## Abstract

Gas-particle partitioning and hydrolysis of organic nitrates (ON) influences their role as sinks and sources of  $\text{NO}_x$  and their effects on the formation of tropospheric ozone and organic aerosol (OA). In this work organic nitrates were formed from the photo-oxidation of  $\alpha$ -pinene in environmental chamber experiments under different conditions. Particle-phase ON hydrolysis rates consistent with observed ON decay exhibited a nonlinear dependence on relative humidity (RH): An ON decay rate of  $2 \text{ day}^{-1}$  was observed when the RH ranged between 20 and 60%, and no significant ON decay was observed at RH lower than 20%. In experiments when the highest observed RH exceeded the deliquescence RH of the ammonium sulfate seed aerosol, the particle-phase ON decay rate was as high as  $7 \text{ day}^{-1}$  and more variable. The ON gas-particle partitioning is dependent on total OA concentration and temperature, consistent with absorptive partitioning theory. In a volatility basis set the ON partitioning is consistent with mass fractions of [0 0.11 0.03 0.86] at saturations mass concentrations ( $C^*$ ) of [1 10 100 1000]  $\mu\text{g m}^{-3}$ .

## 1 Introduction

Organic nitrates (ON) play an important role in atmospheric chemistry as they can act as sinks and sources of  $\text{NO}_x$  ( $\text{NO} + \text{NO}_2$ ) and thereby affect the formation of tropospheric ozone and organic aerosol. The sink reaction – addition of  $\text{NO}$  to a peroxy radical ( $\text{R-O-O}\cdot$ ) to form an organic nitrate ( $\text{R-O-NO}_2$ ) – breaks the  $\cdot\text{OH}$  initiated oxidation cycle and reduces the formation of ozone (Seinfeld and Pandis, 2006). Most  $\text{R-O-NO}_2$  molecules are semi-volatile and are therefore expected to partition between the gas and particle phases. They can be transported in either phase and can become a source of  $\text{NO}_x$  when they are photolyzed or oxidized, contributing to the regional nature of  $\text{NO}_x$  pollution. Attempts to implement organic nitrate decomposition reactions in a chemical transport model which did not account for gas-particle partitioning of organic nitrates resulted in over-prediction of  $\text{NO}_x$  and ozone concentrations (Yarwood et al., 2012), consistent with an over-estimate of the strength of organic nitrates as  $\text{NO}_x$  sources.

Recent studies have suggested that organic nitrates in the condensed phase may undergo hydrolysis, leading to the formation of  $\text{HNO}_3$  (Day et al., 2010; Darer et al., 2011; Hu et al., 2011; Liu et al., 2012; Browne et al., 2013; Jacobs et al., 2014; Rindelaub et al., 2015). This is a more permanent sink for  $\text{NO}_x$  and would decrease the regeneration of  $\text{NO}_x$  from organic nitrates. While these studies have found

35 evidence for hydrolysis of aerosol-phase organic nitrates ( $\text{ON}^{\text{aer}}$ ), it is not clear at which rate ON  
36 hydrolysis occurs. Correctly modeling organic nitrates and ozone formation depends on knowledge of  
37 the ON partitioning and hydrolysis rate.

38 While ON hydrolysis in the bulk phase has been studied for decades (Baker and Easty, 1950; Baker and  
39 Easty, 1952; Boschan et al., 1955), organic nitrate hydrolysis in atmospheric particles has only recently  
40 started to receive attention. Day et al. (2010) observed a decrease in particulate organic nitrates  
41 measured in coastal southern California under acidic conditions at high relative humidity and  
42 hypothesized hydrolysis as the cause. Browne et al. (2013) used ON hydrolysis to justify observations  
43 over the Boreal Forest of higher levels of  $\text{HNO}_3$  despite higher production rates of organic nitrates. The  
44 chamber experiments (0 to >80% RH) performed by Liu et al. (2012) using trimethylbenzene (an  
45 anthropogenic volatile organic compound) and HONO as oxidant were the first to measure the  
46 hydrolysis of condensed organic nitrates. Rindelaub et al. (2015) observed ON hydrolysis while  
47 measuring partitioning of  $\alpha$ -pinene SOA but did not directly quantify it. Boyd et al. (2015) measured  
48 hydrolysis of ON formed from nitrate radical oxidation of  $\beta$ -pinene.

