14	Abstract
15	
16	Among various factors that influence the long-range transport of pollutants in the free troposphere
17	(FT), the prevailing atmospheric weather states probably play the most important role in governing
18	characteristics and efficacy of such transport. The weather states, such as a particular wind pattern,
19	cyclonic or anticyclonic conditions etc, and their degree of persistency determine the spatio-temporal
20	distribution and the final fate of the pollutants. This is especially true in the case of Nordic countries,
21	where baroclinic disturbances and associated weather fronts primarily regulate local meteorology, in
22	contrast to the lower latitudes where convective paradigm plays similar important role. Furthermore,
23	the long-range transport of pollutants in the FT has significant contribution to the total column burden
24	over the Nordic countries. However, there is insufficient knowledge on the large-scale co-variability of
25	pollutants in the FT and atmospheric weather states based solely on observational data over this region.
26	The present study attempts to quantify and understand this statistical co-variability while providing
27	relevant meteorological background.
28	
29	To that end, we select eight weather states that predominantly occur over the Nordic countries and three
30	periods of their persistency (3-days, 5-days, and 7-days), thus providing in total 24 cases to investigate

31 sensitivity of free tropospheric carbon monoxide, an ideal tracer for studying pollutant transport, to

32 these selected weather states. The eight states include four dominant wind directions (namely, NW, NE,

33 SE and SW), cyclonic and anticyclonic conditions, and the enhanced positive and negative phases of

34 the North Atlantic Oscillation (NAO). For our sensitivity analysis, we use recently released Version 6

35 retrievals of CO at 500 hPa from the Atmospheric Infrared Sounder (AIRS) onboard Aqua satellite

- 36 covering 11-yr period from September 2002 through August 2013 and winds from the ECMWF's ERA-
- 37 Interim project to classify weather states for the same 11-yr period.

We show that, among the various weather states studied here, southeasterly winds lead to highest observed CO anomalies (up to +8%) over the Nordic countries while transporting pollution from the central and eastern parts of Europe. The second (up to +4%) and third highest (up to +2.5%) CO anomalies are observed when winds are northwesterly (facilitating inter-continental transport from polluted North American regions) and during the enhanced positive phase of the NAO respectively. Higher than normal CO anomalies are observed during anticyclonic conditions (up to +1%) compared to cyclonic conditions. The cleanest conditions are observed when winds are northeasterly and during the enhanced negative phases of the NAO, when relatively clean Arctic air masses are transported over the Nordic regions in the both cases. In case of nearly all weather states, the CO anomalies consistently continue to increase or decrease as the degree of persistency of a weather state is increased. The results of this sensitivity study further provide an observational basis for the process-oriented evaluation of chemistry transport models, especially with regard to the representation of large-scale coupling of chemistry and local weather states and its role in the long-range transport of pollutants in such models.

68 **1. Introduction**

69

70 Apart from the local sources of pollution that degrade local air quality and hence human health, many 71 studies show that, depending on the global and regional circulation patterns and favourable 72 meteorological conditions, the long range transport of pollutants also contributes to increased pollutant 73 concentrations. In fact, the importance of hemispheric and long range transport of pollutants is now 74 widely recognized in the scientific community, and the research focus in recent years has deservedly 75 been on better characterization of source-to-sink relationships and drivers of pollutant variability 76 during such transport (Brandt et al., 2012; Chin et al., 2007; Christoudias et al., 2012; Creilson et al., 77 2003; Dentener et al., 2010; Duncan and Bay, 2004; Eckhardt et al., 2003; Fiore et al., 2009; Huntrieser 78 et al., 2005; Li et al., 2002; Li et al., 2005; Lin et al., 2012; Pfister et al., 2004; Shindell et al., 2008; 79 Stohl et al., 2002; Trickl et al., 2003). It is important to keep in mind that it is the local meteorology 80 and synoptic scale weather patterns that eventually determine the spatio-temporal distribution of 81 pollutants, their transport characteristics and final fate. One of the main mechanisms by which the 82 pollutants (e.g. from wildfire emissions) get transported from their source regions to the Earth's 83 northern most latitudes as far as the Arctic is through varying states of atmospheric circulation. This 84 was first realized through the phenomenon of Arctic haze observed during the winter/spring months 85 that was first reported in the 1950s (Quinn et al., 2007). It is now known that the major pathways to the 86 Arctic depend upon the season and the position of the Arctic front. For example, during the winter and 87 spring months, the intense Siberian high pressure system pushes the Arctic front towards the south 88 whereby the polluted regions of the Eurasian subcontinent are within the Arctic airmass resulting in the 89 efficient transport of pollutants during this time of the year.

90

91 The spatio-temporal distribution of pollutants over the Nordic countries is a result of complex interplay 92 of local sources, atmospheric circulation patterns, and contributions from the long range transport 93 originating from North America, continental Europe and Asia. The dominant modes of atmospheric 94 variability in the northern hemisphere affecting the Nordic countries, especially in winter, are the North 95 Atlantic Oscillation (NAO) and Arctic Oscillation (AO). The positive and negative phases of NAO are 96 marked by changes in the wind speed and direction over the Atlantic, heat and moisture transport 97 across the Atlantic. The frequency and intensity of the number of storms and warm conveyer belts 98 influence the transatlantic transport of pollutants from North America to Europe, including over the 99 northern European latitudes (Hurrel et al., 2003; Li et al., 2002; Dentener et al., 2010; Duncan and Bey, 100 2004). Eckhardt et al., (2003) observed a strong correlation between the NAO and transport of 101 anthropogenic pollution into the Arctic and Eastern Europe from all the NH continents with an 102 enhanced transport during the positive NAO phase. However, a significant anti-correlation is observed 103 between NAO and the anthropogenic pollutants over western and central Europe (Christoudias et al., 104 2012). Significant correlations between the positive phase of AO and elevated ozone concentrations in 105 western Europe is observed and can be attributed largely to in-situ production associated with the 106 subsidence within the high pressure dome or entrainment of pollutants into this dome (Creilson et al., 107 2005). Pfister et al., (2004) showed that when averaged over Europe, almost 67% of the anthropogenic 108 carbon monoxide (CO) at the surface comes from regional sources, in addition to the transport from 109 North America (14%) and Asia (15%). However, at higher altitudes, the contribution from North 110 America and Asia is significantly higher. Brandt et al., (2012) using the 3D long range chemistry 111 transport hemispheric model showed that the contributions from North American anthropogenic 112 emissions to the ozone levels in European subcontinent is 3.1% and the contributions from European 113 anthropogenic sources to North America is 0.9%.

