Abstract

Ground-level ozone is a secondary pollutant produced photochemically from reactions of NO_x with peroxy radicals produced during VOC degradation. Chemical transport models use simplified representations of this complex gas-phase chemistry to predict

- ⁵ O₃ levels and inform emission control strategies. Accurate representation of O₃ production chemistry is vital for effective predictions. In this study, VOC degradation chemistry in simplified mechanisms is compared to that in the near-explicit MCM mechanism using a boxmodel and by "tagging" all organic degradation products over multi-day runs, thus calculating the Tagged Ozone Production Potential (TOPP) for a selection of VOC
- ¹⁰ representative of urban airmasses. Simplified mechanisms that aggregate VOC degradation products instead of aggregating emitted VOC produce comparable amounts of O₃ from VOC degradation to the MCM. First day TOPP values are similar across mechanisms for most VOC, with larger discrepancies arising over the course of the model run. Aromatic and unsaturated aliphatic VOC have largest inter-mechanisms
- differences on the first day, while alkanes show largest differences on the second day. Simplified mechanisms break down VOC into smaller sized degradation products on the first day faster than the MCM impacting the total amount of O₃ produced on subsequent days due to secondary chemistry.

1 Introduction

²⁰ Ground-level ozone (O₃) is both an air pollutant and a climate forcer that is detrimental to human health and crop growth (Stevenson et al., 2013). O₃ is produced from the reactions of volatile organic compounds (VOCs) and nitrogen oxides (NO_x = NO+NO₂) in the presence of sunlight (Atkinson, 2000).

Background O₃ concentrations have increased during the last several decades due to the increase of overall global anthropogenic emissions of O₃ precursors (HTAP, 2010). Despite decreases in emissions of O₃ precursors over Europe since 1990, EEA

(2014) reports that 98 % of Europe's urban population are exposed to levels exceeding the WHO air quality guideline of $100 \,\mu g \,m^{-3}$ over an 8 h mean. These exceedances result from local and regional O₃ precursor gas emissions, their intercontinental transport and the non-linear relationship of O₃ concentrations to NO_x and VOC levels (EEA, 2014).

Effective strategies for emission reductions rely on accurate predictions of O_3 concentrations using chemical transport models (CTMs). These predictions require adequate representation of gas-phase chemistry in the chemical mechanism used by the CTM. For reasons of computational efficiency, the chemical mechanisms used by global and regional CTMs must be simpler than the nearly-explicit mechanisms which can be used in box modelling studies. This study compares the impacts of different simplification approaches of chemical mechanisms on O_3 production chemistry focusing on the role of VOC degradation products.

$$NO + O_3 \rightarrow NO_2 + O_2$$
(R1

$$NO_2 + h\nu \rightarrow NO + O(^{3}P)$$
(R2

$$O_2 + O(^{3}P) + M \rightarrow O_3 + M$$
(R3)

The photochemical cycle (Reactions R1–R3) rapidly produces and destroys O_3 . NO and NO₂ reach a near-steady state via Reactions (R1) and (R2) which is disturbed in two cases. Firstly, via O_3 removal (deposition or Reaction R1 during night-time and near large NO sources) and secondly, when O_3 is produced through VOC–NO_x chemistry (Sillman, 1999).

VOCs (RH) are oxidised in the troposphere by the hydoxyl radical (OH) forming peroxy radicals (RO₂) in the presence of O₂ (Reaction R4). In high-NO_x conditions, typical of urban environments, RO₂ react with NO (Reaction R5) to form alkoxy radicals (RO),

which react quickly with O₂ (Reaction R6) producing a hydroperoxy radical (HO₂) and a carbonyl species (R'CHO). The secondary chemistry of these first generation carboncontaining oxidation products is analogous to the sequence (Reactions R4–R6), producing further HO₂ and RO₂ radicals. Subsequent generation oxidation products can

continue to react, producing HO₂ and RO₂ until they have been completely oxidised to CO₂ and H₂O. Both RO₂ and HO₂ react with NO to produce NO₂ (Reactions R5 and R7) leading to O_3 production via Reactions (R2) and (R3). Thus the amount of O_3 produced from VOC degradation is related to the number of NO to NO₂ conversions by RO_2 and HO_2 radicals formed during VOC degradation (Atkinson, 2000).

