**Abstract.** During the CARRIBA-campaign (Cloud, Aerosol, Radiation and turbulence in the trade wind regime over Barbados) the interaction between aerosol particles and cloud microphysical properties has been investigated in detail which includes also the influence of clouds on the aerosol formation. During two intensive campaigns in 2010 and 2011 helicopter-borne measurement flights have been performed to investigate the thermodynamic, turbulent, microphysical, and radiative properties of trade wind cumuli over Barbados. During these flights 91 cases with increased aerosol particle number concentrations near clouds were detected. The majority of these cases are also correlated with enhanced irradiance in the ultraviolet spectral wavelength range (UV). This enhancement reaches values up to a factor of 3.3 compared to background values. Thus, cloud boundaries provide a perfect environment for the production of precursor gases for new particle formation. Another feature of cloud edges is an increased turbulence which may also enhance nucleation and particle growth. The observed events have a mean length of 100 m corresponding to a lifetime of less than 300 s. This implies that particles with diameters of at least 7 nm grew several nm per minute which corresponds to the upper end of values in the literature (Kulmala et al., 2004). Such high values cannot be explained by sulfuric acid alone, thus probably extremely low volatile organic compounds (ELVOCs) are involved here.

## 1 Introduction

The influence of the number concentration of available cloud condensation nuclei (CCN) on the number concentration of cloud droplets was shown in Warner and Twomey (1967) for the first time. They demonstrated that smoke from sugar cane fires leads to a significant increase in the number of cloud droplets. Furthermore, a change in CCN followed by a change in the cloud droplet number size distribution leads to a change in the shortwave albedo of clouds (Twomey, 1977). Since these first studies the influence of the availability of aerosol particles on the microphysical properties of clouds has been investigated many times. On the other hand, clouds strongly influence the incoming solar radiation, thus they may also influence the formation and distribution of aerosol particles, e.g. by new particle formation (NPF, Birmili and Wiedensohler, 2000).

The origin of ultrafine aerosol particles (smaller than 20 nm) in the remote marine atmosphere has been an objective already in the 1990s. NPF requires not only low particle surface area concentration but also a sufficient concentration of potential precursor gases. Covert et al. (1992) observed an increase in the number concentration of small particles accompanied by a decrease in the surface area concentration in the marine boundary layer. Shaw (1989) concludes that for clean environments the role of clouds has to be taken into account due to the photochemical production of  $\text{SO}_4^{2-}$  as well as cleansing effect that lowers the aerosol particle surface concentration.

Several studies from the 1990s show increased particle concentrations near the top and outflow of individual marine cumulus clouds (e.g., Clarke et al., 1997, 1998; Perry and Hobbs, 1994). Radke and Hobbs (1991) found regions with high relative humidity around cumulus clouds and increased particle concentrations therein. These regions coincide with regions of increased turbulence. Results from Keil and Wendisch (2001) suggest that this phenomenon happens not only in the marine environment but also at tops of continental clouds, where they found peaks of ultrafine particles at stratocumulus cloud tops over Germany. Garrett et al. (2002) observed high number concentration of aerosol particles  $< 100$  nm at tops of stratiform clouds in the Arctic. Saxena and Grovenstein (1994) observed an increase in CCN concentration within such clouds, which demonstrates the influence of clouds on the aerosol distribution. A model study done by Hegg (1991) demonstrated that bimolecular nucleation within clouds is a viable mechanism for the particle production. Weber et al. (2001) observed regions of increased ultrafine particle number concentrations near a marine frontal cloud in a height of approximately 6 km. Here, the nucleation was observed in 60 km wide bands with enhanced intensity of up-welling short-wave radiation.

The results of these former studies were obtained by aircraft measurements equipped with commercial condensation particle counters (CPC). The observed events had a horizontal extent of approximately 1 km or more and shorter events were not discussed due to limitations in the experimental setup. One commonly used aircraft, the C-130, was operated at an average speed of about  $100 \text{ m s}^{-1}$ . Typical CPCs with a temporal resolution of approximately 1 s therefore allow for detection of events with a length of  $\sim 200$  m.

This study presents results from the Cloud, Aerosol, Radiation and turbulence in the trade wind regime over Barbados (CARRIBA) campaign using two helicopter-borne measurement platforms that simultaneously sampled basic meteorological parameters, in situ cloud microphysical and aerosol variables, and cloud reflected spectral radiation. The advantage of these helicopter-borne measurements is the low true air speed of  $20 \text{ m s}^{-1}$  combined with a high temporal resolution. The observed data from 28 measurement flights were obtained in the marine boundary layer and the cloud layer where 91 individual cases of NPF were found. Besides providing an investigation in a new geographic environment, these measurements were made with very high spatial resolution (approximately 20 m) and with a lower size limit of 6 nm for aerosol detection. This allows for investigation of statistical properties of the NPF events and their correlation with meteorological, microphysical, and radiation variables. An introduction to the CARRIBA-project and the scientific goal is given in Siebert et al. (2013).

