., 2013), and is illustrated by a decrease in downward long-wave radiation and a negative heat flux, as observed in the evening of 605 9 January 2012 (Argentini et al., 2014, Fig. 4). It follows that  $\text{NO}_x$  snow emissions are trapped near the surface, which then leads to a significant increase in  $\text{NO}_x$  mixing ratios below 15 m height measured almost immediately after collapse of the boundary layer (Fig. 2). During 610 22:20–22:40 LT a small increase in  $K_h$ , due to the nightly increase in wind shear (see Frey et al., 2013), was sufficient to cause upward mixing of  $\text{NO}_x$  accumulated near the surface to  $\sim 35$  m height (Fig. 2). The

vertical balloon soundings further underline the unique geographical setting of Dome C or other sites of similar latitude on the East Antarctic Plateau where air chemistry is dominated by strong diurnal cycles, both in down-welling solar radiation and atmospheric stability, contrasting South Pole where diurnal changes are absent and changes are more due to synoptic variability (Neff et al., 2008).

A vertical profile of mixing ratios of  $\text{NO}_x$  and  $\text{O}_3$  in firn air was measured on 12 January 2012 between 10:00 and 18:00 LT, for which depths were sampled in random order for 30–60 min each. Mixing ratio maxima of NO and  $\text{NO}_2$  were  $\sim 1$  and 4 ppbv, respectively, about one order of magnitude above ambient air levels (Table 1), and occurred at 10–15 cm depth, slightly below the typical e-folding depth of 10 cm of wind pack snow at Dome C (France et al., 2011) (Fig. 3a). NO dropped off quickly with depth, reaching 55 pptv at 85 cm, whereas  $\text{NO}_2$  decreased asymptotically approaching  $\sim 2$  ppbv (Fig. 3a).  $\text{NO}_3^-$  concentrations in snow under the firn air probe did not follow the exponential decrease with depth typically observed at Dome C (e.g. Erbland et al., 2013). The firn air probe was installed onto untouched snow, and only removed after the end of the atmospheric sampling period. Thus contamination due to local activity appears unlikely, but a local anomaly remains a possibility as snow pits 5 m next to the lab shelter showed a similar increase of concentration with depth (data not shown). But  $\text{NO}_3^-$  values within one e-folding depth were still in the range measured further away (Profiles P1–P3 in Fig. 3a), justifying a discussion of vertical profiles of mixing ratios.

$\text{O}_3$  mixing ratios in firn air were always below ambient air levels, suggesting the snow pack to be an  $\text{O}_3$  sink as observed previously for the snowpack on the Greenland ice sheet (Peterson and Honrath, 2001), and showed a significant anti-correlation with  $\text{NO}_2$  ( $R = -0.84$ ,  $p < 0.001$ ). This is further evidence for significant release of  $\text{NO}_x$  by the snow matrix into the interstitial air, which then titrates  $\text{O}_3$  through the reaction  $\text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2$  (Fig. 3). In particular, the drop of  $\text{O}_3$  mixing ratios by  $> 10$  ppbv at 45 cm depth was not an outlier since collocated  $\text{NO}_2$  mixing ratios were also significantly elevated compared to adjacent snow layers (Fig. 3a). However, no snow  $\text{NO}_3^-$  measurements were available to further investigate the origin of the  $\text{NO}_2$  peak. The observed vertical trends in  $\text{NO}_x$  suggest that below a few e-folding depths the open pore space of the upper snowpack holds a significant reservoir of  $\text{NO}_2$  produced photolytically above, as hypothesized previously (Frey et al., 2013). In contrast, NO disappears at depths devoid of UV irradiance as it reacts with  $\text{O}_3$ .

### 3.3 Response to UV irradiance

Changes in surface downwelling UV irradiance lead to a quick response of mixing ratios and speciation of  $\text{NO}_x$  in ambient and firn air as observed during a partial solar eclipse and during a shading experiment (Fig. 4). The solar eclipse occurred early in the season, on 25 November 2011, and caused a decrease in ambient NO mixing ratios at 1.0 m by about 10 pptv or 10%, whereas  $\text{NO}_2$  mixing ratios did not change significantly (Fig. 4a and b). The NO gas phase source, UV photolysis of  $\text{NO}_2$ , is reduced during the solar eclipse. But the sink of NO, the fast titration with  $\text{O}_3$ , is unaffected by the reduction in UV irradiance. During the shading experiment on 11 January 2012 plastic sheets were placed at 1 m above the snow surface, alternating in 30 min intervals between UV-opaque and UV-transparent materials. The impact of blocking incident UV irradiance (wavelengths < 380 nm) on firn air mixing ratios at 10 cm snow depth was up to 300 pptv or 30% decrease in mixing ratios of NO, whereas mixing ratios of  $\text{NO}_2$  increased at the same time by  $\sim 150$  pptv or 5%, although often not statistically significant (Fig. 4c and d). Similar to the solar eclipse, the behavior of  $\text{NO}_x$  mixing ratios in firn air is in accordance with a disruption of the fast gas phase interconversion of  $\text{NO}_x$  species. Decrease of NO and increase of  $\text{NO}_2$  mixing ratios are consistent with the suppression of  $\text{NO}_2$  photolysis, which is both a NO source and a  $\text{NO}_2$  sink.

Most importantly varying incident UV irradiance in the wavelength region of  $\text{NO}_3^-$  absorption (action spectrum maximum at 320 nm) over half-hourly time scales does not cause a depletion of  $\text{NO}_2$  in firn air even though  $\text{NO}_2$  is the main product of  $\text{NO}_3^-$  photolysis in the snowpack. A dampened UV response of  $\text{NO}_2$  mixing ratios suggests that the  $\text{NO}_x$  reservoir present in the open pore space of the upper snow pack discussed above must be large as it is not depleted during 30 min filter changes at the sample pump rates used. One implication is that the impact of changes in incident UV irradiance on the snow source and thus  $\text{NO}_x$  flux and mixing ratios is only observable on diurnal and seasonal time scales.

