Response to referee comments on “Uncertainties in isoprene photochemistry and emissions: Implications for the oxidative capacity of past and present atmospheres and for climate forcing agents”.

We thank the reviewers for their feedback and suggestions for minor revisions to further improve the manuscript.

Referee's comments are *in italics*, our responses are in plain text, and changes to the manuscript are in **blue**. (Note: all page and line references are for the “acp-2014-1036-manuscript-version3.pdf” manuscript version.)

REFEREE #1

General comments

The authors have worked hard to respond to the referees' comments and done a valiant job of defending their points. As such, the revised paper is rather long. I am still not completely convinced that the results as currently presented in this paper represent any meaningful scientific advances in understanding LGM-PI chemistry-climate interactions. That said, the large suite of global model sensitivity simulations probably (at least in my view) deserve to be published.

Our discussion section elaborates on how our study contributes to scientific understanding of LGM-PI chemistry-climate interactions: “The main scientific value of our study lies in its demonstration of the importance of biogenic VOC emissions and the fate of their oxidation products in influencing chemistry-climate interactions across the last glacial-interglacial time interval and the industrial era. Because of existing uncertainties in isoprene emissions and photochemistry, there are larger uncertainties in model estimates of the oxidative capacity of past atmospheres than previously acknowledged. These uncertainties, in turn, limit our confidence in estimating radiative forcing due to changes in short-lived species such as SOA over time, as well as our ability to identify the factors controlling global mean OH levels between the LGM and the present day.”

The most important result in the manuscript is that global tropospheric ozone burden changes are not sensitive to uncertainties in isoprene emissions or oxidation mechanism, which the authors seem to downplay.

Section 3.5 discusses the radiative forcing implications of our ozone results. We now also mention these results in our abstract:

We find that different oxidants have different sensitivities to the uncertainties tested in this study. Ozone is relatively insensitive, whereas OH is the most sensitive: changes in the global mean OH levels for the LGM-to-preindustrial transition range between -29 % and +7 %, and those for the preindustrial-to-present day transition range between -8 % and +17 %, across our simulations.

An over-arching remaining community question beyond the scope of their current study is the use of the MEGAN model for simulation isoprene emissions in different global climatic states because MEGAN was actually developed to simulate short-term

weather-related fluctuations in isoprene emission for day-to-day surface air quality applications in the temperate zone. It does not perform well in tropical ecosystems. Soil moisture changes in different climatic states are not independent of the atmospheric CO₂ and temperature changes. Therefore, the authors' argument about simply decoupling the empirical scalars is not valid.

We appreciate the reviewer's comments about the inadequacy of MEGAN, but as the reviewer points out, investigating the effects of soil moisture is beyond the scope of our study.

REFEREE #2

General comments

Achakulwisut et al have dramatically improved this manuscript and the scientific contribution is clearly stated. The only major issue that was not satisfactorily addressed in the first round of revisions is the justification of their “cold LGM” scenario. In their response they cite Holden et al (2010) and Gilder et al (2014), however neither of these papers specifically address tropical SSTs. Holden et al (2010) investigated interhemispheric coupling between the West Antarctic Ice Sheet and the AMOC. Gilder et al (2014) examined how sea ice affected the hydrologic cycle. Using the tropical SSTs from these model sensitivity studies is taking their studies out of context. To my knowledge, the current best proxy-based reconstruction of LGM tropical SSTs comes from the MARGO project that found tropical SSTs that are close to their “warm LGM” scenario SSTs. It is also instructive that the Webb et al (1997) paper is not cited in the IPCC AR5 in the chapter about paleoclimate archives. Instead, the IPCC AR5 table 5.2 lists a host of studies for low latitude SSTs that do not exceed 3.2 C (including reported uncertainties). In addition to the MARGO work, they cite: Ballantyne et al. (2005); Lea et al. (2000); de Garidel-Thoron et al. (2007); Leduc et al. (2007); Pahnke et al. (2007); Stott et al. (2007); Koutavas and Sachs (2008); Steinke et al. (2008); Linsley et al. (2010). It appears that the authors are using the “cold LGM” conditions primarily because this was the model framework used in Murray et al (2014). It is my view that this rationale is insufficient for including the “cold LGM” scenario for these reasons: 1.) Just because someone else did it doesn't mean it should be done again if the justification is lacking. 2.) How many of the conclusions in the present manuscript and to what extent are the magnitudes of the sensitivities dependent on the cold LGM scenario? If future work cites ranges of uncertainties reported in this paper, they will be citing ranges that include a climate scenario that is not consistent with paleoclimate archives. Since one of the central messages of this study is to point out that there are large uncertainties in understanding the oxidative capacity of the atmosphere in the past, this is an important issue.