## 2 The measurement campaign CARRIBA

The CARRIBA campaign was performed in November 2010 and April 2011 near the island of Barbados in the Caribbean Sea. One major objective of CARRIBA was to investigate the influence of aerosol particles on the formation and life cycle of trade wind cumuli. Basic meteorological variables, as well as turbulence, aerosol, and in situ cloud microphysical parameters were measured by the Airborne Cloud Turbulence Observation System (ACTOS) payload. Collocated observations of upward spectral radiances and irradiances have been collected by the Spectral Modular Airborne Radiation measurements system (SMART-HELIOS). Both payloads were attached to the helicopter by means of a 160 m long rope. These measurements were supplemented by ground-based measurements at the eastern most tip of Barbados at the “Ragged Point” station. There, dust measurements have been performed continuously since 1964 by the University of Miami (e.g., Li-Jones and Prospero, 1998) and several systems for thorough ground-based aerosol characterization were deployed additionally for CARRIBA. The second ground-based site contains various remote sensing instruments measuring basic aerosol and cloud parameters over several years and is operated by the Max-Planck-Institute for Meteorology (MPI-M) in Hamburg/ Germany (Nuijens et al., 2014).

Measurement flights of ACTOS started with a vertical profile up to 2 to 3 km above sea level between two pre-defined navigation points over the ocean off the east coast of Barbados. After this profile, flights usually continued with the cloud sampling strategy depending on local cloud conditions. More details about CARRIBA as well as meteorological conditions and examples of flight tracks are given in Siebert et al. (2013).

## 3 Instrumentation

### 3.1 The measurement platform ACTOS

The helicopter-borne measurement payload ACTOS was used to perform measurements with high temporal and spatial resolution within the marine boundary layer up to a height of  $\approx 3000$  m above sea level. ACTOS is an autonomous system that is attached to a helicopter and flown with a true airspeed of about  $20 \text{ m s}^{-1}$  to ensure measurements are safely outside of the helicopter’s downwash (Siebert et al., 2006). The payload is equipped with fast sensors for measuring the three-dimensional wind vector, temperature, static pressure, and humidity. A navigation unit provides attitude angles, position, and velocity vector components to transfer the wind measurements into an Earth-fixed coordinate system. In addition to the meteorological standard parameters, cloud microphysical properties such as liq-

uid water content ( $LWC$ ), and cloud droplet size distribution are measured during cloudy conditions.

A real-time data acquisition system and independent power unit complete ACTOS. A telemetry link to the helicopter ensures online monitoring of basic parameters during the flight. One scientist is onboard to fine tune the flight pattern with regard to the observed cloud situation. In this study all time series are given in seconds of day (sod) in UTC.

### 3.2 Aerosol measurements on ACTOS

Additional instrumentation to measure aerosol particle number size distributions (NSD) between 6 nm and 2.5  $\mu\text{m}$ , as well as the total particle number concentration ( $N$ ) were installed on ACTOS during CARRIBA. A common inlet was used for all aerosol measurements, leading the sample flow through a diffusion dryer to ensure dry measurement conditions ( $< 50\%$  relative humidity). Afterwards, a flow splitter divides the flow line into four lines for the individual instruments. These instruments include a total Condensation Particle Counter (CPC, model 3762A, TSI Inc., St. Paul, MN, USA), a Scanning Mobility Particle Sizer (SMPS) and an Optical Particle Counter (OPC, model 1.129, Grimm Aerosol Technik, Ainring, Germany). The SMPS system was built at TROPOS and mainly consists of a Kr-85 Neutralizer (model 3077A, TSI Inc.), a Hauke type DMA (short version), and a CPC (model 3762A, TSI Inc.). This system was optimized in terms of weight and power consumption for operation on ACTOS. The SMPS measures aerosol particle number size distributions from 6 to 250 nm with a temporal resolution of 120 s. The OPC measures particle number size distributions from 250 nm to 2.5  $\mu\text{m}$  with a temporal resolution of 1 s. Therefore the combination of both instruments provides aerosol number size distributions from 6 nm to 2.5  $\mu\text{m}$  using the inversion described by Pfeifer et al. (2014). SMPS measurements have been corrected for variations in the volume flow due to pressure changes during the flight and also for diffusion losses within the inlet line. The CPC measures the total particle number concentration ( $N_{\text{CPC}}$ ) with particle diameter  $D_p > 6$  nm and a temporal resolution of 1 s. This instrumentation was already introduced in Wehner et al. (2010). The measured aerosol parameters were all corrected for standard temperature ( $T_0 = 288$  K) and pressure ( $p_0 = 1013.15$  hPa).