49 The partitioning of organic nitrates to the particle phase is important to determine their fate as only  
50 condensed organic nitrates are expected to hydrolyze appreciably to  $\text{HNO}_3$ . Absorptive partitioning  
51 theory (Pankow, 1994; Donahue et al., 2006, Rollins et al., 2013; Rindelaub et al., 2015) has been used  
52 to describe the gas-particle partitioning of organic nitrates. Rollins et al. (2013) used partitioning data  
53 from the 2010 CalNex Campaign to find a volatility basis set distribution for ON observed at ambient  
54 aerosol concentrations. Rindelaub et al. (2015) observed the partitioning of organic nitrates formed  
55 from the  $\cdot\text{OH}$  initiated oxidation of  $\alpha$ -pinene at various levels of relative humidity. However, other work  
56 has suggested that the partitioning of organic nitrates to the particle phase is irreversible (Perraud et al.,  
57 2012). The goals of this work were to form organic nitrates in controlled environmental chamber  
58 experiments from the  $\text{OH}\cdot$  initiated oxidation of  $\alpha$ -pinene under high  $\text{NO}_x$  conditions and various relative  
59 humidity levels and:

- 60 1. Quantify the hydrolysis rate of organic nitrates.
- 61 2. Confirm that the gas-particle partitioning of organic nitrates is reversible and can therefore be  
62 modeled by absorptive partitioning theory
- 63 3. Parameterize the gas-particle partitioning of organic nitrates

## 64 **2 Methods**

### 65 **2.1 Environmental Chamber Experiments**

66 All experiments were performed in the Atmospheric Physicochemical Processes Laboratory Experiments  
67 (APPLE) chamber located at the University of Texas at Austin (UT-Austin). The APPLE chamber is a  $\sim 12$   
68  $\text{m}^3$  Teflon<sup>®</sup> bag suspended inside of a temperature-controlled room. The walls of the room are lined  
69 with UV lights which can be used to induce photolysis reactions. The intensity of the UV lights has been  
70 characterized by the photolysis rate of  $\text{NO}_2$ , which was measured to be  $0.4 \text{ min}^{-1}$ , similar to ambient  $\text{NO}_2$

71 photolysis rates (e.g.  $0.46 \text{ min}^{-1}$  at a zenith angle of  $40^\circ$ , Carter et al., 2005). Before each experiment the  
72 bag was flushed for at least 12 hours with clean air from an Aadco clean air generator (Model 737-14A)  
73 at a flow rate exceeding 100 liters per minute (LPM). Ammonium sulfate ( $(\text{NH}_4)_2\text{SO}_4$ ) particles (Fisher  
74 Scientific, 99.5%) were injected both to monitor wall loss rates (Hildebrandt et al., 2009) as well as to act  
75 as seed particles onto which organic vapors can condense. Gas phase NO was injected directly into the  
76 chamber from a cylinder (Airgas, 9.94 PPM  $\pm 2\%$ ) and liquid-phase  $\alpha$ -pinene (Sigma Aldrich, 98%) was  
77 injected to a glass bulb and subsequently evaporated into the chamber with a steady stream of mildly  
78 heated air.  $\text{H}_2\text{O}_2$ , which photolyzes to  $2 \cdot\text{OH}$ , was used as  $\cdot\text{OH}$  radical source and was either injected by  
79 bubbling air through an aqueous  $\text{H}_2\text{O}_2$  solution (Fisher Scientific, 30% weight) or by injecting  $\text{H}_2\text{O}_2$   
80 solution into a glass bulb and subsequently evaporating it into the chamber with a steady stream of  
81 mildly heated air. Some experiments were performed under dry conditions ( $<5\%$  relative humidity); in  
82 other experiments humidity was increased by passing air through clean water and then into the  
83 chamber. Experimental conditions and results are summarized in Table 1. Results are discussed in Sect.  
84 3.

85 Reactions were allowed to proceed for at least 4 hours with continuous UV light. Experiments were run  
86 in a batch mode with no injections or dilution after the experiment was started; the bag volume of 12  
87  $\text{m}^3$  allowed ample time for sampling. In some cases the temperature effects on gas-particle partitioning  
88 were observed by increasing temperature to  $40^\circ\text{C}$  in the chamber after the UV lights had been turned  
89 off (see Sect. 3.2).

90

### 91 **2.1.1 Instrumentation**

92 The composition of  $\text{PM}_{10}$  (particulate matter smaller than 1 micrometer in diameter) was measured using  
93 an Aerosol Chemical Speciation Monitor (ACSM) from Aerodyne Research Inc. (Ng et al., 2011). In the  
94 ACSM, particles are flash-vaporized on a heater at  $600^\circ\text{C}$ , and the resulting gas molecules are ionized  
95 using electron-impact ionization. This harsh ionization method results in fragmentation of most  
96 molecules. The molecular fragments, which are measured by a quadrupole mass spectrometer, are  
97 attributed to four categories—organics, nitrate, sulfate, and ammonium - using a fragmentation table  
98 (Allan et al., 2004). The instrument alternates between normal sampling and sampling through a particle  
99 filter, enabling subtraction of a gas-phase background. During this study the ACSM was operated at a  
100 time resolution (filter/sample cycle length) of approximately 90 seconds. The size distribution of  
101 particles was measured using a Scanning Electrical Mobility System (SEMS) from Brechtel  
102 Manufacturing, Inc. The SEMS uses a Differential Mobility Analyzer (DMA) to size-select particles based  
103 on their electric mobility, which are then counted by a Condensation Particle Counter (CPC). The DMA  
104 continuously cycled between the voltages which select particles ranging from 5 to 1000 nm, resulting in  
105 a time resolution of the particle size distribution of approximately 60 seconds.