114

115 One of the major pathways carrying pollutants from the continental Europe to the Arctic passes over 116 the Nordic countries. Tang et al., (2009) studied the long range transport and weather patterns relating 117 to high ozone events in southern Sweden and using a trajectory model showed that these events 118 occurred during anticyclonic events, especially during summer and vice versa. Most recently, 119 Devasthale and Thomas (2012) investigated co-variation of temperature inversions and CO over 120 Scandinavia during winter using satellite sensor data and showed that the increased levels of CO are 121 observed when westerly winds are stronger during relatively unstable conditions. Apart from long 122 range transport of pollutants in the free troposphere (FT), in cold climate of the Nordic countries, 123 unfavorable meteorological conditions such as thermal inversions, low boundary layer height and low 124 temperatures can contribute to increased pollutant concentrations in the lowermost troposphere near the 125 surface. The above mentioned studies emphasize on the need for a better quantification of the linkages 126 between the pollutant concentrations and atmospheric weather states.

127

128 Many of the studies mentioned above examine CO, since CO is often considered as an excellent tracer

129 to investigate pollution transport characteristics due to its moderate life-time in the atmosphere.

130 Increased carbon monoxide levels would not only enhance carbon dioxide levels in the atmosphere

131 through its reaction with hydroxyl (OH) radicals, but also indirectly increase concentrations of short-

132 lived climate pollutants such as ozone and methane, which would otherwise be depleted by OH

radicals. Therefore, monitoring CO and understanding its sensitivity to large-scale weather patterns,

134 based solely on observations, is important not only to gain insights into long range pollution transport,

but also to serve as an observational basis for the sensitivity studies to evaluate chemistry transportmodels.

137

138 In spite of their importance as mentioned above, there is no consistent observationally based 139 assessment of how the dominant weather states impact free tropospheric CO variability over the Nordic 140 countries. The present study attempts to partially fill this gap. Decreased instrument sensitivity over 141 very cold surfaces, variable snow cover, difficulties in cloud detection etc are some of the factors that 142 limit the use of satellite remote sensing to study the atmospheric composition variability over the 143 Nordic regions, especially in the lowermost troposphere. But the data records of atmospheric 144 composition from satellite sensors, esp. from hyperspectral sounders such as IASI (Clerbaux et al., 2009) and AIRS (Chahine et al., 2006), are continuously improving and we now have better 145 146 understanding of their retrieval quality and sensitivities. More than a decade long data, e.g. from AIRS 147 and MOPITT, can be exploited to investigate statistics on the large-scale co-variability of weather 148 states and trace gases, as attempted here.

149

In the next section, we describe the data set used and methodology adopted, followed by presentation of an overview of dominant atmospheric circulation patterns and corresponding meteorological conditions over the Nordic region, with specific focus on Sweden, in Section 3. We then discuss sensitivity of CO to these patterns and persistency of these patterns in Section 4. The final section presents conclusions.

155

156 2. The Atmospheric Infrared Sounder (AIRS) CO and ERA-Interim data sets

- 157
- 158 AIRS onboard Aqua satellite has 2378 hyperspectral channels, out of which about 36 well-defined
- 159 channels with wavenumbers ranging from 2181.49 cm^{-1} to 2221.12 cm^{-1} are used in V6 to retrieve CO
- 160 (http://disc.sci.gsfc.nasa.gov/AIRS/documentation/v6_docs/v6releasedocs-
- 161 <u>1/V6_Retrieval_Channel_Sets.pdf</u>). A priori profiles (sets of 100 layers) with monthly granularity are
- 162 used to as a first guess. There profiles are based MOZART (Model for OZone And Related chemical
- 163 Tracers) monthly mean hemispheric profiles
- 164 (http://disc.sci.gsfc.nasa.gov/AIRS/documentation/v6_docs/v6releasedocs-
- 165 <u>1/V6_CO_Initial_Guess_Profiles.pdf</u>). By varying the geophysical state, the retrieval algorithm for CO