In addition the recently developed Fast CPC (FCPC) (Wehner et al., 2011) has been implemented on ACTOS and was used to measure the total particle number concentration of aerosol particles  $> 7$  nm with a temporal resolution of  $\approx 10$  Hz. The FCPC has its own inlet on ACTOS which is operated with a higher flow to minimize the residence time between inlet and FCPC.

While the FCPC has been tested intensively on the ground (Wehner et al., 2011), the CARRIBA campaigns were the first application for airborne measurements. The TSI CPC was used as a reference during periods with relatively con-

stant  $N$  to compare the FCPC in terms of long-term stability. During the 2 campaigns no systematic deviation between the two instruments has been observed. During two flights of the first campaign in November 2010 technical problems occurred and those data were excluded from this study. In preparation for the second campaign in 2011 the FCPC was improved and a second one was additionally installed on ACTOS. Thus, for the flights in April 2011 data from two FCPCs are available. Here, both instruments worked well and observed particle number concentrations from the two instruments agree within an uncertainty of  $\pm 10\%$ .

Fig. 1. Time series of the two FCPC (FCPC1 and FCPC2) and the TSI CPC measured during a flight section on April 22, 2011.

Figure 1 shows a time series of  $N_{\text{FCPC}}$  and  $N_{\text{CPC}}$  on April 22, 2011 at cloud level. The background concentration during this flight varied between 150  $\text{cm}^{-3}$  and 250  $\text{cm}^{-3}$  but individual events show particle number concentrations of more than 8000  $\text{cm}^{-3}$ . These events are detected by all three instruments, but the TSI CPC with its lower time resolution is not able to capture the maximum concentration measured by the FCPC. Moreover, the small scale structure is resolved by the two FCPCs only. The time series demonstrates nicely how well both FCPCs agree and in the following figures only data from FCPC1 will be shown.

### 3.3 Radiation measurements using SMART-HELIOS

Instrumentation to sample upward spectral irradiances  $F_{\lambda}^{\uparrow}$  and cloud-reflected spectral radiances  $I_{\lambda}^{\uparrow}$  was installed on SMART-HELIOS. Measurements performed with SMART-HELIOS have been reported in Werner et al. (2013) and Werner et al. (2014). Optical fibers connect each optical inlet to two grating spectrometers, respectively. These cover the wavelength  $\lambda$  range between 180 nm – 1000 nm in the visible to near-infrared spectral wavelength range (VNIR) and between 900 nm – 2200 nm in the shortwave-infrared spectral wavelength range (SWIR). In the VNIR the spectrometers have a spectral resolution, defined by full width at half maximum, of 2 – 3 nm, and in the SWIR 8 – 9 nm. The temporal resolution of sampled  $F_{\lambda}^{\uparrow}$  and  $I_{\lambda}^{\uparrow}$  is 0.1 s - 0.3 s. The field of view of the radiance inlet is  $2^{\circ}$  resulting in a footprint 2.5 m in cross-track and 4.2 m - 8.5 m in along-track direc-

tion (depending on the flight level above cloud top and the integration time of the sample). The optical inlets and spectrometers are calibrated with certified calibration standards traceable to the National Institute of Standards and Technology (NIST). The uncertainties of the  $F_{\lambda}^{\uparrow}$  and  $I_{\lambda}^{\uparrow}$  signals arise from uncertainties introduced during the radiometric calibration, as well as uncertainties in the calibration standards and the spectrometer signal, and are estimated to be  $\pm 6\%$  in the VNIR and  $\pm 10\%$  in the SWIR (Werner et al., 2013).

## 4 Results

For the CARRIBA campaigns the measured particle number concentration in the marine boundary and cloud layer, excluding NPF events, was usually  $\approx 100\text{--}300\text{ cm}^{-3}$  for the analyzed flights. During several flights, short events of increased particle number concentrations with maximum values of up to  $17000\text{ cm}^{-3}$  were observed. In this study, events with a maximum number concentration of more than  $1000\text{ cm}^{-3}$  were considered to be NPF events. This threshold was arbitrarily chosen but exceeds the background value by more than a factor of three. Furthermore, subsequent maxima were considered to be the same event if the concentration decreased to the background value for less than 2 s (or 40 m), otherwise they were counted as individual events. Using these criteria 91 events were detected in the cloud layer during measurements flights with valid FCPC data. The hypothesis is that these particles were formed by nucleation and grew to detectable sizes within the lifetime of the individual cloud sampled. Thus, these events will be called NPF events. Interestingly, almost all of the NPF events were observed in the vicinity of clouds. We did not find any dependence on orientation, flight direction, or upwind versus downwind direction relatively to the cloud. Theoretically, such particles can also be artifacts, created by droplet fragmentation at the inlet (Weber et al., 1998; Craig et al., 2013). In our case with a true airspeed of  $20\text{ m s}^{-1}$  aerodynamic breakup will not occur, and impaction breakup would occur only for cloud droplets larger than approximately  $26\text{ }\mu\text{m}$  in diameter. Most of the cloud droplets observed during CARRIBA were smaller (Schmeissner et al., 2015), thus breakup would not occur. Another aspect excluding such artifacts is that most of the events were observed out of clouds. Furthermore, two different inlets were used for the different CPCs, but all events were observed at both CPCs at the same time.