106 Gas phase reaction products were monitored using a High-Resolution Time-of-Flight Chemical Ionization  
107 Mass Spectrometer (HR-ToF-CIMS) from Aerodyne Research, Inc.. The HR-ToF-CIMS uses softer chemical  
108 ionization which results in minimal fragmentation of parent molecules. Mass spectra are derived from  
109 measurements of the ions' time-of-flight as they are pulsed through a low pressure chamber in a "V"

110 shape. Two chemical reagent ions were used—water clusters ( $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ) and iodide-water clusters ( $\text{I}^-$   
111  $\cdot(\text{H}_2\text{O})_n$ ). Water cluster ionization is most sensitive towards detection of moderately oxidized  
112 hydrocarbons; the ability to ionize and thus sensitivity is based on the relative proton affinity between  
113 the water cluster and the parent molecule (Lindinger et al., 1998). This method was used to monitor  $\alpha$ -  
114 pinene as well as early-generation oxidation products. Iodide-water cluster ionization is most sensitive  
115 towards detection of more highly oxidized hydrocarbons; this method was used to observe later-  
116 generation oxidation products as well as  $\text{HNO}_3$  and  $\text{H}_2\text{O}_2$ . In the work presented here data from the HR-  
117 ToF-CIMS are only used qualitatively since, as it was later discovered, a partially clogged inlet may have  
118 interfered with instrument calibration and quantitative measurements.

119 Concentrations of NO and  $\text{O}_3$  were measured using Teledyne chemiluminescence  $\text{NO}_x$  and absorption  $\text{O}_3$   
120 monitors (200E and 400E, respectively); concentrations of  $\text{NO}_2$  were measured via an  $\text{NO}_2$  monitor from  
121 Environnement (Model AS32M), which uses a Cavity Attenuated Phase Shift (CAPS) method to directly  
122 measure  $\text{NO}_2$  (Kebabian et al., 2008). The advantage of this direct  $\text{NO}_2$  measurement is that it does not  
123 rely on  $\text{NO}_2$  conversion to NO and therefore does not suffer from interference by other oxidized  
124 nitrogen compounds such as HONO and organic nitrates (Winer et al., 1974).

## 125 2.1.2 Data Analysis

126 Data from the ACSM were analyzed in Igor Pro using the software package “ACSM Local,” which includes  
127 a correction for relative ion transmission efficiency as well as changes in the flow rate throughout the  
128 experiment. The SEMS volume concentration was converted to mass using the densities  $1.77 \text{ g/cm}^3$  for  
129 ammonium sulfate and  $1.4 \text{ g/cm}^3$  for organics and organic nitrates (Ng et al., 2007). The time series of  
130 particle mass concentration (not corrected for wall losses) during Expt. 7 is shown in Fig. S1; other  
131 experiments exhibited similar time series.

132 All PM nitrate (measured by the ACSM as  $\text{NO}^+$  and  $\text{NO}_2^+$  fragments) was assumed to be organic because  
133 no inorganic nitrate was introduced in these controlled experiments. Nitric acid is formed in the gas  
134 phase as well as in the particle phase through hydrolysis, but it is assumed that nitric acid  
135 concentrations are negligible in the particle phase due to its high vapor pressure (Fry et al., 2009). A  
136 Henry’s Law calculation suggests that the total amount of aqueous  $\text{HNO}_3$  in particles is 3 orders of  
137 magnitude lower than that in the gas phase.

138 The ACSM does not detect all sampled particles, primarily due to particle bounce at the vaporizer,  
139 resulting in a collection efficiency (CE) smaller than 1. Collection efficiency and wall losses were  
140 accounted for simultaneously by multiplying the ACSM concentrations of organics and organic nitrates  
141 by the mass concentration ratio  $C_{SEMS}^{t=0}/C_{ACSM}^{seed}(t)$  as has been done in previous work (Hildebrandt et al.,  
142 2009). Here,  $C_{SEMS}^{t=0}$  is the mass concentration of ammonium sulfate seed just before the UV lights are  
143 turned on and organic aerosol formation commences and  $C_{ACSM}^{seed}(t)$  is the time dependent mass  
144 concentration of  $(\text{NH}_4)_2\text{SO}_4$  measured by the ACSM throughout the experiment. This correction assumes  
145 that particles on the chamber walls participate in gas-particle partitioning as though they are still in  
146 suspension and that the suspended ammonium sulfate concentration changes only due to wall losses. It  
147 accounts for partitioning of organic vapors into wall-deposited particles (Hildebrandt et al., 2009) but

148 does not account for losses of organic vapors onto the clean Teflon® walls (e.g. Matsunaga and Ziemann,  
149 2010).