$$\begin{array}{ll} \mathsf{RH} + \mathsf{OH} + \mathsf{O}_2 \to \mathsf{RO}_2 + \mathsf{H}_2\mathsf{O} & (\mathsf{R4}) \\ \mathsf{RO}_2 + \mathsf{NO} \to \mathsf{RO} + \mathsf{NO}_2 & (\mathsf{R5}) \\ \mathsf{RO} + \mathsf{O}_2 \to \mathsf{R'}\mathsf{C}\mathsf{HO} + \mathsf{HO}_2 & (\mathsf{R6}) \\ \mathsf{HO}_2 + \mathsf{NO} \to \mathsf{OH} + \mathsf{NO}_2 & (\mathsf{R7}) \end{array}$$

- Three atmospheric regimes with respect to O_3 production can be defined (Jenkin and Clemitshaw, 2000). In the NO_x-sensitive regime, VOC concentrations are much higher than those of NO_{y} and O_{3} production depends on NO_{y} concentrations. On the other hand, when NO_x concentrations are much higher than those of VOC (VOC-sensitive regime), VOC concentrations determine the amount of O₃ produced. Finally, the NO_x-VOC-sensitive regime produces maximal O_3 and is controlled by both VOC and NO_x 15
- concentrations.

These atmospheric regimes remove radicals through distinct mechanisms (Kleinman, 1991). In the NO_x -sensitive regime, radical concentrations are high relative to NO_y leading to radical removal by radical combination Reaction (R8) and bimolecular destruction Reaction (R9) (Kleinman, 1994).

$$RO_2 + HO_2 \rightarrow ROOH + O_2$$
(R8)
$$HO_2 + OH \rightarrow H_2O + O_2$$
(R9)

$$HO_2 + OH \rightarrow H_2O + O_2$$

Whereas in the VOC-sensitive regime, radicals are removed by reacting with NO₂ leading to nitric acid (HNO₃) (Reaction R10) and PAN species (Reaction R11).

 $_{25}$ NO₂ + OH \rightarrow HNO₃

5

$$\mathsf{RC}(\mathsf{O})\mathsf{O}_2 + \mathsf{NO}_2 \to \mathsf{RC}(\mathsf{O})\mathsf{O}_2\mathsf{NO}_2$$

(R10)

(R11)

The NO_x-VOC-sensitive regime has no dominant radical removal mechanism as radical and NO_x amounts are comparable. This chemistry results in O₃ concentrations being a non-linear function of NO_x and VOC concentrations.

Individual VOC impact O_3 production differently through their diverse reaction rates and degradation pathways. These impacts can be quantified using Ozone Production Potentials (OPP) which can be calculated through incremental reactivity (IR) studies using photochemical models. In IR studies, VOC concentrations are changed by a known increment and the change in O_3 production is compared to that of a standard VOC mixture. Examples of IR scales are the Maximal Incremental Reactivity (MIR) and

- ¹⁰ Maximum Ozone Incremental Reactivity (MOIR) scales in Carter (1994), as well as the Photochemical Ozone Creation Potential (POCP) scale of Derwent et al. (1996, 1998). The MIR, MOIR and POCP scales were calculated under different NO_x conditions, thus calculating OPPs in different atmospheric regimes.
- Butler et al. (2011) calculate the maximum potential of VOC to produce O_3 by using NO_x conditions inducing NO_x-VOC-sensitive chemistry over multi-day scenarios using a "tagging" approach the Tagged Ozone Production Potential (TOPP). Tagging involves labelling all organic degradation products produced during VOC degradation with the name of the emitted VOC. Tagging enables the attribution of O_3 production from VOC degradation products back to the emitted VOC, thus providing a detailed in-
- ²⁰ sight into VOC degradation chemistry. Butler et al. (2011), using a near-explicit chemical mechanism, showed that some VOC, such as alkanes, produce maximum O_3 on the second day of the model run; in contrast to unsaturated aliphatic and aromatic VOC which produce maximum O_3 on the first day. In this study, the tagging approach of Butler et al. (2011) is applied to several chemical mechanisms of reduced complexity,
- ²⁵ using conditions of maximum O_3 production (NO_x-VOC-sensitive regime), to compare the effects of different representations of VOC degradation chemistry on O_3 production in the different chemical mechanisms.

A near-explicit mechanism, such as the Master Chemical Mechanism (MCM) (Jenkin et al., 2003; Saunders et al., 2003; Bloss et al., 2005), includes detailed degradation

chemistry making the MCM ideal as a reference for comparing chemical mechanisms. Reduced mechanisms generally take two approaches to simplifying the representation of VOC degradation chemistry: lumped structure approaches; and lumped molecule approaches (Dodge, 2000).