We appreciate the concerns raised by the reviewer and accept that results from the MARGO project are the current best assumption of what tropical SSTs were like at the LGM. However, the goal of our study is to test the robustness of model results to a conservative range of estimates pooled from the literature. Therefore, we choose to publish our model results from the cold LGM scenario.

We have added a sentence to note that estimates of tropical SSTs in our “warm LGM” scenario is more similar to those from the MARGO project, which is the current best assumption of what tropical SSTs were like at the LGM (page 9, end of 1st paragraph):

A more recent estimate from the MARGO project, which is the current best assumption of tropical SSTs at the LGM, found $\Delta SST_{15^\circ S-0^\circ N}$ of -1.7 ± 1.0 °C (Waelbroeck et al., 2009). These estimates are more similar to the warm LGM than the cold LGM scenarios used in this study.

Specific comments

1. Pg 4, line 3 – “of this record” is not needed in this sentence.

We thank the reviewer for the suggestion but we think that the sentence reads better if “of this record” is included.

2. Pg 4, line 7 – “...past variations in atmospheric methane concentration” -> concentration should be plural: “concentrations”

Fixed. This sentence now reads:

Such discrepancies call into question our ability to quantify the relative roles of sources and sinks in driving past variations in atmospheric methane concentrations.

3. Pg 4, end of 1st paragraph – There are other studies here that have been left out, principally: Levine, J. G., E. W. Wolff, A. E. Jones, L. C. Sime, P. J. Valdes, A. T. Archibald, G. D. Carver, N. J. Warwick, and J. A. Pyle. “Reconciling the Changes in Atmospheric Methane Sources and Sinks between the Last Glacial Maximum and the Pre-Industrial Era.” *Geophysical Research Letters* 38 (December 2011). doi:10.1029/2011gl049545.

This reference has now been added to the end of the paragraph:

This issue remains an ongoing debate (e.g., Levine et al., 2011c; Quiquet et al., 2015).

5. In re-reading Levine et al 2011, there should probably be more comparisons with this paper throughout the present manuscript since they cover very similar topics.

We now include a comparison to results from Levine et al. (2011c) in the discussion section (page 31, 1st paragraph):

The main scientific value of our study lies in its demonstration of the importance of biogenic VOC emissions and the fate of their oxidation products in influencing chemistry-climate interactions across the last glacial-interglacial time interval and the industrial era. Because of existing uncertainties in isoprene emissions and photochemistry, there are larger uncertainties in model estimates of the oxidative capacity of past atmospheres than previously acknowledged. For example, Levine et al. (2011c) concluded that the effects of temperature and specific humidity cancel out the effects of biogenic NMVOCs on OH across glacial timescales, with or without consideration of OH-recycling in the isoprene photo-oxidation mechanism. However,

using a more complex tropospheric chemical mechanism, including a more detailed representation of OH-recycling, as well as considering the effects of the CO₂-sensitivity of plant isoprene emissions and of changes in the stratospheric column ozone and tropospheric NO_x emissions, we demonstrate that uncertainties in the LGM-to-preindustrial change in OH remain substantial. Such uncertainties, in turn, limit our confidence in estimating radiative forcing due to changes in short-lived species such as SOA over time, as well as our ability to identify the factors controlling global mean OH levels between the LGM and the present day.

6. *In section 2.4 in the paragraph about prescribed methane concentrations, there is an inaccurate statement. The manuscript says: “In GEOS-Chem, atmospheric methane concentrations are prescribed with imposed meridional gradients derived from observations, except for the tropical LGM in which model results are used (Murray et al., 2014, Table 3).” However, in Murray et al. 2014 they state that present day values come from flask measurements, but BOTH preindustrial & LGM values are derived from ice core measurements for the poles while tropical values are assumed to be 4% higher than Antarctic methane concentrations. There are no preindustrial methane observations from the tropics.*

Our statement is accurate. As stated in Murray et al. (2014), “The preindustrial and LGM simulations use observed methane values from Antarctic, Andean, and Greenland ice cores in the NOAA National Geophysical Data Center (NGDC) Paleoclimatology Program (<http://www.ncdc.noaa.gov/paleo/paleo.html>) (Chappellaz et al., 1990; Etheridge et al., 1998; Blunier et al., 1998; Thompson, 1998; Petit et al., 1999; Campen, 2000; Loulergue et al., 2008).” However, in the case of the LGM, the ice-core data were likely contaminated by in situ methanogenic production, and so Murray et al. (2014) assumed that tropical values were 4% higher than Antarctic methane concentrations based on model results.