150 The ACSM standard fragmentation table was adjusted based on filter measurements taken in each  
151 experiment as described in the supplementary information. Data from the HR-ToF-CIMS were analyzed  
152 in Igor Pro (Wavemetrics) using Tofware, the software provided with the instrument. The data were first  
153 mass calibrated based on HR-ToF-CIMS reagent ions and other known ions. The baseline was subtracted  
154 and the average peak shape was found so it could be used for high resolution analysis, through which  
155 multiple ions can be identified at any given integer  $m/z$ . Ions up to  $m/z$  300 were analyzed in high  
156 resolution mode. Only prominent ions were fit above  $m/z$  200 because of the high number of possible  
157 ions at this high  $m/z$ . After ions were identified in the high resolution spectrum, the peaks were  
158 integrated to yield a time series of ions. Analyte ion concentrations were then normalized by the  
159 reagent ion concentrations – the sum of  $\text{H}_3\text{O}^+$ ,  $\text{H}_3\text{O}^+\cdot(\text{H}_2\text{O})$  and  $\text{H}_3\text{O}^+\cdot(\text{H}_2\text{O})_2$  for water cluster  
160 ionization and the sum of  $\text{I}^-$  and  $\text{I}^-\cdot(\text{H}_2\text{O})$  for iodide-cluster ionization. This correction accounts for  
161 changes in reagent ion concentrations and instrument sensitivity during and between experiments.  
162 Relative humidity can affect instrument sensitivity but this varied by less than 5% during each  
163 experiment.

164 The partitioning coefficient of a species is defined as the ratio of the species concentration in the  
165 particle phase to the total species concentration (gas and particle phase). For a single compound the  
166 partitioning coefficient is the same whether it is on a mass or mole basis. However, for a mix of  
167 compounds, such as those formed in  $\cdot\text{OH}$ -initiated oxidation, the mass and mole-basis partitioning  
168 coefficients will be different, with the coefficient expected higher on a mass basis since higher molecular  
169 weight compounds typically have lower vapor pressure. The partitioning coefficient in this work was  
170 calculated on a mole basis, in part because fragmentation in the ACSM makes it impossible to tell the  
171 original size and identity of ON molecules. This mole-basis partitioning coefficient is also more useful for  
172 most modeling efforts which group chemical species without knowledge of their exact molecular  
173 identity. The particle-phase ON concentration was quantified using data from the ACSM: the mass  
174 concentration of nitrate measured by the ACSM was converted to mixing ratio (ppb) using the molecular  
175 weight of the nitrate functional group (62 g/mol). This assumes that the ON have only one nitrate  
176 functional group. Conversion of the nitrate mass concentration to mixing ratio avoids the need to  
177 assume an ON molecular weight (needed to estimate ON mass concentrations from ACSM) and is  
178 therefore deemed to be a more accurate measure of ON from the ACSM. Quantification of all gas phase  
179 ON species would necessitate calibration and identification of all ON species which is not feasible.  
180 Instead, a chamber box model and nitrogen balance was employed to estimate total gas-phase ON as  
181 described below.

## 182 **2.2 Chamber Modeling and Partitioning Coefficient**

183 In these experiments only five major forms of oxidized nitrogen are present in significant  
184 concentrations— $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{ON}^{\text{gas}}$  and  $\text{ON}^{\text{aer}}$  (gas and aerosol-phase organic nitrates, respectively).  
185 Figure S2 shows that, based on the Statewide Air Pollution Research Center (SAPRC) model  
186 (<http://www.engr.ucr.edu/~carter/SAPRC/>), the concentrations of other forms of reactive nitrogen are  
187 orders of magnitude lower than the concentrations of these five forms. Concentrations of  $\text{NO}$  and  $\text{NO}_2$

188 were measured using gas-phase monitors, and  $\text{ON}^{\text{aer}}$  was measured using the ACSM. Concentrations of  
 189  $\text{HNO}_3$  were approximated using the SAPRC box model. The concentration of  $\text{H}_2\text{O}_2$  cannot be estimated  
 190 from the injection method used in these experiments. Therefore, the  $\text{H}_2\text{O}_2$  concentration used in the  
 191 model was adjusted until the modeled  $\text{NO}$ ,  $\text{NO}_2$ , and  $\text{O}_3$  concentrations closely matched those observed  
 192 throughout each experiment as shown in Fig. S3 for Expt. 7. The modeled  $\text{HNO}_3$  concentration was then  
 193 used with the measured  $\text{NO}$ ,  $\text{NO}_2$ , and  $\text{ON}^{\text{aer}}$  to find the  $\text{ON}^{\text{gas}}$  based on a nitrogen mass balance ( $\text{ON}^{\text{gas}} =$   
 194  $\text{NO}_x^{\text{initial}} - \text{NO}_2 - \text{NO} - \text{ON}^{\text{aer}} - \text{HNO}_3^{\text{model}}$ ). The partitioning coefficient was then calculated as a time series  
 195 for each experiment.