- Lumped structure mechanisms speciate VOC by the carbon bonds of the emitted VOC, examples are the Carbon Bond mechanisms, CBM-IV (Gery et al., 1989) and CB05 (Yarwood et al., 2005). Lumped molecule mechanisms represent VOC explicitly or by aggregating (lumping) many VOC into a single mechanism species. Mechanism species may lump VOC by functionality (MOdel for Ozone and Related chemical
- ¹⁰ Tracers, MOZART-4, Emmons et al., 2010) or OH-reactivity (Regional Acid Deposition Model, RADM2 (Stockwell et al., 1990), Regional Atmospheric Chemistry Mechanisms, RACM (Stockwell et al., 1997) and RACM2 (Goliff et al., 2013)). The Common Representative Intermediates mechanism (CRI) lumps the degradation products of VOC rather than the emitted VOC (Jenkin et al., 2008).
- ¹⁵ Many comparison studies of chemical mechanisms consider modelled time series of O_3 concentrations over varying VOC and NO_x concentrations. Examples are Dunker et al. (1984); Kuhn et al. (1998) and Emmerson and Evans (2009). The largest discrepancies between the time series of O_3 concentrations in different mechanisms from these studies arise when modelling urban rather than rural conditions and are attributed
- to the treatment of radical production, organic nitrate and night-time chemistry. Emmerson and Evans (2009) also compare the inorganic gas-phase chemistry of different chemical mechanisms, differences in inorganic chemistry arise from inconsistencies between IUPAC and JPL reaction rate constants.

Mechanisms have also been compared using OPP scales. OPPs are a useful comparison tool as they relate O₃ production to a single value. Derwent et al. (2010) compared the near-explicit MCM v3.1 and SAPRC-07 mechanisms using first-day POCP values calculated under VOC-sensitive conditions. The POCP values were comparable between the mechanisms. Butler et al. (2011) compared first day TOPP values to the corresponding published MIR, MOIR and POCP values. TOPP values were most

comparable to MOIR and POCP values due to the similarity of the chemical regimes used in their calculation.

In this study, we compare TOPP values of VOC using a number of mechanisms to those calculated with the MCM v3.2, under standardised conditions which maximise

⁵ O₃ production. Differences in O₃ production are explained by the differing treatments of secondary VOC degradation in these mechanisms.

2 Methodology

2.1 Chemical mechanisms

The nine chemical mechanisms compared in this study are outlined in Table 1 with a brief summary below. The reduced mechanisms in this study were chosen as they are commonly used in 3-D models and apply different approaches to representing secondary VOC chemistry.

The MCM (Jenkin et al., 1997, 2003; Saunders et al., 2003; Bloss et al., 2005; Rickard et al., 2015) is a near-explicit mechanism describing the degradation of 125 primary VOC. The MCM v3.2 is the reference mechanism in this study.

The CRI (Jenkin et al., 2008) is a reduced chemical mechanism describing the oxidation of the same primary VOC as the MCM v3.1. VOC degradation in the CRI is simplified by lumping the degradation products of many VOC into mechanism species whose overall O_3 production reflects that of the MCM v3.1. The full version of the CRI

- ²⁰ v2 (http://mcm.leeds.ac.uk/CRI) is used in this study. Differences in O_3 production between the CRI v2 and MCM v3.2 may be due to changes in the MCM versions rather than the CRI reduction techniques, hence the MCM v3.1 is also included in this study. MOZART-4 represents global tropospheric and stratospheric chemistry (Emmons et al., 2010). Explicit species exist for methane, ethane, propane, ethene, propene, isoprene and α -pinene. All other VOC are represented by lumped species determined
 - isoprene and α -pinene. All other VOC are represented by lumped species detection by the functionality of the VOC.

RADM2 (Stockwell et al., 1990) describes regional scale atmospheric chemistry with explicit species representing methane, ethane, ethene and isoprene. All other VOC are assigned to lumped species based on OH-reactivity and molecular weight. RADM2 was updated to RACM (Stockwell et al., 1997) with more explicit and lumped species
⁵ representing VOC as well as revised chemistry. RACM2 is the updated RACM version (Goliff et al., 2013) with substantial updates to the chemistry, including more lumped and explicit species representing emitted VOC.