- 166 basically tries to minimize the weighted difference between clear-sky radiance and the radiance
- 167 computed using forward model. Using averaging kernels, the retrieval algorithm relates estimated CO
- 168 profile to "true" profile and a priori information. The algorithm details are described in Susskind et al.
- 169 (2003) and in Warner et al., (2007, 2010, and 2013).
- 170
- We use recently released Version 6, daily standard and support Level 3 retrievals of CO (AIRS Science
 Team/Joao Texeira, 2013; AIRS-V6L3UG, 2013). Eleven years of data from September 2002 to and
 including August 2013 are analysed. The AIRS retrievals of temperature and CO are validated and
 matured considerably over the years to enable variability studies (Divakarla et al., 2006; Fetzer, 2006;
 Yurganov et al., 2008; Warner et al., 2007, 2010, 2013). The accuracy and biases of AIRS CO are well
 documented in the studies mentioned above.
- 177
- 178 Since the focus of the present study is on free troposphere, we have analysed CO at four different
- 179 vertical levels, namely 850hPa, 700hPa, 500hPa and 400hPa, but the results are shown only for
- 180 500hPa. The reasons for that are a) the signal of pollutant transport in the free troposphere is most
- 181 tangible at this level, b) coincidently AIRS retrievals are of best quality at this level (Yurganov et al.,
- 182 2008; Warner et al., 2010), and c) for the sake of brevity. The tendencies in CO observed at these four
- 183 vertical levels and corresponding wind patterns during selected weather states are not significantly
- 184 different, since many of the weather states, when they are persistent, affect the entire free troposphere
- 185 (as shown later).
- 186
- 187 We analyse AIRS retrievals only when the degrees of freedom value is larger than 0.5. For
- 188 investigating large-scale features and tendencies, as attempted in the present study, AIRS Level 3 CO
- 189 data are quite suitable as for example shown by Devasthale and Thomas (2012). Data from both
- ascending and descending passes of the afternoon Aqua satellite are used. We have allowed up to 30%
- 191 cloud cover while analysing the AIRS CO retrievals based on the findings of our sensitivity studies
- 192 (Devasthale and Thomas, 2012) and previous experience with AIRS data (Devasthale et al., 2010-13).
- 193 Susskind et al (2003) have previously presented detailed analysis of the accuracy of AIRS retrievals in
- 194 presence of clouds. The yield and accuracy of AIRS retrievals should not degrade significantly up to
- 195 30% cloud cover. Recently, Warner et al. (2013) showed that the AIRS CO retrievals in cloud
- 196 contaminated cases are of comparable quality. The degrees of freedom of the signal, an indicator of
- 197 information content, are reduced only by up to 0.2 in cloudy cases (please refer Figs. 3 and 4 in Warner
- 198 et al., 2013). The difference should even be smaller in our cases, since we allow only 30% cloud

199 contamination. Furthermore, the majority of opaque clouds occurring over the study area are low 200 clouds (cloud tops less than 700 hPa). Since we analysed retrievals at 500 hPa, the cloud impact is 201 estimated to be small. Finally, the absence of any spatial correlation between cloud fraction and 202 observed CO anomalies also suggests that the cloud impact is negligible. 203 204 The advantage of using AIRS data lies in the fact that a) the simultaneous retrievals of temperature and 205 humidity in time and space are available which can be used to understand thermodynamical properties 206 of the atmosphere and possible transport of heat and moisture during different weather states, b) the 207 longest (>11yr) data record of CO from hyperspectral measurements is available, and c) the synergy 208 with other A-Train sensors providing aerosol and cloud information can be exploited in future studies. 209 210 For investigating winds, we used 6 hourly zonal (u) and meridional (v) wind components from the 211 ECMWF's ERA-Interim reanalysis (Dee et al., 2011) for the same period when AIRS CO data are 212 available. 213 214 3. An overview of selected weather states 215 216 In the present study, we select 8 weather states that most frequently occur over the study area (42N-217 80N, 10W-40E). Figures 1-5 show an overview of circulation patterns and typical meteorological 218 conditions observed under these weather states. The states are selected based on the synthesis of 219 previous literature (e.g. Chen, 2000; Linderson, 2001) and further confirmed by manual inspection of 220 numerous weather reports from the Swedish Meteorological and Hydrological Institute. Since the 221 persistency of a weather state may enhance or reduce pollution levels in the free troposphere, for each 222 selected weather state, we have also investigated tendencies of CO anomalies under three persistency 223 periods, namely 3-days (P3), 5-days (P5) and 7-days (P7) respectively. For brevity, we present the 224 circulation patterns and meteorological conditions only for the P5 case, but the sensitivity results for 225 CO are shown for all weather states and persistency periods later in this study. 226 The eight identified weather states consist of four dominant wind directions (NW, NE, SE and SW), 227 228 anticyclonic and cyclonic conditions, and two enhanced phases of the NAO. In case of the first four 229 weather states, we chose the center (55N-60N, 12E-20E) of the study area (45N-80N, 10W-40E) to

average daily wind speed and direction at 850hPa from the ERA-Interim reanalysis. Based on these

231 daily averages we selected days when a particular wind direction prevailed and persisted for at least 3,

- 232 5 and 7 days. The same procedure is applied for selecting anticyclonic and cycloninc conditions based 233 on average mean sea level pressure (MSLP) over the center of the study region. For the remaining two 234 weather states, the selection of days is based on NAO indices. The overlapping dates among weather 235 states are intuitively avoided by the algorithm, but they are inclusive within their persistency periods. 236 For example, when a particular weather state persists for 7 consecutive days, then the first three and 237 five days of such event are included in the corresponding P3 and P5 cases as well.
- 238

239 During the selected 11-yr study period, relatively speaking, these states occur 9%, 3%, 4%, 14%, 28%,

240 27%, 6% and 9% of the time respectively. The number of events studied for each state is mentioned in

241 Table 1. The probability of a particular weather state prevailing over the study area decreases with

242 increasing persistency. Consequently, the results for 7-day periods, shown later, are in some cases

243 patchy. However, the CO anomalies exceed at least one standard deviation and hence are significant.

244 Figs. 1 and 2 show the composites of wind direction and strength at 850 hPa for the P5 case for much

- 245 broader area to better understand the pathways of the air masses entering the study area. The actual
- 246 stud area is marked by black rectangles.
- 247

248 When the winds are of NW origin, the air masses are transported from across the northernmost Atlantic 249 into the Nordic countries and Eastern Europe (Fig. 1a). This results in colder than average temperatures 250 and drier conditions in the eastern parts of the study area and warmer and moist conditions in the west 251 as reflected in Fig. 5 that shows the corresponding temperature anomalies. However, when the winds 252 have a NE component, the airmasses transported across the Atlantic from North America travel 253 northward almost perpendicular to the latitude belts up to 75N is merged with the Arctic air mass and 254 merges with the anticyclonic flow with the center of this flow located over southern Norway (Fig. 1b). 255 This anticyclonic flow further transports heat from the continental Europe and eastern Atlantic over the 256 Norwegian Sea as visible in Fig. 5. In the SW case, it can be seen that the air masses that travel to 257 Scandinavia likely originate from a much higher trajectory (north of 50N) in North America and are 258 mixed with east Atlantic gyre (Fig. 2a). The warm winds from the southerly latitudes (in comparison to 259 the NW case) cause warming of the middle troposphere over much of the eastern study area (Fig. 5). 260 The anticyclonic flow centered over Finland in the SE case draws in warm airmasses from the central 261 and eastern parts of Europe (Fig. 2b) also resulting in warmer temperatures (Fig. 5). 262