196 SAPRC simulations were conducted with the reaction mechanism Carbon Bond 6 revision 2 (CB6r2),  
 197 which includes organic nitrate hydrolysis through a rate estimated from a combination of the work of Liu  
 198 et al. (2012) and Rollins et al. (2013) (Hildebrandt Ruiz and Yarwood, 2013). Experiments were modeled  
 199 with and without organic nitrate hydrolysis to see the effect this has on the predicted ON partitioning  
 200 coefficient. The overall effect of this process was small, with a maximum effect being a 5% decrease to  
 201 the partitioning coefficient by removing the hydrolysis mechanism from the model. This corresponded  
 202 to a 17% decrease in  $\text{HNO}_3$ , which suggests that the partitioning coefficient estimated in this work is not  
 203 very sensitive to changes in the modeled  $\text{HNO}_3$  concentrations. For the results and analysis presented  
 204 here the  $\text{HNO}_3$  concentrations were taken from CB6r2 with the inclusion of the ON hydrolysis process  
 205 for experiments above 20% RH and without the hydrolysis process for experiments below 20% RH.

206 According to absorptive partitioning theory (Pankow, 1994; Donahue et al., 2006), the gas-particle  
 207 partitioning of an organic species depends on its vapor pressure and the concentration of organic  
 208 material in the particle phase. The fraction of a compound  $i$  in the particle phase ( $Y_i$ ) is given by  
 209 (Donahue et al., 2006):

$$210 \quad Y_i = \left(1 + \frac{C_i^*}{C_{\text{OA}}}\right)^{-1} \quad (1)$$

211 where  $C_{\text{OA}}$  is the organic aerosol concentration and  $C_i^*$  is the saturation mass concentration of species  $i$   
 212 (the saturation vapor pressure converted to concentration units). In the volatility basis set (VBS,  
 213 Donahue et al., 2006), organic species are lumped by  $C_i^*$  spaced logarithmically. This leads to an overall  
 214 partitioning coefficient

$$215 \quad Y_{\text{tot}} = \sum_{i=1}^n F_i \left(1 + \frac{C_i^*}{C_{\text{OA}}}\right)^{-1} \quad (2)$$

216 (Rollins et al., 2013), where  $F_i$  is the fraction of organic species in the volatility bin described by  $C_i^*$ . In  
 217 this work we used measurements of  $C_{\text{OA}}$  and  $Y_{\text{tot}}$  to fit the  $F_i$  using a Matlab optimization routine. These  
 218 VBS parameters can be used in models to represent the gas-particle partitioning of organic nitrates and  
 219 account for changes in partitioning with temperature and  $C_{\text{OA}}$ .

## 220 **3 Results and Discussion**

221 A typical time series of compounds containing oxidized nitrogen is shown in Fig. 1 (Expt. 7). Initially the  
222 chamber contains only NO and a small amount of NO<sub>2</sub>, in addition to  $\alpha$ -pinene and inorganic seed  
223 aerosol. When the UV lights are activated at time = 0 the NO immediately begins to react with ·OH and  
224 other radicals to form NO<sub>2</sub> and additional NO<sub>y</sub> compounds such as organic nitrates. Table 1 summarizes  
225 results from all experiments. Concentrations of O<sub>3</sub>, ON<sup>air</sup>, PM organics, and ON<sup>gas</sup> are averaged over  
226 approximately 20 minutes of the time when PM organics and nitrates peak in concentration. This  
227 averaging period was chosen so that experiments with different H<sub>2</sub>O<sub>2</sub> concentrations could be compared  
228 even though they reach their maximum concentrations at different rates. Higher initial loading of NO<sub>x</sub>,  
229  $\alpha$ -pinene, and H<sub>2</sub>O<sub>2</sub> resulted in higher concentrations of ozone and PM.

230 Figure 2 shows time series of molecular ions identified using the HR-ToF-CIMS using water cluster  
231 (“positive mode”) and iodide-water cluster (“negative mode”) ionization. Many compounds are  
232 identified with the CIMS and a select few of the most prominent compounds were chosen for Fig. 2. In  
233 short time periods after switching reagent ions the sensitivity of the HR-ToF-CIMS slowly adjusts to a  
234 steady state value. Minor changes during these short time periods should be taken with caution but the  
235 overall trends over the 4.5 hour experiment are useful in viewing oxidation trends. The initial data  
236 collected in negative mode show that formation of organic nitrates begins immediately after oxidation  
237 has started. Later in the experiment the less-oxygenated compounds observed in positive mode begin to  
238 decrease while the more highly oxygenated compounds observed in negative mode continue to  
239 increase, consistent with oxidation and conversion of less oxidized compounds to more highly oxidized  
240 compounds continuing throughout the experiment. Highly oxidized compounds which still contain ten  
241 carbon atoms (as the precursor  $\alpha$ -pinene) begin to decrease towards the end of the experiment while  
242 fragmented compounds (containing less than ten carbon atoms) continue to increase, consistent with  
243 fragmentation of the carbon backbone during oxidation. Molecular weights of the gas-phase compounds  
244 identified here range from 221 to 279 g mol<sup>-1</sup> and align well with the range of molecular weights  
245 estimated by Fry et al. (2009) for particle-phase organic nitrates formed from NO<sub>3</sub> oxidation of  $\alpha$ -pinene  
246 (229±12 to 434±25 g mol<sup>-1</sup>). Gas-phase organic nitrates identified here are therefore expected to be  
247 semi-volatile and to partition significantly to the particle phase.