### 3.4 $\text{NO}_2$ : NO ratios, peroxy and halogen radicals

In 2011–2012 the  $\text{NO}_2$  : NO ratios at 1.0 m were up to 3 times larger than in 2009–2010 (Table 2). A previous steady-state analysis indicated that high peroxy and possibly halogen radical levels must be present to explain large deviations from the simple Leighton steady-state (Frey et al., 2013). The OPALE campaign provided observations needed to further investigate the  $\text{NO}_2$  : NO ratios at Dome C.

During summer 2011–2012 median concentrations of  $\text{RO}_2$  radicals at 3 m, thought to consist mainly of  $\text{HO}_2$

and  $\text{CH}_3\text{O}_2$ , were  $9.9 \times 10^7$  molecule  $\text{cm}^{-3}$  (Kukui et al., 2014).

Figure 5 shows the BrO results, where the apparent vertical amounts at  $15^\circ$  are much larger than those at lower elevations – ~~the AMFs are incorrect, and this shows that the vertical profile of BrO used to calculate AMFs, whereby all the BrO is in the boundary layer, must be incorrect. And~~ interestingly, as at Halley in 2007 (Roscoe et al., 2014), much of the BrO must be in the free troposphere. The average of BrO at the three elevations is about  $0.8 \times 10^{13}$  molecule  $\text{cm}^{-2}$ , with a slight decrease during the campaign. The average at Halley in 2007 was about  $2.5 \times 10^{13}$  molecule  $\text{cm}^{-2}$ , so mixing ratios of BrO at Dome C are about a third those at Halley. The Dome C data were not inverted to determine the mixing ratio near the surface, but the changes in slant column with elevation angle are similar to those at Halley in 2007 (Roscoe et al., 2014). ~~So if the Halley inversion results are simply divided by 3, based on the similarity of relative changes of slant BrO with elevation angles to those of Halley in 2007, and the approximate ratio of the slant columns at Halley in 2007 to those at Dome C of 3, the Dome C values imply 2–3 pptv of BrO near the surface. Higher levels prevailing in the free troposphere possibly originate from a sea ice source in coastal Antarctica (Theys et al., 2011) or from stratospheric descent (Salawitch et al., 2010).~~

Assuming steady-state the total radical concentration  $[\text{OX}] = [\text{HO}_2] + [\text{RO}_2] + 2[\text{XO}]$ , with  $\text{XO} = \text{BrO}$ , can be calculated based on observed  $\text{NO}_2$  : NO ratios and  $J(\text{NO}_2)$  (Ridley et al., 2000). Repeating the calculation as described in Frey et al. (2013) for 19 December 2011 to 9 January 2012 yields a median  $[\text{OX}]$  of  $2.2 \times 10^9$  molecule  $\text{cm}^{-3}$  or 116 pptv. ~~Median – However, during the same period observations showed a median concentration of  $9.9 \times 10^7$  molecule  $\text{cm}^{-3}$  or 5 pptv observed during the same period (Kukui et al., 2014) and of  $[\text{RO}_2] + [\text{HO}_2]$  (Kukui et al., 2014) and approximately 3 pptv of BrO yield – BrO, yielding a total radical concentration  $[\text{OX}]$  of 11 pptv. Hence, the estimated total radical concentration exceeds  $[\text{OX}]$  deduced from measured  $\text{NO}_2$  : NO ratios exceeds available observations by a factor 10.3. To estimate the impact of  $\text{NO}_2$  mixing ratios were then corrected for a potential interference by  $\text{HO}_2\text{NO}_2$  we corrected the mixing ratios, assuming that additional is measured in the CLD from thermal decomposition, equivalent to 25% (100%) of ambient on the order –, assuming ambient levels of 130 pptv. We then find It is found that the median steady-state estimate of total oxidant concentrations is still a factor 9.6 (3.3) larger than that observed –. Thus, only a part of the inconsistency may be~~

~~explained by the interference with (not measured) larger than the sum of observed radical mixing ratios.~~  
 Hence, the large  $\text{NO}_2 : \text{NO}$  ratios observed at Dome C are either the result of an unknown measurement bias or of an unidentified mechanism in boundary layer oxidation chemistry. A similar conclusion was reached in companion papers on the OPALE project (e.g. Legrand et al., 2014; Kukui et al., 2014; Savarino et al., 2015).

### 3.5 Drivers of seasonal $\text{NO}_x$ variability

On diurnal time scales  $\text{NO}_x$  mixing ratios at Dome C are controlled by the interplay between snowpack source strength and atmospheric physical properties, i.e. turbulent diffusion of heat  $K_h$  and mixing height  $h_z$  of the boundary layer. The median diurnal cycles of  $\text{NO}_x$  mixing ratios in 2011–12 show with the exception of Period II. (~~1–8 December~~) previously described behaviour (Frey et al., 2013), that is a strong increase around 1800 LT to maximum values, which last into the night time hours (Fig. 6a). Night-time peaks of  $\text{NO}_x$  are plausible if the weakening of snow emissions is offset by a corresponding decrease of the chemical sink of  $\text{NO}_x$ , i.e. the  $\text{NO}_2 + \text{OH}$  reaction, assuming no significant change in  $h_z$ . This is consistent to a first order taking into account that observed OH concentrations (Kukui et al., 2014) and  $F_{\text{NO}_x}$  vary in a similar way, by up to a factor 5 between local noon and midnight.

During Period III. (~~9–22 December 2011~~) noon time values are similar to Period II. but the increase in the evening has a larger amplitude and generally larger mixing ratios prevail during night time (Fig. 6a). Increased  $\text{NO}_x$  mixing ratios during Period III. are consistent with the observed  $\text{NO}_x$  emission flux  $F_{\text{NO}_x}$ , which always peaked at local noon, but also showed during Period III. a strong increase at all times of the day with a near doubling of the noon time median (Fig. 6b). During Period IV. (~~23 December 2011–2012 January 2012~~) the diurnal cycles of both  $\text{NO}_x$  mixing ratios and  $F_{\text{NO}_x}$  returned to low values and small diurnal amplitudes (Fig. 6a–b).

Below we evaluate potential causes of the unusual variability in  $\text{NO}_x$  mixing ratios and flux observed on seasonal time scales.