### 4.1 New particle formation events: Examples

NPF events occurred at different locations relative to surrounding clouds. Figure 2 shows examples of observed NPF to illustrate the variety of cases. Some instances were found near cloud edges (at both upwind and downwind sides) or between clouds where the decrease of  $LWC$  was closely connected with an increase in  $N$  (see Fig. 2(a) and (b)).

Increased particle concentrations were observed during entering and leaving clouds which rules out the possibility of artificial particle production. Furthermore, increased values in  $N$  were found in the entrainment zone, i. e. in regions at the cloud edge where the  $LWC$  was nonzero but fluctuating (see Fig. 2(c)). Other cases like the one shown in Fig. 2(d) seem to occur without the presence of a nearby cloud, although from the in situ measurements alone the possibility that these observations were performed above cloud top cannot be excluded. These four cases will be discussed later in more detail.

The examples shown in Figs. 2(a)–(d) also demonstrate the different resolution of the two CPCs: the laminar flow type CPC with its time resolution of 1 s cannot resolve the smallest structures that can be measured by the FCPC. Thus, also the maximum concentration cannot be resolved by the CPC because the variations appear smoother in this instrument. Some of the events last only a few seconds which is close to the detection limit of the CPC.

The events have been identified by a significant increase in the total particle number concentration, however, the events are too short to obtain a complete particle number size distribution for the respective period. Thus, we have to speculate about size and origin of these particles. There are no anthropogenic particle sources because the measured concentration of  $\text{CO}_2$  does not follow  $N$  in any case. Since there are no other sources the observed particles are very likely produced by new particle formation, i.e. they were formed by homogeneous nucleation from one or more condensable species, and grew subsequently into detectable sizes.

Because the SMPS measure individual particle diameter ranges sequentially within a scan, even with limited time resolution these measurements can give insight into whether these particles occur mainly in the ultrafine particle size range. During some events the observed diameter from the SMPS was in the ultrafine particle range ( $< 20\text{ nm}$ ) and the number size distribution showed a maximum around this value. This was the case for the NPF event in Fig. 2(c). The SMPS started a scan from 6 nm at 52924 seconds of day, which is shown in Fig. 3 together with the following number size distribution without NPF. Around 20 s later between 52940 and 52950 sod the event was observed in  $N_{\text{FCPC}}$  corresponding to a selected diameter in the SMPS between 10 and 20 nm. 120 s later, the SMPS reaches the upper end and measures at 230 nm. Similar cases have been observed a few more times, but never at larger diameters in the  $NSD$ . This finding confirms our hypothesis that the event of increased particle number concentrations are caused by the formation of ultrafine particles and that these cases are indeed NPF events. However, the presented NSD is only representative for one NPF event and different events might exhibit a different distribution. Furthermore the maximum of the NSD does not show the real maximum of the NPF event, because

**Fig. 2.** Time series of  $N_{CPC}$ ,  $N_{FCPC}$ , and  $LWC$  over 40 s each during an event of increased particle number concentration (a) at a cloud edge, (b) between clouds, (c) in the entrainment region, and (d) without clouds nearby.

**Fig. 3.** Number size distributions (NSD) measured on April 23, 2011, starting at 52924 sod (cf. Fig. 2 (c)).

**Fig. 4.** Frequency distribution of the horizontal extent of the observed 91 new particle formation events.

the SMPS was measuring in a certain diameter range, defined by the measurement program.

355

## 4.2 Statistics

FCPC data from 28 flights are available. During 4 of them no NPF events were detected and during 24 flights between 1 and 13 individual events were counted. This means that during 83% of the investigated flights NPF events were observed. Figure 4 shows the distribution of the horizontal extent of each individual event, assuming a constant flight speed of  $20 \text{ m s}^{-1}$ . More than 50% of all events were observed to have a horizontal extent of less than 100 m. This explains why they have rarely been observed during former aircraft experiments. Such aircraft have a flight speed of at least  $50 - 70 \text{ m s}^{-1}$  (www.eufar.net) and most commercial CPCs in the past had a time resolution of  $\geq 1 \text{ s}$ . Thus, events

360

365

of increased number concentrations that cover a distance of 100 m or less could not be resolved with these systems.