CBM-IV (Gery et al., 1989) simulates polluted urban conditions and represents ethene, formaldehyde and isoprene explicitly while all other emitted VOC are lumped

- ¹⁰ by their carbon bond types. All primary VOC were assigned to lumped species in CBM-IV as described in Hogo and Gery (1989). For example, the mechanism species PAR represents the C–C bond. Pentane, having five carbon atoms, is represented as 5 PAR. A pentane mixing ratio of 1200 pptv would be assigned to 6000 (= 1200 × 5) pptv of PAR in CBM-IV. CBM-IV was updated to CB05 (Yarwood et al., 2005) by including further explicit encodes representing methane, others and asstaldebude. Other updates include
- plicit species representing methane, ethane and acetaldehyde. Other updates include revised allocation of primary VOC and updated rate constants.

2.2 Model Setup

The modelling approach and set-up follows the original TOPP study of Butler et al. (2011). The approach is summarised here; further details can be found in the Supple-²⁰ ment and in Butler et al. (2011). We use the MECCA boxmodel, originally described by (Sander et al., 2005), and as subsequently modified by Butler et al. (2011) to include MCM chemistry. In this study, the model is run under conditions representative of 34° N at the equinox (broadly representative of the city of Los Angeles, USA).

Maximum O_3 production is achieved in each model run by balancing the chemical source of radicals and NO_x at each timestep by emitting the appropriate amount of NO. These NO_x conditions induce NO_x -VOC-sensitive chemistry. Ambient NO_x conditions are not required as this study calculates the maximum potential of VOC to produce O_3 .

mechanism. Thus differences between the O_3 produced by the mechanisms are due to the treatment of organic degradation chemistry.

15

20

The MCM v3.2 approach to photolysis, dry deposition of VOC oxidation intermediates and RO₂-RO₂ reactions was used for each mechanism; details of these adaptations can be found in the Supplement. Some mechanisms include reactions which are only important in the stratosphere or free troposphere. For example, PAN photolysis is

format. The inorganic gas-phase chemistry described in the MCM v3.2 was used in each run to remove any differences between treatments of inorganic chemistry in each

only important in the free troposphere (Harwood et al., 2003) and was removed from 25 MOZART-4, RACM2 and CB05 for the purpose of the study, as this study considers processes occurring within the planetary boundary layer.

40 ppbv and then allowed to evolve freely. The VOCs used in this study are assigned to mechanism species following the recommendations from the literature of each mechanism (Table 1), the representation of each VOC in the mechanisms is found in Table 2. Emissions of lumped species are weighted by the carbon number of the mechanism species ensuring the total amount

were determined for the MCM v3.2. These emissions are subsequently used for each mechanism, ensuring the amount of each VOC emitted was the same in every model run. Methane (CH₄) was fixed at 1.8 ppmv while CO and O₃ were initialised at 200 and 10

Future work should verify the extent to which the maximum potential of VOC to produce O_3 is reached under ambient NO_x conditions.

Discussion VOCs typical of Los Angeles and their initial mixing ratios are taken from Baker 15, 12389–12422, 2015 et al. (2008), listed in Table 2. Following Butler et al. (2011), the associated emissions Paper ⁵ required to keep the initial mixing ratios of each VOC constant until noon of the first day A comparison of chemical mechanisms using Discussion **TOPP** analysis J. Coates and T. M. Butler Paper of emitted reactive carbon was the same in each model run. The MECCA boxmodel is based upon the Kinetic Pre-Processor (KPP) (Damian Abstract et al., 2002). Hence, all chemical mechanisms were adapted into modularised KPP

Discussion Paper

Discussion Paper

ACPD

2.3 Tagged Ozone Production Potential (TOPP)

This section summarises the tagging approach described in Butler et al. (2011) which is applied in this study.

2.3.1 O_x family and tagging approach

15

20

O₃ production and loss is dominated by rapid photochemical cycles, such as Reactions (R1)–(R3). The effects of rapid production and loss cycles can be removed by using chemical families that include rapidly inter-converting species. In this study, we define the O_x family to include O₃, O(³P), O(¹D), NO₂ and other species involved in fast cycling with NO₂, such as HO₂NO₂ and PAN species. Thus, production of O_x can be used as a proxy for production of O₃.

The tagging approach follows the degradation of emitted VOC through all possible pathways by labelling every organic degradation product with the name of the emitted VOC. Thus, each emitted VOC effectively has its own set of degradation reactions. Butler et al. (2011) showed that O_x production can be attributed to the VOC by following the tags of each VOC.