#### 3.5.1 Atmospheric mixing vs. snow source strength

Similar to explaining diurnal  $\text{NO}_x$  cycles at Dome C the seasonal variability of daily mean  $\text{NO}_x$  mixing ratios during the first half of December 2011 can be attributed to a combination of changes in  $F_{\text{NO}_x}$  and  $h_z$  (Fig. 1). The strong increase of  $\text{NO}_x$  around 11 December 2011 falls into a Period when  $F_{\text{NO}_x}$  almost tripled, while wind speeds slightly decreased and shallow boundary layer heights prevailed (Fig. 1, Table 2). For example, on 12

December 2011 and 13 December 2011 the modelled diurnal ranges of  $h_z$  were 3.4–224 m and 3.6–251 m, respectively, while sodar observations yielded 10–150 m and 5–125 m, respectively (Gallée et al., 2015). After 13 December 2011  $F_{\text{NO}_x}$  remained at high values, thus, the decrease of  $\text{NO}_x$  mixing ratios appears to be primarily caused by stronger upward mixing into a larger volume, and wind speeds increased and daily  $h_z$  maxima grew, exceeding 600 m on 18 December 2011 (Fig. 1). After 23 December 2011  $\text{NO}_x$  mixing ratios drop to low levels, due to smaller  $F_{\text{NO}_x}$  and a deep boundary layer (Fig. 1).

$F_{\text{NO}_x}$  depends on atmospheric turbulence ( $K_h$ ) and concentration difference ( $\Delta\text{NO}_x$ ), which in turn is determined by the strength of the photolytic snow pack source at a given  $K_h$  (Eq. 1–2). However, the relative importance of  $K_h$  and snow pack source strength can vary. For example, during Period IV. (~~23 December 2011–12 January 2012~~) the median  $F_{\text{NO}_x}$  was  $1.3 \times 10^{13} \text{ molecule m}^{-2} \text{ s}^{-1}$ , about twice that observed during the same period in 2009–2010 (Fig. 6g; Table 2). The inter-seasonal difference can be explained by both, significantly larger atmospheric turbulence and more negative  $\Delta\text{NO}_x$  during all times of the day in 2011–2012 (Fig. 6h and i). Median  $K_h$  was  $0.08 \text{ m}^2 \text{ s}^{-1}$ , double that in 2009–2010, and median  $\Delta\text{NO}_x$  was  $-51 \text{ pptv}$  compared to  $-32 \text{ pptv}$  in 2009–2010 (Table 2).

In contrast, during 2011–2012 the observed intra-seasonal variability of  $F_{\text{NO}_x}$  is dominated by changes in the snow pack source strength. During Period III. (~~9–22 December 2011~~) median  $K_h$  values ( $\sim 0.05 \text{ m}^2 \text{ s}^{-1}$ ) and diurnal cycles were smaller than thereafter (Fig. 6c; Table 2), while  $\Delta\text{NO}_x$  values were among the largest observed so far at Dome C, about three times those during the rest of the season, and therefore primarily caused the tripling of  $F_{\text{NO}_x}$  (Fig. 6d and i). In section 3.5.2 we'll discuss underlying causes of changes in the strength of the snow source.

Previously, non-linear  $\text{HO}_x\text{-NO}_x$  chemistry and the associated increase in  $\text{NO}_x$  lifetime were suggested to be an additional factor needed to explain large increases in  $\text{NO}_x$  mixing ratios observed at South Pole (Davis et al., 2008, and references therein). In order to assess the relevance of this factor at Dome C we apply a simple box model to estimate net  $\text{NO}_x$  production rates as done previously (Frey et al., 2013). It is assumed that mixing is uniform and instantaneous, that the snow emission flux  $F_{\text{NO}_x}$  is the main  $\text{NO}_x$  source and the reaction with the OH radical is the dominant  $\text{NO}_x$  sink and

$$\frac{d[\text{NO}_x]}{dt} \sim \frac{F_{\text{NO}_x}}{h_z} - k[\text{NO}_2][\text{OH}] \quad (4)$$

where  $k$  is the respective reaction rate coefficient. In 2009–10 no OH observations were available at Dome C and average values from South Pole were used instead. In 2009–10 estimated net production rates of

NO<sub>x</sub> at night were on the order of 100 pptv h<sup>-1</sup> and therefore explained the average increase in NO<sub>x</sub> from 110 to 300 pptv observed from 1700 to 1900 LT (Frey et al., 2013). In 2011–12 the same analysis is repeated using OH measurements available for most of Period IV. (Kukui et al., 2014) as well as  $h_z$  calculated with the MAR model (Gallée et al., 2015). Resulting night time values of net NO<sub>x</sub> production rates are with about 40 pptv h<sup>-1</sup> smaller than in 2009–10 but again to a first order consistent with a smaller observed increase in NO<sub>x</sub> mixing ratios in the evening hours; i.e. during Period IV. median NO<sub>x</sub> increased between 1630 and 1930 LT from 114 to 242 pptv (Fig. 6a,f). The above model is oversimplified as the ~~very~~-likely presence of HO<sub>2</sub>NO<sub>2</sub> will modulate the diurnal variability of NO<sub>x</sub> sinks and sources with an impact on NO<sub>x</sub> lifetime as suggested by Davis et al. (2008). However without any information on the diurnal cycle of HO<sub>2</sub>NO<sub>2</sub> at Dome C further modelling is not warranted.