### 248 **3.1 Hydrolysis of Organic Nitrates**

249 Concentrations of wall-loss corrected (normalized to SO<sub>4</sub>) PM nitrate were observed to decrease at the  
250 end of most experiments. These decreases of PM nitrate are attributed to physical or chemical  
251 processes in the gas and aerosol phases, and an exponential decay was fit to the data to quantify the  
252 decay. The exception was experiments 1 and 3 during which production of SOA was slow (primarily due  
253 to lower initial H<sub>2</sub>O<sub>2</sub> and  $\alpha$ -pinene) and continued throughout the experiment, so a decay could not be  
254 observed. Examples of the decay for a humid and dry experiment are shown in Fig. S4. The decay rates  
255 for each experiment are reported in Table 1 and appear to depend on relative humidity as shown in Fig.  
256 3. When the RH ranged between 20 and 60%, an ON decay rate of 2 day<sup>-1</sup> was observed; no significant  
257 ON decay was observed at RH lower than 20%. Experiments conducted at an average RH of 67% or  
258 higher can exhibit a significantly higher decay rate, probably due to effects of being near the  
259 deliquescence relative humidity of the ammonium sulfate seed aerosol. In experiments 10 and 12, which

260 have decay rates well above  $2 \text{ day}^{-1}$ , the chamber was initially cooled to  $20 \text{ }^\circ\text{C}$  before the UV lights were  
261 turned on. Once the UV lights were activated the temperature then increased to  $25 \text{ }^\circ\text{C}$  and the RH  
262 settled at the values indicated in Table 1. For these experiments the RH was above 80% (the  
263 deliquescence RH, DRH, of  $(\text{NH}_4)_2\text{SO}_4$  for several minutes, potentially resulting in aqueous aerosol.  
264 Experiment 11 also reached a relative humidity above deliquescence, yet it shows a lower nitrate loss  
265 rate than Expts. 10 and 12. The ratio of organics and nitrates to sulfate (seed) particles was much lower  
266 in Expt. 11 compared to Expts. 10 and 12, but whether and why this would result in a different nitrate  
267 loss rate is currently unclear. The relative humidity in Expt. 4 did not reach the DRH of  $(\text{NH}_4)_2\text{SO}_4$ . Future  
268 work should focus on the fate of ON at higher ( $> 60\%$ ) relative humidity. The generally higher nitrate loss  
269 rate at higher RH makes hydrolysis of particulate nitrate functional groups the most plausible  
270 explanation for the observed decay.

271 PM organics also decreased in some experiments, but their loss rate was lower and more variable than  
272 that of nitrate. Based on the work by Chuang et al. (2015) the addition of a nitrate functional group  
273 decreases volatility of a compound by 2.5 orders of magnitude – slightly more than the resulting alcohol  
274 group from hydrolysis. Thus, the organic compound resulting from ON is more volatile than the original  
275 organic nitrate, and as a result could partition to the gas phase, resulting in a decrease in PM organics.

276 No direct observation of hydrolysis (conversion of the  $-\text{ONO}_2$  group to an  $-\text{OH}$  group) has been made in  
277 this or previous work. The estimated hydrolysis lifetime of 12 hours (loss rate of  $2 \text{ day}^{-1}$ ) for particulate  
278 organic nitrates is similar to hydrolysis rates suggested by other studies under humid conditions. Liu et  
279 al. (2012) observed a trend similar to that shown in Fig. 3 in chamber experiments in which ON were  
280 formed from the oxidation of tri-methyl benzene using HONO as the  $\cdot\text{OH}$  and  $\text{NO}_x$  source. In those  
281 experiments, PM nitrate was found to have negligible loss rate below 20% RH but a lifetime of 6 hours at  
282 40% RH and higher. Perring et al. (2009) estimated the lifetime of isoprene nitrates to be between 95  
283 minutes and 16 hours depending on their branching ratio in isoprene  $\cdot\text{OH}$  oxidation. Boyd et al. (2015)  
284 measured a lifetime of 3-4.5 hours for 10% of ON formed from  $\text{NO}_3$  oxidation of  $\beta$ -pinene, with a much  
285 longer lifetime for the remaining 90%. This suggests that 10% of the ON functional groups were tertiary  
286 with the rest being primary or secondary as those have been shown to hydrolyze much slower in the  
287 bulk phase (Darer et al., 2011; Hu et al., 2011). In our results hydrolysis is not limited to 10% of ON,  
288 suggesting that a higher portion is tertiary ON functional groups.