263 Another important characteristic of the Earth's atmosphere is pressure distribution as it defines the wind

264 and weather patterns globally. Fig. 3 shows the composites of the magnitude and wind direction at 850

265	hPa during high MSLP conditions and low MSLP conditions over the center of the study. During high
266	MSLP conditions, the winds seem to favour the transatlantic transport towards the northernmost
267	latitudes. The anticyclonic flow further circulates airmasses from the continental Europe to over
268	Norwegian Sea and the northern parts of the study area. On the other hand during low MSLP
269	conditions, the winds have a much lower trajectory in the Atlantic and the air masses advected from
270	across the Atlantic are transported over continental Europe and are caught up in the cyclonic flow
271	centered around central Scandinavia. The circulation pattern during anticylonic (cyclonic) conditions
272	leads to enhanced (reduced) heat and moisture transport over the western part of Scandinavia and
273	northeast Atlantic Ocean as shown in Fig. 5.
274	
275	The gradients in pressure and hence, the winds, force different types of oscillations. One such
276	prominent oscillation, manifested in boreal winter as a see-saw in pressure over the Atlantic, is the
277	North Atlantic Oscillation. As described in the introduction, the NAO phases play an important role in
278	the transatlantic transport of pollutants. Shown in Fig. 4 are respectively the 850 hPa winds associated
279	with enhanced positive (EP: NAO index $> +1$) and enhanced negative NAO conditions (EN: NAO
280	index $<$ -1) and when these conditions prevail for at least five consecutive days. The daily NAO index
281	for the period in study was downloaded from the following link
282	http://www.cpc.ncep.noaa.gov/products/precip/CWlink/pna/nao.shtml. The NAO index itself does not
283	show any significant trend during the last decade as shown in the Supplementary Figure S1.
284	
285	During the enhanced positive NAO phase, the winds are stronger and there is a significant advection of
286	air masses across the Atlantic from northern US and Canada into northern Europe and Scandinavia
287	(Fig. 4a). In fact, there is striking resemblance between warmer temperature anomalies (Fig. 5) and
288	wind pattern in the EP case, suggesting the efficiency of atmospheric transport. During the EN phase,
289	the winds are much weaker (Fig. 4b) and the cold Arctic air masses propagate into Scandinavian
290	countries (also clearly visible in Fig. 5) and there is a relatively stronger south westerly flow over
291	northern Europe.
292	
293	The normalized frequency of number of days of data available for each weather state as function of
294	months is shown in Fig. 6. The distribution of their occurrence is not always uniform as expected, since

- 295 different weather states are dominant during different times of a year except for anticyclonic and
- 296 cyclonic periods (i.e. during above normal and below normal MSLP conditions) when their
- 297 occurrences are distributed evenly. The frequency distribution of EP and EN phases is such that the

299 negative NAO phases during the other half of the year. This unequal distribution of samples as a 300 function of months makes it difficult to compare their relative impact of weather states on observed CO 301 levels due to interference of seasonality of CO. To address this, we calculate 11-yr annual climatology 302 of CO by taking a weighted average based on the distribution of occurrence for a particular state as a 303 function of month as follows. $C = \sum_{i=1}^{12} w_i * Cmc \lim$ 304 (1)where *i* is month, w_i is monthly weight (based on figure shown above), c_{mclim} is monthly 305 306 climatology of CO. We then subtract this climatology from the composite of CO observed under that state to compute 307 308 anomalies. This ensures that we remove the seasonal variations while comparing different states and 309 that the observed CO anomalies are indeed due to contribution from that particular weather state and its 310 persistency. 311 312 4. Sensitivity of CO to weather states and their persistency 313 314 The sources of CO over the study are mainly anthropogenic resulting from fossil fuel burning, 315 vehicular emissions and industrial activities. The biomass burning (natural and anthropogenic) also 316 contributes to the total CO budget. The seasonality in photochemical production and loss gains 317 importance with increasing altitude. This in combination with long-range and inter-continental 318 transport drives the seasonal variability of CO in the free troposphere over the study area. The 319 climatological seasonal distribution of CO at 500 hPa over is shown in the Supplementary Figure S2. 320 As expected the CO concentrations are higher in the late winter to early spring due to their increased 321 lifetime as the photochemical loss is at its minimum because of the lack of sunlight, and due to 322 increased emissions and efficient transport during this time of the year. The CO concentrations at 500 323 hPa show decreasing trend over the study area in all seasons during the 11-yr AIRS record. The 324 decrease is strongest in boreal spring (see Supplementary Figure S3). It is worth mentioning that this 325 trend is not likely to influence our analysis as the observed anomalies shown below often exceed the 326 trend and the analysed cases are randomly distributed in time without any strong bias toward particular 327 years. 328 329 Fig. 7 shows CO anomalies in the free troposphere (500 hPa) for four chosen wind directions and

enhanced positive NAO phases more prominent during the winter half of the year, while enhanced

330 persistency periods of P3, P5 and P7. Only statistically significant anomalies exceeding one standard 331 deviation are shown. When the winds are NW, above normal CO concentrations are observed over 332 northern Europe and CO anomalies increase significantly from P3 to P7. The examination of 333 circulation patterns and meteorological conditions for this weather state suggests that the NW air 334 masses may efficiently transport pollutants from across the Atlantic into the study region. The wind 335 speed also increases from P3 to P7. However, a different picture is observed when the winds are from 336 NE directions. In the P3 case, CO concentrations are much higher towards central Europe compared to 337 the Nordic countries. As the persistency of NE winds increases (from P3 to P7), reduced CO levels are 338 observed and the FT becomes comparatively clean. This can be explained by the fact that the 339 transatlantic pollutants that assimilate into the cyclonic flow observed during the NE cases are diluted 340 by the even stronger and cleaner Arctic air mass intrusions into Scandinavia under P7 period. When the 341 winds are SE, as mentioned before, the major pathway of pollution transport into the Nordic countries 342 is from central and Eastern Europe, as seen in Fig. 2. Comparatively much lower CO anomalies are 343 observed when the winds are SW. This may be because the air masses that travel to northern Europe 344 have their source regions from northern North American subcontinent (north of 45 N) which is comparatively cleaner than the air masses from other wind directions. The southwesterly winds are 345 346 further mixed with cleaner air masses by the Atlantic gyre.