 O_x production from lumped mechanism species are re-assigned to the VOC of Table 2 by scaling the O_x production of the mechanism species by the fractional contribution of each represented VOC. For example, TOL in RACM2 represents toluene and ethylbenzene with fractional contributions of 0.87 and 0.13 to TOL emissions. Scaling the O_x production from TOL by these factors gives the O_x production from toluene and ethylbenzene in RACM2.

Many reduced mechanisms use an operator species as a surrogate for RO_2 during VOC degradation enabling these mechanisms to produce O_x while minimising the number of RO_2 species represented. O_x production from operator species is assigned

²⁵ as O_x production from the organic degradation species producing the operator. This allocation technique is also used to assign O_x production from HO₂ via Reaction (R7).

2.3.2 Definition of the Tagged Ozone Production Potential (TOPP)

Attributing O_x production to individual VOC using the tagging approach is the basis for calculating the TOPP of a VOC, which is defined as the number of O_x molecules produced per emitted molecule of VOC. The TOPP value of a VOC that is not represented explicitly in a chemical mechanism is calculated by multiplying the TOPP value of the mechanism species representing the VOC by the ratio of the carbon numbers of the VOC to the mechanism species. For example, CB05 represents hexane as 6 PAR, so the TOPP value of hexane in the CB05 is 6 times the TOPP of PAR. MOZART-4 represents hexane by the five carbon species BIGALK. Thus hexane emissions are represented molecule for molecule as $\frac{6}{5}$ of the equivalent number of molecules of BIGALK, and the TOPP value of hexane in MOZART-4 is calculated by multiplying the TOPP value of BIGALK by $\frac{6}{5}$.

3 Results

25

3.1 Ozone time series and O_x production budgets

Figure 1 shows the time series of O₃ mixing ratios obtained with each mechanism. There is an 8 ppbv difference in O₃ mixing ratios on the first day between RADM2, which has the highest O₃, and RACM2, which has the lowest O₃ mixing ratios when not considering the outlier time series of RACM. The difference between RADM2 and RACM, the low outlier, was 21 ppbv on the first day. The O₃ mixing ratios in the CRI v2
are larger than those in the MCM v3.1, which is similar to the results in Jenkin et al. (2008) where the O₃ mixing ratios of the CRI v2 and MCM v3.1 are compared over

a five day period. The day-time O_x production budgets allocated to VOC for each mechanism are shown in Fig. 2. The relationships between O_3 mixing ratios in Fig. 1 are mirrored in Fig. 2 where mechanisms producing high amounts of O_x also have high O_3 mixing

ratios. The conditions in the box model lead to a daily maximum of OH that increases with each day leading to an increase on each day in both the reaction rate of the OH-oxidation of CH_4 and the daily contribution of CH_4 to O_x production.

The first day mixing ratios of O_3 in RACM are lower than other mechanisms due to a lack of O_x production from aromatic VOC on the first day in RACM (Fig. 2). Aromatic degradation chemistry in RACM results in net loss of O_x on the first day, described later in Sect. 3.2.1.

RADM2 is the only reduced mechanism producing higher O_3 mixing ratios than the more detailed mechanisms (MCM v3.2, MCM v3.1 and CRI v2). Higher mixing ratios of O_3 in RADM2 are produced due to increased O_x production from propane compared to the MCM v3.2; on the first day, the O_x production from propane in RADM2 is triple that of the MCM v3.2 (Fig. 2). Propane is represented as HC3 in RADM2 (Stockwell et al., 1990) and on the first day HC3 degradation produces about 17 times the amount of acetaldehyde (CH₃CHO) produced by the MCM v3.2. The OH-oxidation of CH₃CHO starts a degradation chain that produces O_x through the reactions of CH₃CO₃

¹⁵ CH₃CHO starts a degradation chain that produces O_x through the reactions of CH₃CO₃ and CH₃O₂ with NO; thus the higher amounts of CH₃CHO in RADM2 during propane degradation leads to increased O_x production from propane degradation in RADM2 compared to the MCM v3.2.