Figure 5 shows the distribution of maximum particle concentration for each individual event. To exclude the influence of individual outliers the 95th percentile was used as a proxy for the maximum concentration. The maximum observed concentration during CARRIBA was  $17000 \text{ cm}^{-3}$ , the most frequent maximum concentration occurred between 1000 and  $2000 \text{ cm}^{-3}$  and the frequency decreased with increasing number concentration.

**Fig. 5.** Maximum concentration (95th percentile) of the observed 91 new particle formation events.

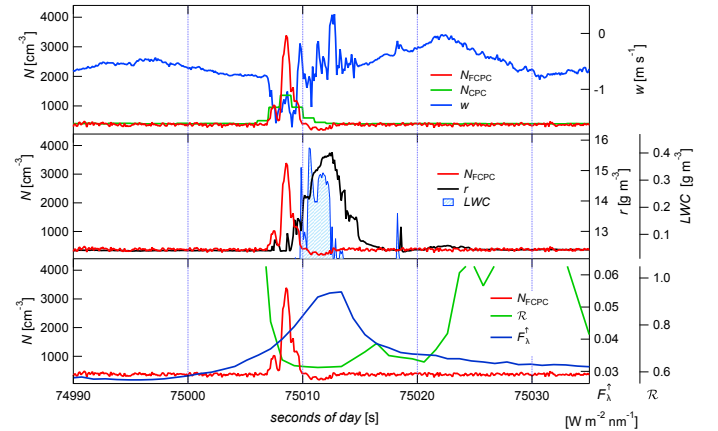

### 4.3 Correlation of new particle formation with other variables

The 91 NPF events occurred at various locations within the cloud layer, varying in length, maximum concentration, shape, and the correlation with other parameters. An interpretation of the nucleation and growth processes inherent in the observed NPF events is complicated because of two reasons: (i) The FCPC measures particles  $> 7$  nm, i.e. the nucleation process has occurred some time before the measurement and conditions may have changed, and (ii) there are no measurements of potential precursor gases. However, ACTOS and SMART-HELIOS provide meteorological, microphysical, and upward radiation measurements that can be compared to NPF events for suggestions of correlation. NPF events have been observed at heights between 600 m and 2200 m, always within the cloud layer. Interestingly, NPF of a specific measurement flight occurred in a narrow height range, i. e. within 200 - 300 m. These height ranges were often connected to a change in the number concentration in the vertical profile. Thus mixing with cleaner air may play a role for the NPF event.

First, we consider correlations of NPF and existence of nearby cloud. During the second CARRIBA campaign in 2011 measurements of the upward spectral irradiance  $F_{\lambda}^{\uparrow}$  and cloud-reflected spectral radiance  $I_{\lambda}^{\uparrow}$  by SMART-HELIOS are available for all flights. The  $I_{\lambda}^{\uparrow}$  data yield the benefit of giving information about the cloud field directly around and below ACTOS. As shown by Werner et al. (2014), comparing spectra sampled over cumuli with those sampled over the ocean surface or the island allows for a clear differentiation between these surfaces via radiance-ratios  $\mathcal{R} = \frac{I_{\lambda_1}^{\uparrow}}{I_{\lambda_2}^{\uparrow}}$ . In this work  $\lambda_1 = 720$  nm and  $\lambda_2 = 644$  nm, resulting in a range indicating cloudy data between  $\mathcal{R} = 0.6 - 0.75$ , depending on the cloud optical thickness and solar zenith angle. Samples

over the ocean show  $\mathcal{R} < 0.6$ , while  $\mathcal{R} > 1$  for measurements over the island due to the sharp increase in reflectivity of vegetation in the near infrared. The cloud ratio  $\mathcal{R}$  yields a reliable estimate of the position of each NPF event relative to the respective cloud field. This is in contrast to in situ measured  $LWC$  data, because due to the inhomogeneous cloud structure ACTOS sometimes dipped in and out of cloud tops or entered (left) the cloud later (earlier) than the cloud edge at lower levels. In 2011, 38 of the 44 NPF events were connected to clouds: at the cloud edge, only a few seconds away from a cumulus or above a cloud. These findings emphasize the strong connection between NPF and cloud boundaries.

Correlations with other measured variables can also be explored. In the following, three representative examples of time series including NPF events are given to illustrate the differences between individual events and potential correlations with other parameters. Presented variables are:  $w$ : vertical wind speed,  $r$ : water vapor mixing ratio,  $N$ : total particle number concentration  $> 7$  nm measured by CPC and FCPC,  $LWC$ : liquid water content to show areas where clouds were present,  $F_{\lambda}^{\uparrow}$ : spectral upward irradiance with  $\lambda = 333$  nm and  $\mathcal{R}$ : cloud ratio.

**Fig. 6.** Section of the measurement flight on April 14, 2011 through a cumulus cloud. Presented variables are:  $w$ : vertical wind speed,  $F_{\lambda}^{\uparrow}$ : spectral upward irradiance at 333 nm,  $r$ : water vapor mixing ratio,  $N_{CPC}$  and  $N_{FCPC}$ : total particle number concentration measured by CPC and FCPC,  $LWC$ : liquid water content, and  $\mathcal{R}$ : cloud ratio.