### 3.5.2 Snow source strength

The NO<sub>x</sub> flux observed above polar snow is on the order of 10<sup>12</sup> to 10<sup>13</sup> molecule m<sup>-2</sup> s<sup>-1</sup> and contributes significantly to the NO<sub>x</sub> budget in the polar boundary layer. At the lower end of the range are  $F_{\text{NO}_x}$  observations at Summit, Greenland (Honrath et al., 2002) and at Neumayer in coastal Antarctica (Jones et al., 2001) with 2.5 × 10<sup>12</sup> molecule m<sup>-2</sup> s<sup>-1</sup>, whereas on the Antarctic Plateau  $F_{\text{NO}_x}$  values are up to ten times larger. For example, the average  $F_{\text{NO}_x}$  at South Pole during 26–30 November 2000 was 3.9 × 10<sup>12</sup> molecule m<sup>-2</sup> s<sup>-1</sup> (Oncley et al., 2004), whereas at Dome C observed fluxes are 2–6 times larger, with seasonal averages of 8–25 × 10<sup>12</sup> molecule m<sup>-2</sup> s<sup>-1</sup> (Frey et al., 2013, this work). Due to the uncertainties in the processes leading to NO<sub>x</sub> production it had been difficult to explain inter-site differences, e.g. by simply scaling  $F_{\text{NO}_x}$  with UV irradiance and NO<sub>3</sub><sup>-</sup> in the surface snow pack (Davis et al., 2004). Some of the variability in flux values may be due to differences in experimental set up or in the employed flux estimation method (e.g. Davis et al., 2004; Frey et al., 2013). For example, the  $F_{\text{NO}_x}$  estimates for South Pole are based on measured NO gradients only, inferring NO<sub>x</sub> from photochemical equilibrium and using the Bowen ratio method (Oncley et al., 2004), whereas the  $F_{\text{NO}_x}$  estimates for Dome C are based on observations of both atmospheric nitrogen oxides (NO and NO<sub>2</sub>) and the flux-gradient method (Frey et al., 2013).

Model predictions of  $F_{\text{NO}_x}$  show in general a low bias on the Antarctic Plateau when compared to observations. A first 3-D model study for Antarctica included NO<sub>x</sub> snow emissions parameterised as a function of temperature and wind speed to match the observed  $F_{\text{NO}_x}$  at South Pole (Wang et al., 2007). How-

ever, the model under-predicts NO mixing ratios observed above the wider Antarctic Plateau highlighting that the model lacks detail regarding the processes driving the emission flux (Wang et al., 2007). The first model study to calculate  $F_{\text{NO}_x}$  based on NO<sub>3</sub><sup>-</sup> photolysis in snow, as described in this work, reports 1–1.5 × 10<sup>12</sup> molecule m<sup>-2</sup> s<sup>-1</sup> for South Pole in summer (Wolff et al., 2002), about a factor 4 smaller than the observations by Oncley et al. (2004) and up to 16 times smaller than what is needed to explain rapid increases in NO<sub>x</sub> mixing ratios over a few hours (Davis et al., 2008, and references therein). Recent model improvements reduced the mismatch with the South Pole flux observations and included the use of updated absorption cross sections and quantum yield of the NO<sub>3</sub><sup>-</sup> ion-anion, as well as e-folding depths measured in surface snow on the Antarctic Plateau, and resulted in a factor 3 increase of flux calculated for South Pole (France et al., 2011). In light of major remaining uncertainties, which include the spatial variability of NO<sub>3</sub><sup>-</sup> in snow and the quantum yield of NO<sub>3</sub><sup>-</sup> photolysis (Frey et al., 2013), we discuss below the variability of  $F_{\text{NO}_x}$  observed at Dome C.

A number of factors may contribute to changes in snow source strength of NO<sub>x</sub>. One possibility to explain increases in  $F_{\text{NO}_x}$  is that the NO<sub>2</sub> reservoir in the open pore space of the upper snowpack discussed above may undergo venting upon changes in atmospheric pressure. However, no statistically significant relationship between  $F_{\text{NO}_x}$  and atmospheric pressure is found (data not shown). The main cause of large  $F_{\text{NO}_x}$  values appears rather to be related to changes in snow production rates of NO<sub>x</sub> from NO<sub>3</sub><sup>-</sup> photolysis, which depend on the NO<sub>3</sub><sup>-</sup> photolysis rate coefficient  $J_{\text{NO}_3^-}$  and the NO<sub>3</sub><sup>-</sup> concentration in the photic zone of the snow pack (Eq. 3).

Trends in down-welling UV irradiance due to stratospheric O<sub>3</sub> depletion were suggested previously to drive  $J_{\text{NO}_3^-}$  and therefore  $F_{\text{NO}_x}$  and the associated increase in net production of surface O<sub>3</sub> observed at South Pole in summer since the 1990's (Jones and Wolff, 2003). At Dome C the observed increase in  $F_{\text{NO}_x}$  and strongly negative  $\Delta\text{NO}_x$  values coincided with a period when total column O<sub>3</sub> declined from > 300 to about 250 DU (Fig. 7a and c). During Period III. ~~(9–22 December 2011)~~ the median column O<sub>3</sub> was about 8% lower than during the time periods before and after (Table 2). However, associated changes in  $J_{\text{NO}_3^-}$  on the order of ~ 10% are too small to account alone for the observed tripling in  $F_{\text{NO}_x}$  (Fig. 6e; Table 2).

Instead changes in  $F_{\text{NO}_x}$  can be linked to the temporal variability of NO<sub>3</sub><sup>-</sup> present in the snow skin layer. During the end of Period II. and beginning of Period III. skin layer NO<sub>3</sub><sup>-</sup> concentrations were up to two times larger than before and after (Fig. 7b).  $F_{\text{NO}_x}$  is high during the

end of Period II. and beginning of Period III., however  
 985 drops off one week after the decrease of nitrate concentrations in surface snow (Fig. 7c). To confirm the link  
 990 between  $\text{NO}_x$  emissions and  $\text{NO}_3^-$  in snow  $F_{\text{NO}_2}$  values were modelled (Eq. 3) based on observed  $J_{\text{NO}_3^-}$ , daily  
 995 sampling of skin layer  $\text{NO}_3^-$  and two depth profiles, at 100 m (P1) and 5 km (P2) distance from the lab shelter,  
 1000 in order to account for spatial and temporal variability of  $\text{NO}_3^-$  in snow. Modelled  $F_{\text{NO}_2}$  capture some of  
 1005 the temporal trends in observational estimates of  $F_{\text{NO}_x}$  confirming the link with  $J_{\text{NO}_3^-}$  and  $\text{NO}_3^-$  concentrations  
 1010 (Fig. 7c). However, median ratios of observed  $F_{\text{NO}_x}$  and modelled  $F_{\text{NO}_2}$  values are 30–50 during Period III. and  
 1015 15–30 during Period IV. (Fig. 7c).