3.2 Time dependent O_x production

- ²⁰ Time series of daily TOPP values for each VOC are presented in Fig. 3 and the cumulative TOPP values at the end of the model run obtained for each VOC using each of the mechanisms, normalised by the number of atoms of C in each VOC are presented in Table 3. In the MCM and CRI v2, the cumulative TOPP values obtained for each VOC show that by the end of the model run larger alkanes have produced more O_x
- per unit of reactive C than alkenes or aromatic VOC. By the end of the runs using the lumped structure mechanisms (CBM-IV and CB05), alkanes produce similar amounts of O_x per reactive C while aromatic VOC and some alkenes produce less O_x per reactive C than the MCM. Whereas in lumped molecule mechanisms (MOZART-4, RADM2,

RACM, RACM2), practically all VOC produce less O_x per reactive C than the MCM by the end of the run. This lower efficiency of O_x production from many individual VOC in lumped molecule and structure mechanisms would lead to an underestimation of O_3 levels downwind of an emission source, and a smaller contribution to background O_3 when using lumped molecule and structure mechanisms.

The lumped intermediate mechanism (CRI v2) produces the most similar O_x to the MCM v3.2 for each VOC, seen in Fig. 3 and Table 3. Higher variability in the time dependent O_x production is evident for VOC represented by lumped mechanism species. For example, 2-methylpropene, represented in the reduced mechanisms by a variety of lumped species, has a higher spread in time dependent O_x production than ethene, which is explicitly represented in each mechanism.

In general, the largest differences in O_x produced by aromatic and alkene species are on the first day of the simulations, while the largest inter-mechanism differences in O_x produced by alkanes are on the second and third days of the simulations. The reasons for these differences in behaviour will be explored in Sect. 3.2.1 which ex-

¹⁵ reasons for these differences in behaviour will be explored in Sect. 3.2.1 which examines differences in first day O_x production between the chemical mechanisms and Sect. 3.2.2 which examines the differences in O_x production on subsequent days.

3.2.1 First day ozone production

10

The first day TOPP values of each VOC from each mechanism, representing O₃ pro duction from freshly emitted VOC near their source region, are compared to those obtained with the MCM v3.2 in Fig. 4. The root mean square error (RMSE) of all first day TOPP values in each mechanism relative to those in the MCM v3.2 are also included in Fig. 4. The RMSE value of the CRI v2 shows that O_x production on the first day from practically all the individual VOC matches that in the MCM v3.2. All other
 reduced mechanisms have much larger RMSE values indicating that the first day O_x production from the majority of the VOC differs from that in the MCM v3.2.

The reduced complexity of reduced mechanisms means that aromatic VOC are typically represented by one or two mechanism species leading to differences in O_x pro-

duction of the actual VOC compared to the MCM v3.2. For example, all aromatic VOC in MOZART-4 are represented as toluene, thus less reactive aromatic VOC, such as benzene, produce higher O_x whilst more reactive aromatic VOC, such as the xylenes, produce less O_x in MOZART-4 than the MCM v3.2. RACM2 includes explicit species representing benzene, toluene and each xylene resulting in O_x production that is the most similar to the MCM v3.2 than other reduced mechanisms.

Figure 3 shows a high spread in O_x production from aromatic VOC on the first day indicating that aromatic degradation is treated differently between mechanisms. Toluene degradation is examined in more detail by comparing the reactions contributing to O_x production and loss in each mechanism, shown in Fig. 5. These reactions are deter-

mined by following the "toluene" tags in the tagged version of each mechanism.

10

Toluene degradation in RACM includes several reactions consuming O_x that are not present in the MCM resulting in net loss of O_x on the first two days. Ozonolysis of the cresol OH-adduct mechanism species ADDC contributes significantly to O_x loss

in RACM. This reaction was included in RACM due to improved cresol product yields when comparing RACM predictions with experimental data (Stockwell et al., 1997). Other mechanisms that include cresol OH-adduct species do not include ozonolysis and these reactions are not included in the updated RACM2.

The total O_x produced on the first day during toluene degradation in each reduced ²⁰ mechanism is less than that in the MCM v3.2 (Fig. 5). Less O_x is produced in all reduced mechanisms due to a faster break down of the VOC into smaller fragments than the MCM, described later in Sect. 3.3. Moreover in CBM-IV and CB05, less O_x is produced during toluene degradation as reactions of the toluene degradation products CH₃O₂ and CO do not contribute to the O_x production budgets, which is not the case in any other mechanism (Fig. 5).

Maximum O_x production from toluene degradation in CRI v2 and RACM2 is reached on the second day in contrast to the MCM v3.2 which produces peak O_x on the first day. The second day maximum of O_x production in CRI v2 and RACM2 from toluene degradation results from increased $C_2H_5O_2$ production from degradation of unsaturated di-

carbonyls; C $_2{\rm H}_5{\rm O}_2$ is not produced during degradation of unsaturated dicarbonyls in the MCM v3.2.