347

348 The deviation of the CO concentrations under anticyclonic and cyclonic conditions and their 349 persistency is shown in Fig. 8. The CO concentrations are in general higher over northern Europe 350 during anticyclonic conditions compared to cyclonic. The CO concentrations continue to increase as 351 anticyclonic conditions persist, and vice versa for cyclonic situations. A careful analysis of wind 352 patterns reveal that, during anticyclonic conditions, the polluted air masses from continental Europe 353 and North America are being drawn and circulated over the Nordic regions whereas, during cyclonic 354 conditions, cleaner Arctic air is mixed in the circulation gyre thereby being more efficient in the 355 removal and dispersal of pollutants resulting in relatively cleaner conditions.

356

Lastly, the sensitivity of CO to NAO phases and their persistency is shown in Fig. 9. The CO anomalies are higher during the EP phase compare to the EN phase during all persistency periods. Furthermore, there is clear tendency that, as the positive phases of the NAO persist, CO concentrations tend to increase, especially in the higher latitudes. The free troposphere on the other hand becomes cleaner when the negative phases of NAO persist. When the westerlies are weakened, cold and clean Arctic air is drawn over the northern Europe during the negative phase. The tendencies in CO observed during positive and negative phases of NAO are consistent with previous studies that use models simulations
(Eckhardt et al., 2003; Christoudias et al., 2012). For example, from the analysis of 15-year
simulations, Eckhardt et al. (2003) show enhanced tracer transport to the Arctic that passes over the
Nordic countries during positive phases of the NAO. Christoudias et al. (2012) also arrive at similar
conclusion with regard to transport towards northern Europe.

368

369 To quantify the importance of the different synoptic states, Fig. 10 shows the percentage change in CO 370 at free troposphere observed during the different weather states and persistency periods over the study 371 area. It can be seen that in nearly all the cases, the CO concentrations either steadily increased or decreased with increased persistency of each weather state. The highest CO contribution, almost 4-8% 372 373 depending on the degree of persistency, is observed when the winds had a south-easterly component. 374 The second (up to 4%) and third highest (2.5%) anomalies are observed under NW winds and the 375 enhanced positive phases of the NAO respectively. The CO anomalies of completely opposite signs 376 during positive and negative phases of the NAO confirm the significance of the role of natural 377 variability in pollutant transport and diffusion. The anticyclonic and cyclonic conditions also show 378 opposite signs of CO anomalies, with maximum anomalies in the order of 1% observed during 379 anticyclonic conditions. The remaining weather states discussed in this study are more efficient in 380 reducing the build up of CO concentrations in the free troposphere, thereby lead to cleaner conditions. 381 It is to be kept in mind that these percentage changes in FT CO are based on averages and that the 382 individual short-term intrusion of pollution or strong but short-lived episodic transport can lead to 383 much higher changes in CO over the study area.

384

385 As mentioned earlier in Section 2, although we show results of CO variability at 500 hPa, we have 386 investigated this variability at four different levels in the free troposphere and in the total column CO as 387 well. As the persistency period of the chosen weather states increases, they are expected to affect the 388 CO variability in the entire troposphere in a systematic manner. This is evident in the Supplementary 389 Figure S4 that shows an example of the impact of wind directions on the total column CO variability. 390 The tendencies in CO total column anomalies under different wind directions and across persistency 391 periods are strikingly similar to those observed at 500 hPa. This underscores the importance of chosen 392 weather states in regulating CO variability *in the entire troposphere*. Under certain conditions, for 393 example very cold winters and surfaces, the sensitivity and information content of AIRS may peak only 394 in the middle troposphere and the total column values are affected by this problem. But keeping in 395 mind that our samples are spread across the entire year (not just in winter months) and that the

396	tendencies in CO anomalies are corroborated by wind and temperature anomaly patterns, it is most
397	likely that the results shown in S3 are realistic.
398	
399	Finally, it should be mentioned that, apart from the horizontal transport and photochemical production,
400	convective mixing is also likely to contribute the observed anomalies. But we argue that the impact of
401	the latter is minimal due to following reasons. Firstly, the boundary layer is decoupled from the free
402	troposphere most of the year due to presence of inversions (Devasthale and Thomas, 2012). Then the
403	circulation patterns manifest themselves in such a way that the Nordic countries are at the receiving
404	end of the large-scale energy descend or the eventual intercontinental or hemispheric transport of
405	pollutants to the Arctic is dominating in the free troposphere. And finally, the likelihood of strong
406	episodic vertical injections of pollutants exists only during summer months (via dry or moist
407	convection), but it is very small since such events are usually few in number. The Warm Conveyor
408	Belts (Madonna et al., 2014) contribute to the transport of pollutant in some of the weather states
409	studied here, but we do not see any inconsistency in our interpretations since, irrespective of the
410	mechanism that initiates the transport of the pollutants, it is local weather state at the receiving end
411	(e.g. our study area) that will regulate the distribution of these pollutants.
411	(e.g. our study area) that will regulate the distribution of these pollutants.
412	(e.g. our study area) that will regulate the distribution of these pollutants.