Disagreement between model and observations was  
 1020 previously attributed to ~~uncertainties in the the poorly~~  
 1025 ~~constrained~~ quantum yield of  $\text{NO}_3^-$  photolysis in natural snow (Frey et al., 2013). The model employed here uses  
 1030 a constant quantum yield, i.e. its value at the mean ambient temperature at Dome C ( $-30^\circ\text{C}$ ) of 0.0019 (Chu  
 1035 and Anastasio, 2003). However, quantum yield may vary  
 1040 with time, as the same lab study reports a positive relationship between quantum yield and temperature (Chu  
 1045 and Anastasio, 2003). Comparison of time periods before and after 18 December 2011 shows an increase of  
 1050 mean air temperature from  $-34.2^\circ\text{C}$  to  $-27.7^\circ\text{C}$  and  
 1055 a decrease of its mean diurnal amplitude from 13 to  
 1060 9.7 K (Fig. 1a). However, observations of  $F_{\text{NO}_x}$  showed  
 1065 behaviour opposite to that expected from a temperature  
 1070 driven quantum yield, i.e.  $F_{\text{NO}_x}$  values decreased as air  
 1075 temperature increased (Fig. 1a and d). Yet, the large  
 1080 diurnal amplitude of air temperature at Dome C could  
 1085 explain diurnal changes of  $F_{\text{NO}_x}$  by a factor 1.5–1.75. ~~The~~  
 1090 ~~temperature effect is however~~ ~~However, contributions~~  
 1095 ~~from the temperature effect are~~ small when compared to  
 1100 the up to 20-fold change between night and day ~~observed~~  
 1105 ~~in  $F_{\text{NO}_x}$ , which is driven by actinic flux~~. A recent lab  
 1110 study found that the quantum yield of photolytic loss of  
 1115  $\text{NO}_3^-$  from snow samples collected at Dome C decreased  
 1120 from 0.44 to 0.003 within what corresponds to a few  
 1125 days of UV exposure in Antarctica (Meusinger et al.,  
 1130 2014). The authors argue that the observed decrease in  
 1135 quantum yield is due to  $\text{NO}_3^-$  being made of a photo-  
 1140 labile and a photo-stable fraction, confirming a previous  
 1145 hypothesis that the range of quantum yields reflects the  
 1150 location of  $\text{NO}_3^-$  within the snow grain and therefore  
 1155 availability to photolysis (Davis et al., 2008; Frey et al.,  
 1160 2013). Thus, the  $F_{\text{NO}_x}$  values observed at Dome C fall  
 1165 well within the range of predictions based on quantum  
 1170 yield values measured in snow samples from the same  
 1175 site, which exceed that used in the current model by  
 1180 a factor 2–200. A systematic decrease in quantum yield  
 1185 due to depletion of photo-labile  $\text{NO}_3^-$  in surface snow  
 1190 may have contributed to the observed decrease in  $F_{\text{NO}_x}$

after 22 December 2011. However, a lack of information  
 on snow grain morphology or  $\text{NO}_3^-$  location within the  
 snow grain limits further exploration of the impact of  
 a time variable quantum yield on  $F_{\text{NO}_x}$ . It should be  
 noted that during 2009–2010 large skin layer  $\text{NO}_3^-$  values  
 did not result in  $F_{\text{NO}_x}$  values comparable to those in  
 2011–2012 which may be due to a different partitioning  
 between photo-labile and photo-stable  $\text{NO}_3^-$  in surface  
 snow (Fig. 7b and c; Table 2).

The consequences of large  $\text{NO}_x$  fluxes consist not only  
 in contributing to high  $\text{NO}_x$  mixing ratios but also in  
 influencing local  $\text{O}_3$  production, as suggested by significantly  
 higher surface  $\text{O}_3$  mixing ratios ( $> 30$  ppbv) during  
 9–22 December in 2011–2012 (Period III.) compared  
 to 25 ppbv in 2009–2010 (Fig. 7d).

## 4 Conclusions

Measurements of  $\text{NO}_x$  mixing ratios and flux carried out  
 as part of the OPALE campaign at Dome C in 2011–  
 2012 allowed to extend the existing data set from a previous  
 campaign in 2009–2010.

Vertical profiles of the lower 100 m of the atmosphere  
 confirm that at Dome C large diurnal cycles in solar  
 irradiance and a sudden collapse of the atmospheric  
 boundary layer in the early evening control the variability  
 of  $\text{NO}_x$  mixing ratios and flux. In contrast, at South Pole  
 diurnal cycles are absent and changes more due to synoptic  
 variability (Neff et al., 2008).  
~~Understanding atmospheric composition and air-snow  
 interactions in inner Antarctica requires studies at both  
 sites as they together encompass the spectrum of diurnal  
 variability expected across the East Antarctic Plateau  
 (King et al., 2006; Frey et al., 2013).~~ Large mixing  
 ratios of  $\text{NO}_x$  at Dome C arise from a combination of  
 several factors: continuous sunlight, large  $\text{NO}_x$  emissions  
 from surface snow and shallow mixing depths after the  
 evening collapse of the convective boundary layer. Unlike  
 at South Pole it is not necessary to invoke non-linear  
 $\text{HO}_x$ - $\text{NO}_x$  chemistry to explain increases in  $\text{NO}_x$  mixing  
 ratios. However, uncertainties remain regarding atmospheric  
 levels of  $\text{HO}_2\text{NO}_2$  and its impact on  $\text{NO}_x$  life time being  
 a temporary  $\text{NO}_x$  reservoir.  
~~Understanding atmospheric composition and air-snow  
 interactions in inner Antarctica requires studies at both  
 sites as they together encompass the spectrum of diurnal  
 variability expected across the East Antarctic Plateau  
 (King et al., 2006; Frey et al., 2013).~~

Firm air profiles suggest that the upper snow pack at  
 Dome C is an  $\text{O}_3$  sink and holds below a few e-folding  
 depths a significant reservoir of  $\text{NO}_2$  produced  
 photolytically above, whereas  $\text{NO}$  disappears at depths  
 devoid of UV as it reacts with  $\text{O}_3$ . Shading experiments  
 showed that the presence of such a  $\text{NO}_2$  reservoir dampens the

1090 response of  $\text{NO}_x$  mixing ratios above or within the snow-  
 pack due to changes in down-welling UV irradiance on 1145  
 hourly time scales. Thus, systematic changes in  $\text{NO}_x$   
 mixing ratios and flux due to the impact of UV on the  
 snow source are only observable on diurnal and seasonal  
 1095 time scales.