Unsaturated aliphatic VOC generally produce similar amounts of O_x between mechanisms, especially explicitly represented VOC, such as ethene and isoprene. On the

- ⁵ other hand, unsaturated aliphatic VOC that are not explicitly represented produce differing amounts of O_x between mechanisms (Fig. 3). For example, the O_x produced during 2-methylpropene degradation varies between mechanisms; differing rate constants of initial oxidation reactions and non-realistic secondary chemistry lead to these differences, further details are found in the Supplement.
- ¹⁰ Non-explicit representations of aromatic and unsaturated aliphatic VOC coupled with differing degradation chemistry and a faster break down into smaller size degradation products results in different O_x production in lumped molecule and lumped structure mechanisms compared to the MCM v3.2.

3.2.2 Ozone production on subsequent days

¹⁵ Alkane degradation in CRI v2 and both MCM mechanisms produces a second day maximum in O_x that increases with alkane carbon number (Fig. 3). The increase in O_x production on the second day is reproduced for each alkane by the reduced mechanisms; except octane in RADM2, RACM and RACM2. However, larger alkanes produce less O_x than the MCM on the second day in all lumped molecule and structure mechanisms.

The lumped molecule mechanisms (MOZART-4, RADM2, RACM and RACM2) represent many alkanes by mechanism species which may lead to unrepresentative secondary chemistry for alkane degradation. For example, three times more O_x is produced during the degradation of propane in RADM2 than the MCM v3.2 on the first day

²⁵ (Fig. 2). Propane is represented in RADM2 by the mechanism species HC3 which also represents other classes of VOC, such as alcohols. The secondary chemistry of HC3 is tailored to produce O_x from these different VOC and differs from alkane degradation in the MCM v3.2 by producing more CH₃CHO in RADM2.

As will be shown in Sect. 3.3, another feature of reduced mechanisms is that the breakdown of emitted VOC into smaller sized degradation products is faster than the MCM. Alkanes are broken down quicker in CBM-IV, CB05, RADM2, RACM and RACM2 through a higher rate of reactive carbon loss than the MCM v3.2 (shown for pentane

and octane in Fig. 8); reactive carbon is lost through reactions not conserving carbon. Despite many degradation reactions of alkanes in MOZART-4 almost conserving carbon, the organic products have less reactive carbon than the organic reactant also speeding up the breakdown of the alkane compared to the MCM v3.2.

For example, Fig. 6 shows the distribution of reactive carbon in the reactants and products from the reaction of NO with the pentyl peroxy radical in both MCM mechanisms and each lumped molecule mechanism. In all the lumped molecule mechanisms, the individual organic products have less reactive carbon than the organic reactant. Moreover, in RADM2, RACM and RACM2 this reaction does not conserve reactive carbon leading to faster loss rates of reactive carbon.

¹⁵ The faster breakdown of alkanes in lumped molecule and structure mechanisms on the first day limits the amount of O_x produced on the second day, as less of the larger sized degradation products are available for further degradation and O_x production.

3.3 Treatment of degradation products

The time dependent O_x production of the different VOC in Fig. 3 results from the varying rates at which VOC break up into smaller fragments (Butler et al., 2011). Varying break down rates of the same VOC between mechanisms could explain the different time dependent O_x production between mechanisms. The break down of pentane and toluene between mechanisms is compared in Fig. 7 by allocating the O_x production to the number of carbon atoms in the degradation products responsible for O_x production on each day of the model run in each mechanism. Some mechanism species in

RADM2, RACM and RACM2 have fractional carbon numbers (Stockwell et al., 1990, 1997; Goliff et al., 2013) and O_x production from these species was reassigned as O_x production of the nearest integral carbon number.

The degradation of pentane, a five-carbon VOC, on the first day in the MCM v3.2 produces up to 50 % more O_x from degradation products also having five carbon atoms than any reduced mechanism. Moreover, the contribution of the degradation products having five carbon atoms in the MCM v3.2 is consistently higher throughout the model

⁵ run than in reduced mechanisms (Fig. 7). Despite producing less total O_x , reduced mechanisms produce up to double the amount of O_x from degradation products with one carbon atom than in the MCM v3.2. The lower contribution of larger degradation products indicates that pentane is generally broken down faster in reduced mechanisms, consistent with the specific example shown for the breakdown of the pentyl peroxy radical in Fig. 6.