427 We investigated free tropospheric CO variability during eight weather states often prevailing over the
428 Nordic countries. Selected states include four wind directions (NW, NE, SE, and SW), anticyclonic and

429 cyclonic conditions, and positive and negative phases of the NAO. Furthermore, we investigated 430 tendencies in CO under three different degrees of persistency (3-day, 5-day and 7-day) of each weather 431 state. For nearly all the weather states, CO levels consistently continued to increase or decrease as the 432 degree of their persistency increased. Among the weather states studied here, relatively speaking, the 433 highest CO anomalies were observed when winds had southeasterly component, transporting pollutants 434 from the central and eastern European regions to over the Nordic countries. The second largest 435 contribution was from the northwesterly winds, most likely carrying pollutants as a result of long-range 436 transport from polluted North-American regions. The third largest anomalies are observed during 437 enhanced positive phase of the North Atlantic Oscillation, confirming the importance of this natural 438 variability in controlling pollutant distribution and transport over the study region. The cleanest 439 conditions were observed under prevailing northeasterly winds and the enhanced negative phase of the 440 NAO. The results from this sensitivity study provide an observational foundation for the process-441 oriented evaluation of chemistry transport models.

442

It must be mentioned that although we provide relevant information on atmospheric circulation and meteorology while inferring the potential role of long-range pollution transport in the observed sensitivity of CO to weather states, the actual attribution and precise quantification of contribution from different transport pathways must be done using trajectory or chemistry transport models.

Table 1: The number of events studied for each of the weather state and its persistency.

689 Fig. 1: Atmospheric circulation patterns at 850 hPa when winds (in m/s) are NW and NE over the center of the study area. The colorbar indicates wind strength (in m/s). The study area is marked with

black rectangle.

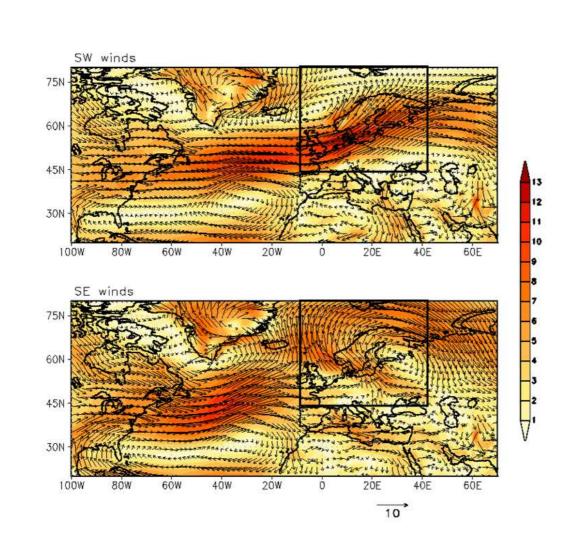

Fig. 2: Same as in Fig. 1, but for the SW and SE directions.

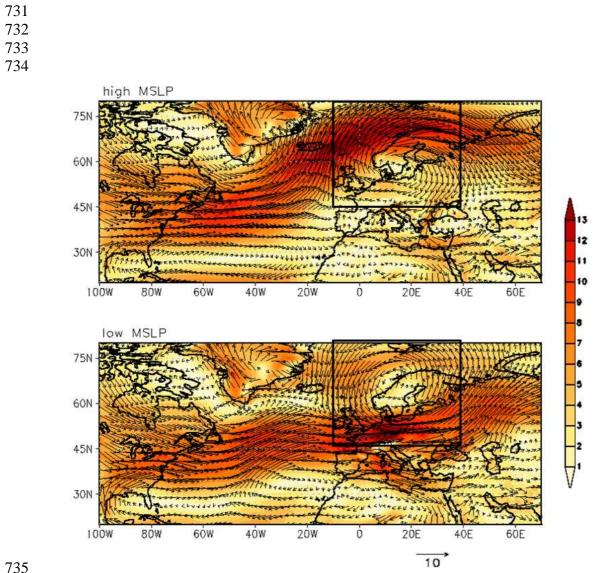

Fig. 3: Atmospheric circulation patterns at 850 hPa during high and low MSLP conditions.

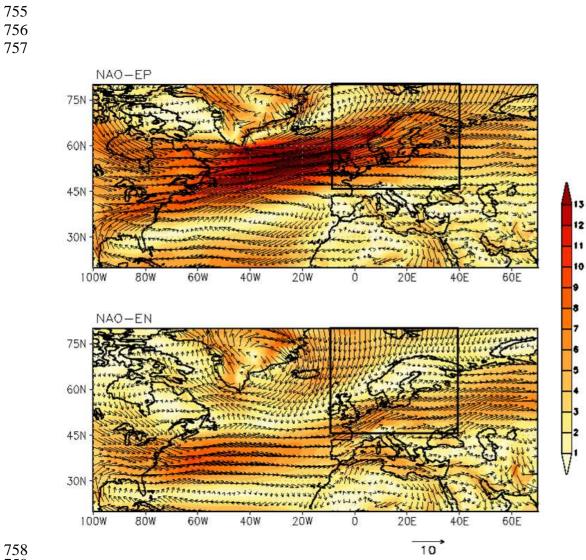

Fig. 4: Atmospheric circulation patterns at 850 hPa during enhanced positive and negative phases ofNAO.

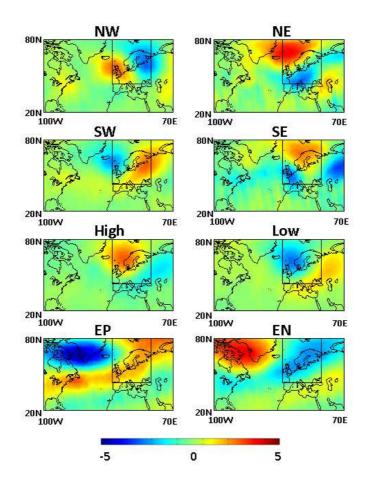

Fig. 5: Temperature anomalies at 850 hPa [in K] observed during selected weather states.