289 Similar VOC precursors such as  $\alpha$ -pinene and  $\beta$ -pinene can form different fractions of primary/secondary  
290 and tertiary ON. When  $\text{NO}_3$  reacts and bonds with the terminal double bond of  $\beta$ -pinene, an alkyl radical  
291 is formed in either a primary or tertiary position (opposite of the carbon-nitrate bond). The tertiary alkyl  
292 radical is more stable, so primary organic nitrates are expected to be more abundant. The double bond  
293 in  $\alpha$ -pinene is not terminal, so the  $\text{NO}_3$  reaction produces either a secondary or tertiary ON and alkyl  
294 radical.  $\text{NO}_3$  typically bonds with the less substituted carbon of a double bond so that a more highly  
295 substituted alkyl radical is formed. The reverse is true for  $\text{OH}+\text{NO}$  chemistry. In this case  $\text{NO}$  reacts with  
296 the peroxy-radical to form the nitrate group. The peroxy-radical, a product of  $\text{O}_2$  and an alkyl radical, is  
297 likely to be on a more substituted carbon as this would have been the more stable alkyl radical. Thus,  
298 more highly substituted ON are expected from  $\text{OH} + \text{NO}_x$  than from  $\text{NO}_3$  chemistry. This has important  
299 implications for attempts to model ON and the resulting  $\text{NO}_x$  recycling.

300 As Table 1 shows experiments were conducted at varying  $\text{NO}_x$  and  $\alpha$ -pinene concentrations, relative  
301 humidity, and hydrogen peroxide ( $\cdot\text{OH}$  radical source) levels, which resulted in different final  
302 concentrations of PM nitrate and total OA. Liu et al. (2012) suggested that a lower PM nitrate / OA ratio  
303 at higher RH could be due to ON hydrolysis. In these experiments, the correlation between the ratio of  
304 PM nitrate/total OA (measured when total OA was highest) and RH was very low ( $R^2 = 0.02$ ). Thus, based  
305 on these experiments, differences in the observed final PM nitrate / OA are due to experimental  
306 conditions other than relative humidity.

### 307 **3.2 Gas-particle Partitioning of Organic Nitrates**

308 In order to test the reversibility of ON partitioning the temperature of the chamber was increased after  
309 OA had formed (and when the UV lights were off) in some experiments. Figure 4 shows gas and particle-  
310 phase measurements taken from a representative experiment (Expt. 2). After the UV lights are turned  
311 off there is a 60 minute period in which the temperature stabilizes around 15 °C. This is followed by ~90  
312 minutes of heating to a final temperature of 45 °C. After this the chamber is quickly cooled back to 15  
313 °C. Figure 4b shows a time series of the  $\text{Org}/\text{SO}_4$  and  $\text{ON}^{\text{aer}}/\text{SO}_4$  ratios measured by the ACSM. Sulfate  
314 has a low vapor pressure and does not evaporate significantly at the temperatures investigated;  
315 therefore changes in the  $\text{ON}^{\text{aer}}/\text{SO}_4$  and  $\text{Org}/\text{SO}_4$  ratios with chamber temperature can be attributed to  
316 partitioning of organic nitrates and other organic species between the gas and particle phases or wall  
317 losses of gas-phase species. As Fig. 4b shows,  $\text{Org}/\text{SO}_4$  and  $\text{ON}^{\text{aer}}/\text{SO}_4$  decreased with increasing  
318 temperature and increased with decreasing temperature, suggesting evaporation of species at higher  
319 temperatures and their re-partitioning to the particle phase at lower temperatures.

320 Figure 4c shows the effects of temperature on various compounds measured in the gas phase. Several  
321 organic compounds – with and without ON functional groups - increase with increasing temperature.  
322 This suggests that these compounds are present in both the gas and particle phases and evaporate at  
323 higher temperature resulting in increased gas phase concentrations. As temperature is increased the  
324 percent change in the concentration of gas-phase  $\text{C}_{10}\text{H}_{16}\text{O}_2$  is less than the change in  $\text{C}_{10}\text{H}_{16}\text{O}_4$  and the  
325 percent change in the concentration of gas-phase  $\text{C}_{10}\text{H}_{15}\text{NO}_4$  is less than the change in  $\text{C}_{10}\text{H}_{15}\text{NO}_6$ . This is  
326 consistent with the more highly oxidized compounds having a lower vapor pressure and evaporating  
327 less. As the temperature is decreased back to 15 °C the concentrations return to the pre-heating trends,  
328 suggesting that re-condensation to the particle-phase has occurred. These observations, as well as the  
329 trends seen in particle-phase measurements are consistent with equilibrium partitioning and  
330 inconsistent with the irreversible partitioning of ON recently suggested by Perraud et al. (2012).

331 Other processes may influence particle and gas concentrations of organic compounds. Continuing  
332 reactions with  $\text{O}_3$  and nitrate radicals (since  $\text{O}_3$  and  $\text{NO}_2$  are both present) limit the ability to stop all  
333 chemical activity. This is seen in the gas phase compounds, some of which appear to be changing in  
334 concentration after the UV lights are off. Despite this a clear change is seen in all compounds with a  
335 temperature increase. During the cooling phase (beginning at  $t = 320$  minutes) the particle phase  
336 organic and nitrate concentrations do not return to the original levels. It is likely that some organic  
337 compounds are lost to the walls of the Teflon chamber, especially since they reach the coldest  
338 temperatures during active cooling, and thus  $\text{Org}/\text{SO}_4$  does not return to the values seen before

339 temperature changes began. Despite these limitations it is clear that both the Org/SO<sub>4</sub> and ON<sup>aer</sup>/SO<sub>4</sub>  
340 ratios decrease with heating, consistent with semi-volatile organics and organic nitrates.