Figure 6 shows a NPF case at the edge of a cumulus cloud indicated by  $LWC > 0$  adjacent to increased values in  $N$ . Furthermore,  $\mathcal{R}$  shows values between 0.6 and 0.7 around this cloud indicating that ACTOS was measuring above a cloudy area when at the location of the NPF event. Before and after the cloud area,  $\mathcal{R}$  increased to values above 1 indicating measurements over the island without cloud coverage. The total particle number concentration increases from  $\approx 300$   $\text{cm}^{-3}$  to  $3500$   $\text{cm}^{-3}$  at the cloud edge. The irradiance increases above the cloud by a factor of two compared to the

445 region further away from the cloud. The reason is the higher  
 450 reflectivity of the cloud surface compared to the darker ocean  
 (e.g., Eck et al., 1987). From the cloud ratio it can be con-  
 cluded that the NPF event occurs above a part of the cloud,  
 i. e. still in the region with enhanced irradiance. Interestingly  
 the NPF event also corresponds to a downdraft region rela-  
 tive to the cloud. During the NPF, a correlation between  $N$   
 and  $r$  is observed.

**Fig. 7.** Section of the measurement flight on April 22, 2011, same variables as in Figure 6.

Figure 7 shows another case of NPF where the enhanced number concentration occurred between two cloud traverses by ACTOS. April 22, 2014 was characterized by the lowest particle number concentrations in the cloud-free back-  
 455 ground during the whole campaign. In the selected section shown in Figure 7  $N$  varied between 100 and 150  $\text{cm}^{-3}$  and increased to more than 12500  $\text{cm}^{-3}$  during the NPF event.  
 460 The cloud ratio  $\mathcal{R}$  indicates that there was continuous cloud coverage below the measurement height, indicating that the three individual regions of enhanced  $LWC$  (sampled in situ by ACTOS) belong to the same cloud. This can occur when ACTOS briefly leaves the cloud top and reenters the cloud a little later. The irradiance is enhanced over the whole re-  
 465 gion by a factor of 2 compared to the cloud-free background. Here, the NPF occurs in a region where  $r$  is still increased compared to background values.

Figure 8 shows a third NPF case observed at the cloud edge but also within the cloud (entrainment region), where increased particle number concentrations are correlated with  
 470 a decrease in  $LWC$ . The background concentration in the cloud-free regions was around 200  $\text{cm}^{-3}$  and the maximum during the event around 14000  $\text{cm}^{-3}$ . The cloud ratio  $\mathcal{R}$  indicates that ACTOS was still above a cloud at  $\approx 52950$  sod, i.e. the NPF event occurred above the cloud. Around the ob-  
 475 served cloud  $\mathcal{R}$  is fluctuating, i.e. there were some shreds of clouds below ACTOS.  $F_{\lambda}^{\dagger}$  has its maximum at the same side of the cloud as  $N$  which is also the side reflecting the sun

**Fig. 8.** Section of the measurement flight on April 23, 2011, same variables as in Figure 6.

during that flight.  $F_{\lambda}^{\dagger}$  is enhanced by a factor of 1.8 above the background value in the cloud-free environment.

The short NPF event within the cloud is related to a minimum in  $LWC$  and occurs in the so-called entrainment region at the cloud edge. This region is characterized by strong small-scale mixing processes leading to an evaporation of cloud droplets and therefore a release of potential precursor gases. In combination with turbulent mixing and an increased irradiance this region provides preferable conditions for NPF. The eddy-like structures in  $LWC$  and  $N$  illustrate the mixing at the cloud edge nicely and has also been observed in a few more cases. This is in good agreement with results from Clarke et al. (1998) who identified new particle formation in the outflow regions of cumulus clouds driven by enhanced gas concentrations in connection with photochemical activity.

From these examples a connection between NPF events and clouds as regions with increased UV radiation is obvious. During this campaign 38 out of 44 cases were directly connected to a cloud and an enhanced irradiance has been measured. These 38 NPF events in the vicinity of clouds can be additionally divided into two categories, depending on the relative position of ACTOS to the respective cloud and the solar azimuth angle of the sun. Cases with ACTOS between cloud and sun, such as ACTOS approaching and leaving the illuminated side of an individual cumulus, are characterized by increased reflectivity in the UV spectrum (Vant-Hull, 2007). Cases where ACTOS is in a position above a cloud are included in this category, which comprises 32 of the observed 38 NPF events associated with clouds. In the remaining 6 NPF events the cloud is positioned between ACTOS and the sun suggesting that ACTOS and SMART-HELIOS were probing in a cloud shadow. Thus, these cases are associated with increased UV radiation which cannot be explained

with the flight direction relative to the cloud-sun-axis alone. Here, maybe 3D effects occur, i.e. the enhanced irradiance is caused by reflections at another part of the cloud. Together with the fact that 38 out of 44 cloud cases are directly connected to an increase in  $F_{\lambda}^{\uparrow}$  the UV irradiance seems to be an important factor for new particle production in cloudy regions.