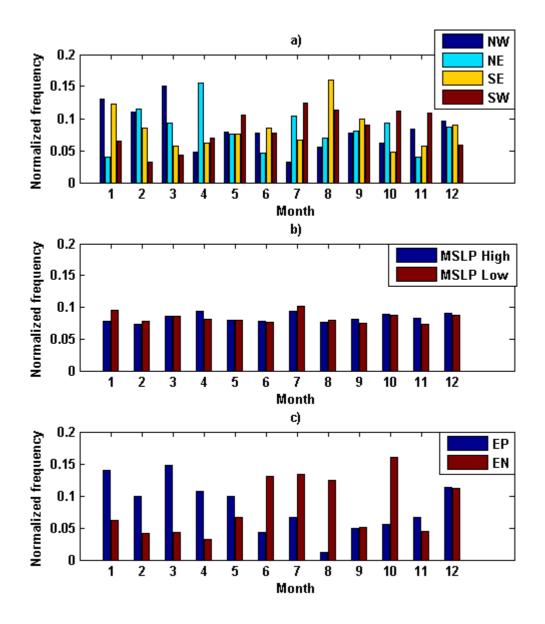

Fig. 6: Normalised distribution of the number of weather events as a function of month when they sustained for 5 days for a) wind directions, b) anticyclonic and cyclonic cases and c) for enhanced positive and negative NAO.

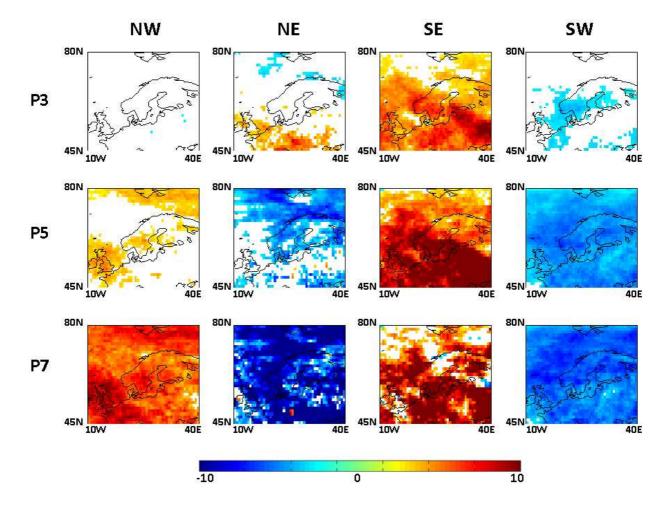

Fig. 7: CO anomalies (in ppbv) at 500 hPa observed under different wind conditions and their persistency periods. Only those anomalies exceeding one standard deviation are shown.

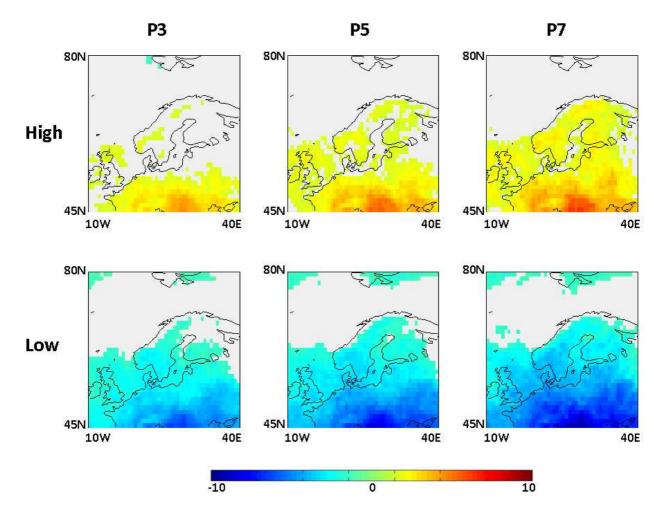

Fig. 8: Same as in Fig. 7, but under high and low MSLP conditions and their persistency periods.

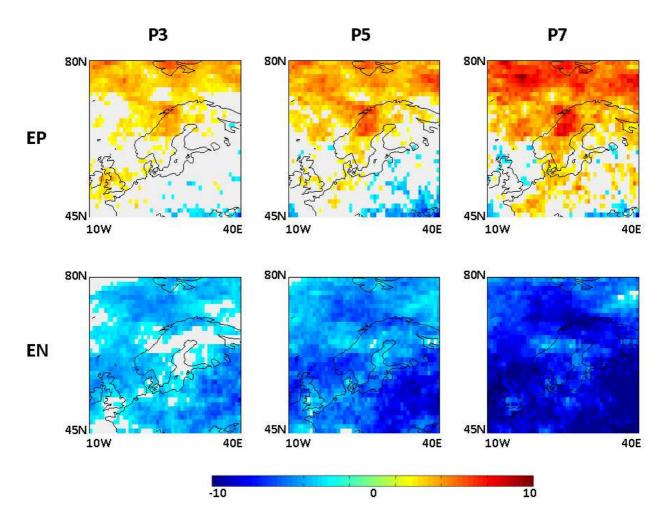

Fig. 9: Same as in Fig. 7 but under enhanced positive and negative phases of NAO and their
persistency periods.