341 Table 1 summarizes the ON partitioning coefficient averaged over approximately 20 minutes from when  
342 PM organics and nitrates peak in concentration. Partitioning data is not calculated for experiments  
343 above 60% RH. As discussed, these experiments had higher and less consistent nitrate decay rates which  
344 may affect partitioning. In addition, the wall loss correction used here and in previous work (Hildebrandt  
345 et al., 2009) assumes that particles lost to the walls still participate in partitioning as though they were  
346 still in suspension. This assumption may be poor if small amounts of water condense onto the walls of  
347 the chamber in these high RH experiments.

348 Data from the lower-concentration experiments (Expts 1, 2, and 3) were fit to a volatility basis set as  
349 these experiments were conducted under conditions which are more atmospherically relevant.  
350 Experimental data were used after total PM organics (corrected for wall losses) had reached 2 µg m<sup>-3</sup> to  
351 avoid effects of noise and model uncertainty at the beginning of the experiments when concentrations  
352 of both gas- and particle-phase organic nitrates were low. Outlying points (for example, when PM  
353 organics temporarily rose above 2 µg m<sup>-3</sup> but subsequent data suggested that condensation had not  
354 begun) were removed as well. Figure 5 shows the data used to find the volatility basis set along with the  
355 fit. The C\* values used for this were 1, 10, 100, and 1000 µg m<sup>-3</sup>; the corresponding mass fractions (F<sub>i</sub>)  
356 calculated to give the best fit for Eq. (2) (Sect. 2.2) are F<sub>i</sub> = 0, 0.11, 0.03, and 0.86.

357 As seen in Fig. 5 these results indicate that under typical ambient conditions (< 40 µg/m<sup>3</sup> of OA) 5-10%  
358 of organic nitrates formed from the photo-oxidation of α-pinene under high NO<sub>x</sub> conditions are  
359 expected to partition to the particle phase. This is significantly lower than the organic nitrate  
360 partitioning calculated by Rollins et al. (2013) for organic nitrates measured in Bakersfield, CA during the  
361 CalNex campaign in 2010. In those measurements >30% partitioning of ON was observed at organic  
362 aerosol concentrations of 10 µg/m<sup>3</sup>. The difference could be attributed to differences in precursor  
363 molecules and levels of oxidation. Studies have shown that high NO<sub>x</sub> conditions can shift photochemical  
364 oxidation products of terpenes towards higher volatility compounds (Wildt et al. 2014). Rollins et al.  
365 determined using the SPARC model (Hilal et al., 2003) that precursor molecules (a mix of C5-C15 VOCs)  
366 would need two stages of oxidative chemistry beyond the initial oxidation of the VOC to reach the point  
367 when 19-28% would partition to the particle phase for a C<sub>OA</sub> of 3 µg m<sup>-3</sup>. This may suggest that the ON  
368 formed in our experiments have undergone fewer than three generations of oxidation as they are more  
369 volatile than the ON measured in Bakersfield during CalNex 2010. It should also be noted that the  
370 thermal dissociation-laser induced fluorescence (TD-LIF) instrument used by Rollins et al. (2013) has  
371 been shown in a recent study to measure PM ON a factor of two higher than the ON measured by  
372 aerosol mass spectrometers (Ayres et al., 2015) which utilize similar measurement and detection  
373 techniques as the ACSM used in this work. While the reasons for this difference are unknown it would  
374 result in a higher partitioning coefficient compared to the one calculated from the AMS (or ACSM) and  
375 explain part of the observed difference.

## 376 **4 Conclusions**

377 Organic nitrates formed during the oxidation of  $\alpha$ -pinene decay in the particle phase at a rate of  $2 \text{ day}^{-1}$   
378 when RH is between 20 and 60%, with no significant decay observed below an RH of 20%. During  
379 experiments when the highest observed RH exceeded the deliquescence RH of the ammonium sulfate  
380 seed aerosol, the particle-phase ON decay was as high as  $7 \text{ day}^{-1}$  and more variable. The dependence of  
381 observed decay rate on relative humidity suggests organic nitrate hydrolysis as the most plausible  
382 explanation. The gas-particle partitioning of ON determines their potential to hydrolyze. Partitioning of  
383 the ON is reversible and can be described by a volatility basis set.

384 The conversion of NO<sub>x</sub> to organic nitrates affects local ozone production. Partitioning and hydrolysis of  
385 organic nitrates affect regional concentrations of organic particulate matter and ozone. The organic  
386 nitrate partitioning coefficient and hydrolysis rates from this work can be used to include these  
387 processes in chemical transport models and more accurately represent the effect of organic nitrates on  
388 concentrations of ozone and particulate matter.