Figure 9 shows the increase of measured irradiance compared to a background value without cloud for the observed cases from April 2011. The increase varies between 1.2 and 3.3 with a median of 1.78. This is in good agreement with the study from Weber et al. (2001) who published model simulations to demonstrate that an UV enhancement of a factor of 2 produces reasonable values in  $\text{H}_2\text{SO}_4$  compared with their observations. From ACTOS-measurements no measurements of chemical precursors are available but  $\text{H}_2\text{SO}_4$  is very likely involved in the nucleation process.

**Fig. 9.** Probability density function of the relative increase of measured irradiance at 333 nm above the individual cloud compared to a background value without cloud for all NPF events during April 2011.

#### 4.4 Estimated age of particle bursts and implications for particle growth rate

The observations of new particle formation events are often characterized by short, burst-like spikes with remarkably sharp edges, implying that they have not become well mixed and diluted by turbulence. At the same time, NPF events are only observable when they have diameters above 7 nm. In this section we use these two observations to estimate a lower bound on the particle growth rate. In order to make a quantitative estimate we select one burst, shown in Fig. 10, which was chosen because it is representative of a typical NPF event.

The total horizontal extent of the burst is approximately 50 m, and we take this as the characteristic dimension of the

**Fig. 10.** Penetration of a cloud field with a burst of increased number concentrations  $N$  of ultrafine particles between two cloud penetrations. The clouds are marked by the blue areas which represent  $LWC$  in arbitrary units. Additionally the dots show the local energy dissipation rate  $\varepsilon$  averaged over a relative flight path of roughly 20 m.

puff of newly formed particles. We can ask, what is the time required for a spatially localized population of particles to reach this size through turbulent diffusion? The concept of Richardson pair dispersion describes the relative separation of two fluid elements in a turbulent flow for length scales within the inertial subrange, or approximately 1 mm to  $\sim 100$  m. The mean-square separation distance scales as  $\langle |\delta x|^2 \rangle = g \varepsilon t^3$ , where  $\varepsilon$  is the turbulent kinetic energy dissipation rate and  $g$  is the Richardson constant (typically thought to have a value of 0.1 to  $\sim 5$ ) (Davidson, 2004). Recent laboratory (Ott and Mann, 2000) and direct numerical simulation (Boffetta and Sokolov, 2002) results suggest  $g \approx 0.5$ , so while we will consider the full range of possible values, we take this as the most likely value. We do not have any information about the size of the initial burst, but to be conservative in estimates of growth rate we assume that it is at the bottom of the turbulence inertial subrange, e.g.,  $\sim 1$  mm. In that case, we can obtain an approximate age of the burst as  $\mathcal{T} = (\mathcal{L}^2/g\varepsilon)^{1/3}$ , where  $\mathcal{L} = \langle |\delta x|^2 \rangle^{1/2}$  is the characteristic size of the burst.

The time series of  $\varepsilon$  is also shown in Fig. 10, and we use the mean value over the length of the burst,  $\varepsilon \approx 2 \times 10^{-3} \text{ m}^2 \text{ s}^{-3}$ . Using  $\mathcal{L} \approx 50$  m, we estimate  $\mathcal{T} \approx 136$  s. Assuming the particles must reach  $d = 7$  nm (starting at a cluster size below 1 nm) within this time we can estimate a growth rate of  $3 \text{ nm min}^{-1}$ . Accounting for the range of possible  $g$  results in growth rates of  $2 \text{ nm min}^{-1}$  to  $7 \text{ nm min}^{-1}$ . For this growth rate  $\approx 1 - 4 \cdot 10^9 \text{ cm}^{-3}$  vapor molecules are needed (see Nieminen et al., 2010). In practise it is very probable that besides sulphuric acid also extremely low volatile organic compounds (ELVOCs) are involved in the process (see Ehn et

575 al., 2014; Kulmala et al., 1998), because the saturation vapor  
pressure of condensing vapors should be very small for effective  
molecular flux into growing newly formed particles, and ELVOCs fulfill these criteria. ELVOC precursors could live  
580 inside clouds and convection could transport ELVOC precursors to cloud edges as well as SO<sub>2</sub> as sulfuric acid precursor. 590  
The solar radiation outside the cloud and precursors coming from evaporating cloud are able to make photochemical reactor  
efficient enough to produce ELVOCs. Actually this kind of growth rates have previously been observed at coastal sites  
585 like Mace Head (Kulmala et al., 2004).