First-time observations of BrO at Dome C sug-1150  
 gest ~~2–3 that mixing ratios of BrO near the ground~~  
~~, with higher levels in the free troposphere similar~~  
~~to Halley, possibly originating from a sea-ice source~~  
~~in coastal Antarctica (Theys et al., 2011) or from~~  
 1100 ~~stratospheric descent (Salawitch et al., 2010) are low~~  
~~certainly less than 5 pptv. Assuming steady-state~~  
~~observed mixing ratios of BrO and  $\text{RO}_2$  radicals are~~  
~~about a factor ten too low to explain the  $\text{NO}_2$  :  $\text{NO}$~~   
~~ratios measured in ambient air. The likely presence~~  
 1105 ~~A potential interference of  $\text{HO}_2\text{NO}_2$  at Dome C~~  
~~(not measured) may cause an overestimate of with~~  
~~the detection method employed and explain a with~~  
~~the  $\text{NO}_2$  measurements explains only a small part~~  
 1110 ~~of this inconsistency. Hence, the large  $\text{NO}_2$  :  $\text{NO}$~~   
~~ratios observed at Dome C are either the result of an~~  
~~unknown measurement bias or of a yet unidentified~~  
~~mechanism in boundary layer oxidation chemistry,~~  
~~as similarly concluded in OPALE companion papers~~  
 1115 ~~(e.g. Legrand et al., 2014; Kukui et al., 2014; Savarino et al., 2015).~~

During 2011–2012  $\text{NO}_x$  mixing ratios and flux were  
 larger than in 2009–2010 consistent with also larger  
 surface  $\text{O}_3$  mixing ratios resulting from increased net  
 1120  $\text{O}_3$  production. Large  $\text{NO}_x$  mixing ratios and signifi-  
 cant variability during December 2011 were attributed  
 to a combination of changes in mixing height and  $\text{NO}_3^-$   
 snow emission flux  $F_{\text{NO}_x}$ . Trends in  $F_{\text{NO}_x}$  were found  
 to be controlled by atmospheric turbulence and the  
 1125 strength of the photolytic snowpack source, of which  
 the relative importance may vary in time. Larger median  
 $F_{\text{NO}_x}$  values in 2011–2012 than those during the  
 same period in 2009–2010 can be explained by both, sig-  
 1130 nificantly larger atmospheric turbulence and a slightly  
 stronger snowpack source. However, the tripling of  $F_{\text{NO}_x}$   
 in December 2011 was largely due to changes in snow  
 pack source strength driven primarily by changes in  
 $\text{NO}_3^-$  concentrations in the snow skin layer, and only  
 to a secondary order by the decrease of total column  
 1135  $\text{O}_3$  and the associated increase in  $\text{NO}_3^-$  photolysis rates.  
 Median ratios of observed  $F_{\text{NO}_x}$  and modelled  $F_{\text{NO}_2}$  val-  
 ues ranged from 15 to 50 using the quantum yield of  
 $\text{NO}_3^-$  photolysis reported by Chu and Anastasio (2003).  
 1140 Model predictions based on quantum yield values mea-  
 sured in a recent lab study on Dome C snow samples  
 (Meusinger et al., 2014) yield 2–200 fold larger  $F_{\text{NO}_2}$   
 values encompassing observed  $F_{\text{NO}_x}$ . In particular, a de-  
 crease in quantum yield due to depletion of photo-labile

$\text{NO}_3^-$  in surface snow may have contributed to the ob-  
 served decrease in  $F_{\text{NO}_x}$  after 22 December 2011. Yet in  
 2009–2010 large skin layer  $\text{NO}_3^-$  values did not result in  
 elevated  $F_{\text{NO}_x}$  values as seen in 2011–2012 possibly due  
 to different partitioning of  $\text{NO}_3^-$  between a photo-labile  
 and photo-stable fraction.

In summary the seasonal variability of  $\text{NO}_x$  snow  
 emissions important to understand atmospheric com-  
 position above the East Antarctic Plateau depends not  
 only on atmospheric mixing but also critically on  $\text{NO}_3^-$   
 concentration and availability to photolysis in surface  
 snow, as well as incident UV irradiance. However, the  
 1155 boundary layer chemistry of reactive nitrogen is not fully  
 understood yet. Future studies on the Antarctic Plateau  
 need to reduce uncertainties in  $\text{NO}_2$  and HONO mea-  
 surements, obtain also observations of  $\text{HO}_2\text{NO}_2$  and as-  
 sess how quantum yield of  $\text{NO}_3^-$  photolysis in snow varies  
 as a function of snow chemical and physical properties.  
 This is important to be able to close the mass budget of  
 reactive nitrogen species between atmosphere and snow  
 above Antarctica.

Acknowledgements. M. M. Frey is funded by the Natural  
 Environment Research Council through the British Antarc-  
 tic Survey Polar Science for Planet Earth Programme. This  
 study was supported by core funding from NERC to BAS's  
 Chemistry & Past Climate Program. The OPALE project  
 was funded by the ANR (Agence National de Recherche) con-  
 tract ANR-09-BLAN-0226. National financial support and  
 field logistic supplies for the summer campaign were pro-  
 vided by Institut Polaire Français-Paul Emile Victor (IPEV)  
 within programs No. 414, 903, and 1011. J. L. France and  
 M. D. King wish to thank NERC NE/F0004796/1 and  
 NE/F010788, NERC FSF 20 grants 555.0608 and 584.0609.  
 We thank B. Jourdain for assistance with balloon soundings  
 and firn air experiments, PNRA for meteorological data and  
 IPEV for logistic support. We are also grateful to J. Dibb and  
 D. Perovich for valuable input on the design of the firn air  
 probe. Collected data are accessible through NERC's Polar  
 Data Centre.