The rate of change in reactive carbon during pentane, octane and toluene degradation was determined by multiplying the rate of each reaction occurring during pentane, octane and toluene degradation by its net change in carbon, shown in Fig. 8. Pentane is broken down faster in CBM-IV, CB05, RADM2, RACM and RACM2 by losing reac-

¹⁵ tive carbon more quickly than the MCM v3.2. MOZART-4 also breaks pentane down into smaller sized products quicker than the MCM v3.2 as reactions during pentane degradation in MOZART-4 have organic products whose carbon number is less than the organic reactant, described in Sect. 3.2.2. The faster break down of pentane on the first day limits the amount of reactive carbon available to produce further O_x on subse-²⁰ guent days leading to lower O_y production after the first day in reduced mechanisms.

Figure 3 showed that octane degradation produces peak O_x on the first day in RADM2, RACM and RACM2 in contrast to all other mechanisms where peak O_x is produced on the second day. Octane degradation in RADM2, RACM and RACM2 loses reactive carbon much faster than any other mechanism on the first day so that there are

²⁵ not enough degradation products available on the second day to produce peak O_x on the second day (Fig. 8). This loss of reactive carbon during alkane degradation leads to the lower accumulated ozone production from these VOC shown in Table 3.

As seen in Fig. 3, O_x produced during toluene degradation has a high spread between the mechanisms. Figure 7 shows differing distributions of the sizes of the degra-

dation products that produce O_x . All reduced mechanisms omit O_x production from at least one degradation fragment size which produces O_x in the MCM v3.2, indicating that toluene is also broken down more quickly in the reduced mechanisms than the more explicit mechanisms. For example, toluene degradation in RACM2 does not produce O_x from degradation products with six carbons, as is the case in the MCM v3.2. Figure 8 shows that all reduced mechanisms lose reactive carbon during toluene degradation faster than the MCM v3.2. Thus the degradation of aromatic VOC in reduced mechanisms are unable to produce similar amounts of O_x as the explicit mechanisms.

10 4 Conclusions

20

Tagged Ozone Production Potentials (TOPPs) were used to compare O_x production during VOC degradation in reduced chemical mechanisms to the near-explicit MCM v3.2. First day mixing ratios of O_3 are similar to the MCM v3.2 for most mechanisms; the O_3 mixing ratios in RACM were much lower than the MCM v3.2 due to a lack of O_x production from the degradation of aromatic VOC. Thus, RACM may not be the appropriate chemical mechanism when simulating atmospheric conditions having a large fraction of aromatic VOC.

The lumped intermediate mechanism, CRI v2, produces the most similar amounts of O_x to the MCM v3.2 for each VOC. The largest differences between O_x production in CRI v2 and MCM v3.2 were obtained for aromatic VOC, however overall these differences were much lower than any other reduced mechanism. Thus, when developing chemical mechanisms the technique of using lumped intermediate species whose degradation are based upon more detailed mechanism should be considered.

Many VOC are broken down into smaller sized degradation products faster on the first day in reduced mechanisms than the MCM v3.2 leading to lower amounts of larger sized degradation products that can further degrade and produce O_x . Thus, many VOC in reduced mechanisms produce a lower maximum of O_x and lower total O_x per reac-

tive C by the end of the run than the MCM v3.2. This lower O_x production from many VOC in reduced mechanisms leads to lower O_3 mixing ratios compared to the MCM v3.2.

Alkanes produce maximum O_3 on the second day of simulations and this maximum is lower in reduced mechanisms than the MCM v3.2 due to the faster break down of alkanes into smaller sized degradation products on the first day. The lower maximum in O_3 production during alkane degradation in reduced mechanisms would lead to an underestimation of the O_3 levels downwind of VOC emissions, and an underestimation of the VOC contribution to tropospheric background O_3 when using reduced mechanisms in regional or global modelling studies.

This study has determined the maximum potential of VOC represented in reduced mechanisms to produce O_3 , this potential may not be reached as ambient NO_x conditions may not induce NO_x -VOC-sensitive chemistry. Moreover, the maximum potential of the VOC to produce O_3 may not be reached when using these reduced mechanisms in 3-D models due to the influence of additional processes, such as mixing and meteorology. Future work shall examine the extent to which the maximum potential of VOC to produce O_3 in reduced chemical mechanisms is reached using ambient NO_x conditions and including processes found in 3-D models.