## 5 Conclusions

This study presents meteorological, aerosol, cloud and radiation measurements from the CARRIBA campaign that was performed close to the Caribbean island Barbados, in the trade wind cumulus environment. 91 cases of strongly increased particle number concentration caused by new particle formation were detected in the cloud layer and analyzed to consider event properties and correlations. No new particle formation events have been observed in the always cloud-free sub-cloud layer, while cumulus clouds were present during all flights in the cloud layer. The available database does not allow for process studies but we have sought to identify conditions favoring new particle formation. Most of the NPF cases were connected to clouds representing an environment  
600 with increased irradiance in the ultra-violet spectral wavelength range (UV). NPF requires photochemical activity for the production of precursor gases. In our case no measurements of gases are available but the increased UV irradiance at cloud boundaries provides a perfect region for the production of precursors. This could be intensified by turbulent mixing  
605 which is typical for the entrainment regions and therefore for cloud edges. This was also observed for some cases in this study by high fluctuations of thermodynamic variables in the region where NPF occurs. Such small-scale mixing processes may enhance the formation rate of new particles because of  
610 strong nonlinearities in the system (Easter and Peters, 1994). From vertical profiles we found variations in particle number concentrations in the height where NPF occurred for the majority of cases, thus mixing with cleaner air may also be  
615 one aspect forcing nucleation and growth. Probably, the connection of the different issues is required: enhanced UV radiation to produce the precursor gases, cloud edges as a region with increased turbulence, and mixing with cleaner air reducing the condensational sink. Radke and Hobbs (1991)  
620 observed increased particle number concentrations in the surrounding region of cumulus clouds which were also characterized by high relative humidities. During CARRIBA, also regions with high relative humidities around clouds were detected by Katzwinkel et al. (2014). In this study also a few  
625 cases with correlations between NPF and humidity were observed, but for other cases there was no relationship found.

The presented results agree with earlier publications suggesting that marine clouds do not only play an important role as particle sinks due to activation and the following effects  
630 on the radiation budget but also as a source for aerosol particles. Cloud edges or cloud tops have been identified as preferred regions for NPF in earlier studies but these were limited to a few individual cases only. Here, we detected 91 cases demonstrating the relevance for the marine environment. In combination with results from earlier publications  
635 (e.g., Clarke et al., 1997, 1998; Perry and Hobbs, 1994; Keil and Wendisch, 2001; Weber et al., 2001) this leads to the conclusion that this phenomenon is not only of regional interest since it was found in completely different regions of

640 the world. The results are also consistent in general with a  
 modeling study by Kazil et al. (2011) and earlier observa-  
 tions from Petters et al. (2006) where Aitken particles were  
 also connected to new particle formation near clouds. This  
 was explained by a reduction of the condensation sink due  
 645 to clouds and precipitation. In addition, cloud updrafts loft  
 dimethyl sulfide from the ocean to the cleaner cloud layer,  
 where it is oxidized to SO<sub>2</sub> and H<sub>2</sub>SO<sub>4</sub>. This step requires  
 enhanced radiation and provides precursor gases for new par-  
 ticle formation. 700

650 Another interesting result from this study is the estimate  
 of the lifetime of particle bursts. The mean length of the ob-  
 served NPF events was 100 m resulting in a lifetime of less  
 than 300 s. Aerosol instrumentation on ACTOS is restricted  
 to measure particles larger than 7 nm only, thus these parti-  
 cles grew within this lifetime to detectable sizes, i.e. 7 nm.  
 655 This implies growth rates of several nm per minute which is  
 in contrast to typical growth rates mainly from ground-based  
 measurements reported in the literature (1 – 7 nm h<sup>-1</sup>, Kul-  
 mala et al. (2004)) and is possibly caused by the additional  
 effect of turbulent mixing. However, Dal Maso et al. (2002)  
 660 reported growth rates up to 200 nm h<sup>-1</sup> (3.3 nm min<sup>-1</sup>) from  
 a coastal site in Ireland, thus the values deduced here are real-  
 istic. However, these growth rates are not possible due to sul-  
 furic acid alone in particular under clean marine conditions  
 665 and it is very probable that extremely low volatile organic  
 compounds (ELVOCs) are involved here (Ehn et al., 2014).

*Acknowledgements.* We thank the experienced and highly engaged  
 pilots Alwin Vollmer and Milos Kapetanovic for the safe helicopter  
 flights in the Caribbean. We thank Joe Prospero for access to his  
 670 infrastructure at Ragged Point. We are grateful to Thomas Conrath  
 from TROPOS and Christoph Klaus and Dieter Schell from the en-  
 viscope company for their excellent technical support during the  
 campaigns. Thanks also to David Farrel from the Caribbean Insti-  
 tute for Meteorology and Hydrology (CIMH) for logistical support.