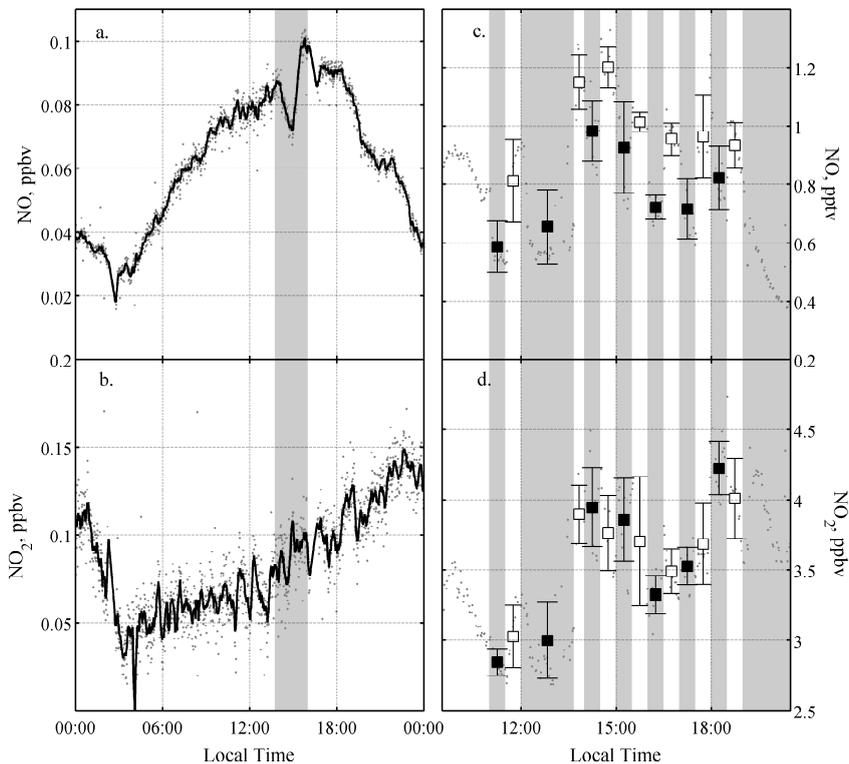

**Figure 1.** Meteorology and  $\text{NO}_x$  observations at Dome C in summer 2011–2012 (highlighted periods I.–IV. as referred to in text and Table 2): **(a)** air temperature ( $T$ ) at 1.6 m and modeled mixing height ( $h_z$ ) (Gallée et al., 2015), **(b)** wind speed (wspd) and direction (wdir) at 3.3 m **(c)**, 1 min averages of  $\text{NO}_x$  mixing ratios at 1 m (red line is 1 day running mean) and **(d)** 10 min averages of observational estimates of  $\text{NO}_x$  flux ( $F_{\text{NO}_x}$ ) between 0.01 and 1 m (red line is 14 day running mean).

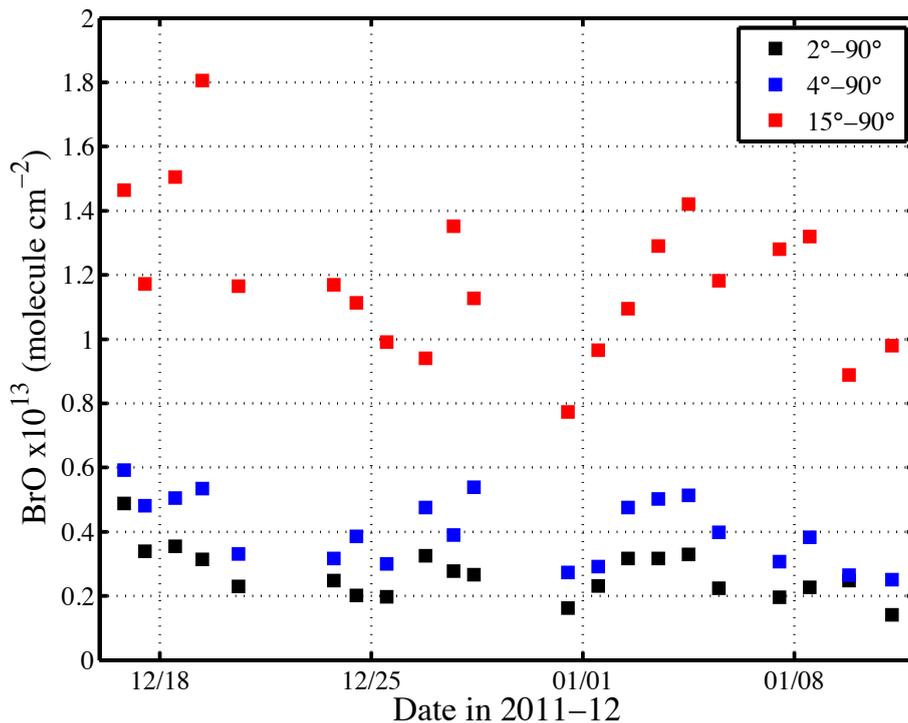

**Figure 2.** Balloon profiles (vertical dashed lines) from 9 January 2012: **(a)** modelled mixing height  $h_z$  (10 min running mean) and observed turbulent diffusion coefficient of heat  $K_h$  at 1 m (symbols: 10 min averages; black line: 30 min running mean). **(b)** interpolated vertical profiles of  $\text{NO}_x$  mixing ratios with contour lines representing 60 pptv intervals. The lower 100 m appear well mixed during the day, while after collapse of the convective boundary layer in the early evening snow emissions of  $\text{NO}_x$  are trapped near the surface causing a strong increase in mixing ratios near the ground.