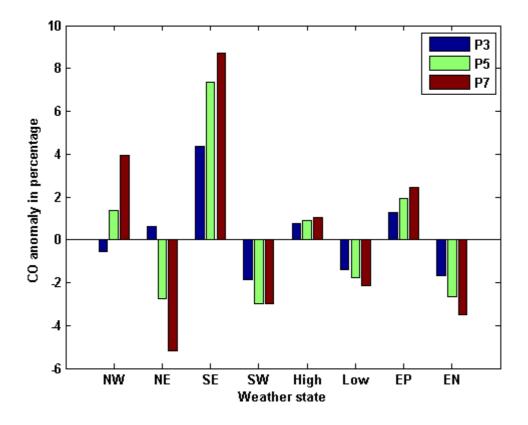

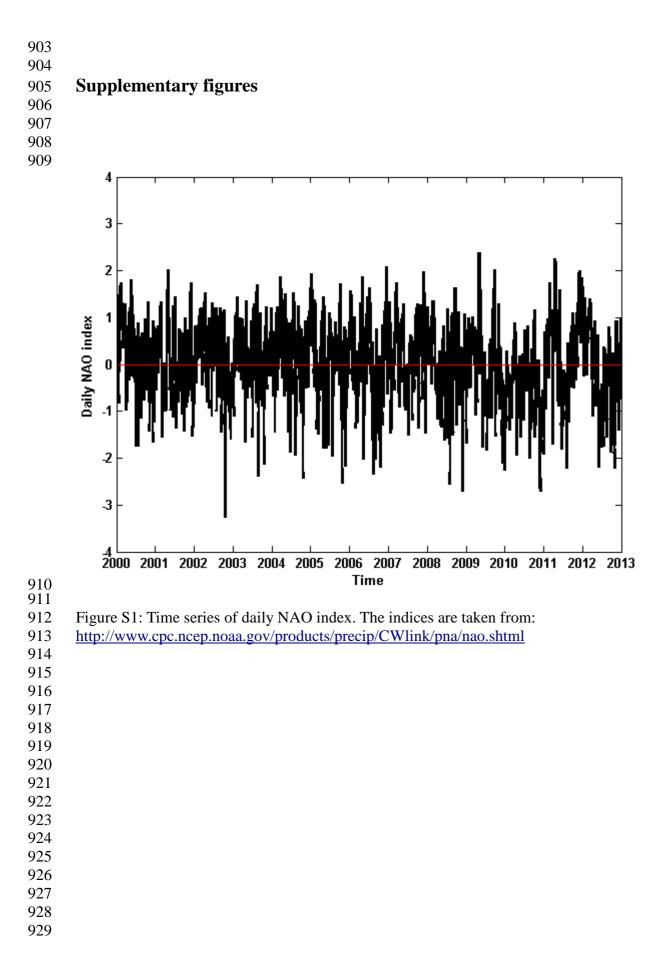

Fig. 10: Percentage increase or decrease in CO at 500 hPa observed during different weather states and
their persistency periods compared to respective weighted climatologies over the study area.

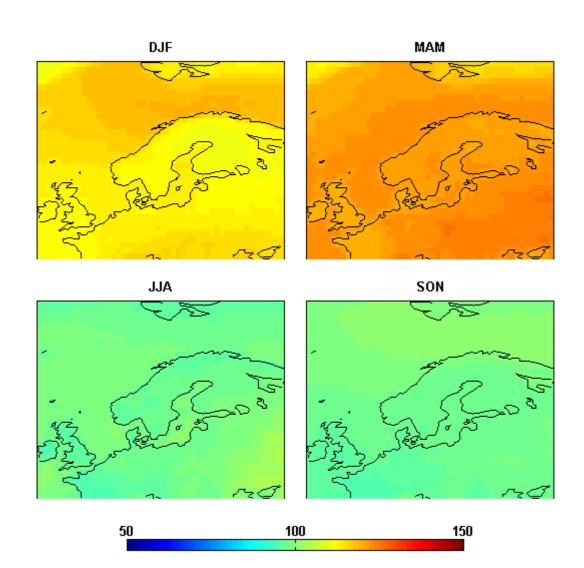

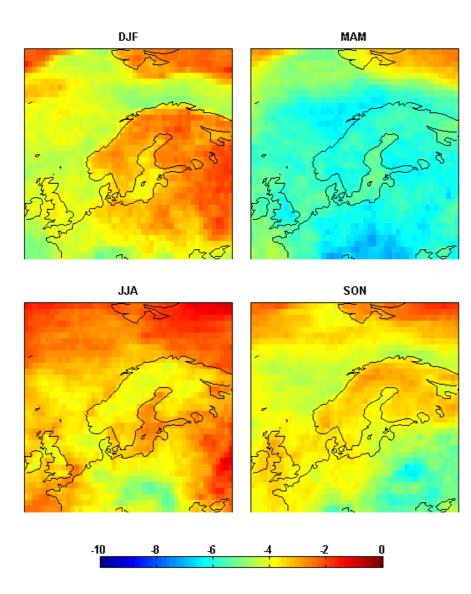

Figure S2: Mean seasonal CO (in ppbv) over the study area at 500 hPa. The entire 11-yr AIRS record is
used to compute means.

955 956 957 Figure S3: Seasonal trends in CO concentrations (in ppbv per decade) at 500 hPa based on 11-yr AIRS data.

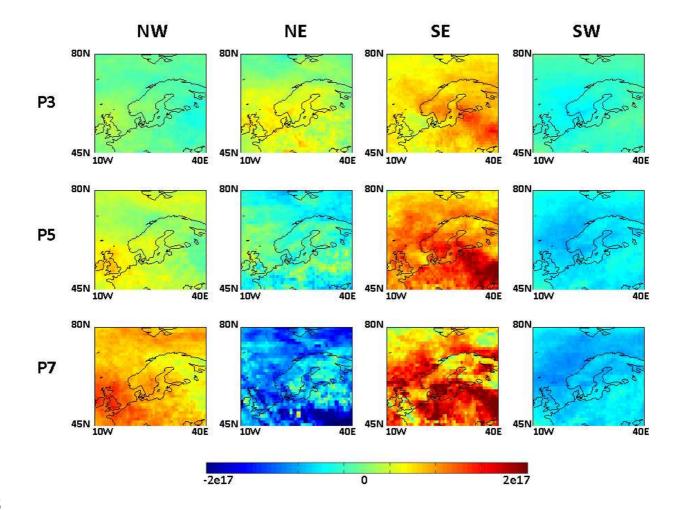

Figure S4: Total column CO anomalies (in molecules/cm²) under different wind conditions.