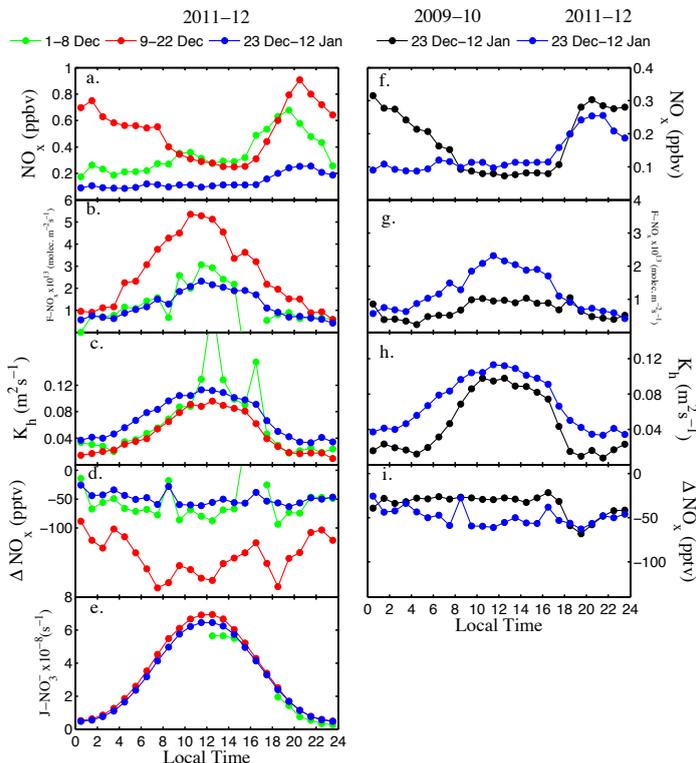

**Figure 3.** Firn air mixing ratios of (a)  $\text{NO}_x$  and (b)  $\text{O}_3$ , observed on 12 January 2012. Symbols represent 30 min averages. Solid and dashed lines are results from 20 m and 50 m long intake lines, respectively. Shown are also  $\text{NO}_3^-$  concentrations in snow at 100 m (P1) and 5 km (P2) distance from the lab shelter as well as from under the firn probe (P3).

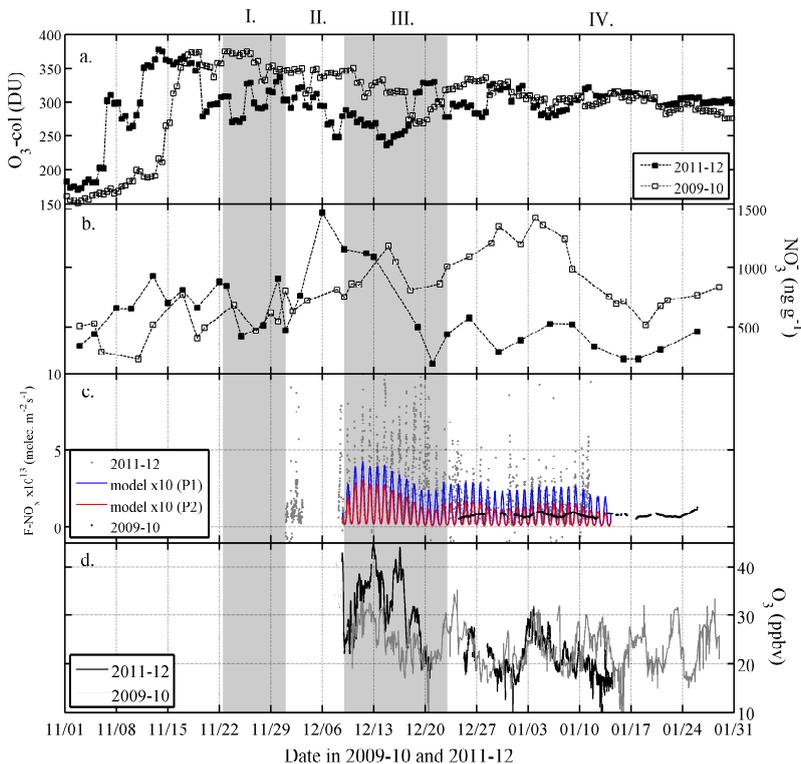

**Figure 4.** The impact of rapid changes in incident solar radiation on atmospheric NO<sub>x</sub> mixing ratios (1 min values). **(a–b)** ambient concentrations at 1 m during a partial solar eclipse on 25 November 2011 (shaded area) with black lines representing the 10 min running mean. **(c–d)** firm air concentrations at 10 cm depth during a shading experiment using UV-filters on 11 January 2012. Square symbols and error bars represent interval averages and standard deviation, respectively. Shaded areas and filled squares indicate time periods when the UV filter was in place.

**Figure 5.** Median daily values of MAX-DOAS BrO vertical amounts from Dome C during sunny days or part-days only, after subtracting zenith amounts (see text). Reference spectrum from near-noon on 18 December 2011 until 6 January 2012, then from near noon on 7 January 2012. The apparently larger vertical amounts at higher elevations show that much of the BrO is in the free troposphere.

**Figure 6.** Observed median diurnal cycles during selected intervals in **(a–e)** 2011–2012 (referred to as periods II–IV in Table 2, Figs. 1, 7) and **(f–i)** 2009–2010. Shown are **(a, f)**  $\text{NO}_x$  mixing ratios at 1 m, **(b, g)**  $\text{NO}_x$  flux ( $F\text{-NO}_x$ ) between 0.01 and 1 m, **(c, h)** the turbulent diffusion coefficient of heat ( $K_h$ ) at 1 m, **(d, i)** the difference in  $\text{NO}_x$  mixing ratios ( $\Delta\text{NO}_x$ ) between 1.0 and 0.01 m, and **(e)** the  $2\pi$  downwelling nitrate photolysis rate coefficient ( $J_{\text{NO}_3^-}$ ). Note comparable observations of  $J_{\text{NO}_3^-}$  are not available from 2009–2010.

**Figure 7.** (a) Total column  $O_3$  above Dome C. (b)  $NO_3^-$  concentrations in the skin layer of surface snow (top 0.5 cm). (c) observational estimates of  $NO_x$  flux ( $F_{NO_x}$ ) between 0.01 and 1 m (10 min averages) and modelled  $F_{NO_2}$  (multiplied by 10) based on  $NO_3^-$  in the skin layer and depth profiles observed at 100 m (P1) and 5 km (P2) distance from the lab shelter (see Fig. 3a); the 1 day running mean of  $F_{NO_x}$  during 2009–2010 is shown for comparison (from Frey et al., 2013) (d) atmospheric  $O_3$  mixing ratios. Highlighted periods I–IV, as referred to in text and Table 2.