7. Pg 28, 1st paragraph: “Results from this sensitivity studies...” should be “Results from THESE sensitivity studies...”

Fixed. This sentence now reads:

Results from these sensitivity studies, however, underscore the large uncertainties in current model estimates of SOA radiative forcing across long time scales (e.g., Scott et al., 2014; Unger and Yue, 2014; Unger, 2014a).

8. *This is a stylistic note, but on pg 29, last paragraph the part starting with “We are reluctant to offer “best guess” estimates...” seems to undercut or qualify their central contribution before they describe what their central contribution actually is. I would suggest moving this section to the end of the first paragraph on page 31. However, this is up to the authors.*

We thank the reviewer for this suggestion, but the last paragraph on page 29 lays out the potential caveats in our study. We then lay out our scientific contributions on pages 30-31.

Abstract

Isoprene and its oxidation products are major players in the oxidative chemistry of the troposphere. Current understanding of the factors controlling biogenic isoprene emissions and of the fate of isoprene oxidation products in the atmosphere has been

5 evolving rapidly. We use a climate-biosphere-chemistry modeling framework to evaluate the sensitivity of estimates of the tropospheric oxidative capacity to uncertainties in isoprene emissions and photochemistry. Our work focuses on two climate transitions: from the Last Glacial Maximum (LGM, 21 000 years BP) to the preindustrial (1770s); and from the preindustrial to the present day (1990s). We find that different oxidants

10 have different sensitivities to the uncertainties tested in this study, ~~with OH being~~ Ozone is relatively insensitive, whereas OH is the most sensitive: changes in the global mean OH levels for the LGM-to-preindustrial transition range between -29 % and +7 %, and those for the preindustrial-to-present day transition range between -8 % and +17 %, across our simulations. We find little variability in the implied relative LGM-

15 preindustrial difference in methane emissions with respect to the uncertainties tested in this study. Conversely, estimates of the preindustrial-to-present day and LGM-to-preindustrial changes in the global burden of secondary organic aerosol (SOA) are highly sensitive. We show that the linear relationship between tropospheric mean OH and tropospheric mean ozone photolysis rates, water vapor, and total emissions of NO_x

20 and reactive carbon – first reported in Murray et al. (2014) – does not hold across all periods with the new isoprene photochemistry mechanism. This study demonstrates how inadequacies in our current understanding of isoprene emissions and photochemistry impede our ability to constrain the oxidative capacities of the present and past atmospheres, its controlling factors, and the radiative forcing of some short-lived species

25 such as SOA over time.

1 Introduction

A key player in the coupling between climate change and atmospheric chemical composition is the oxidative capacity of the troposphere, primarily characterized by the burden of the four most abundant and reactive oxidants: OH, ozone, H_2O_2 , and NO_3 .

5 Estimates of the oxidative capacity of past atmospheres remain uncertain due to the limited number of historical and paleo-observations, which hinders our ability to understand the chemical, climatic, and ecological consequences of past changes in the oxidative capacity. Multiple factors govern the abundance of tropospheric oxidants, including emissions of reactive volatile organic compounds (VOCs). Isoprene (2-methyl-
10 1,3-butadiene, C_5H_8), primarily emitted by plants, is the most abundant VOC in the present-day atmosphere after methane (Pike and Young, 2009). Recent studies have suggested the need to revise our understanding of the environmental factors controlling biogenic isoprene emissions and of its atmospheric photo-oxidation mechanism (e.g., Paulot et al., 2009a, b; Possell and Hewitt, 2011). These advances call into question
15 the validity of existing model estimates of the oxidative capacity of past atmospheres. In this study, we use a climate-biosphere-chemistry modeling framework (Murray et al., 2014) to explore the sensitivity of the simulated oxidative capacity to uncertainties in isoprene emissions and photochemistry, and the implications for radiative forcing on preindustrial-present and on glacial-interglacial timescales. To our knowledge, this
20 study is the first systematic evaluation of the effects of these recent developments on model estimates of the chemical composition of past atmospheres.

25 The atmospheric oxidative capacity determines the lifetime of many trace gases important to climate, chemistry, and human health (e.g., Isaksen and Dalsøren, 2011; Fiore et al., 2012). It may also induce oxidative stress or alter the deposition of oxidized nutrients to terrestrial and marine ecosystem (Sitch et al., 2007; Paulot et al., 2013). Furthermore, oxidants modify the radiative effects of aerosols by influencing their evolution, lifetime, and physical properties (Sofen et al., 2011). However, due to the high reactivity of most atmospheric oxidants, direct measurement of their past abundances

is not currently possible for most species. Late 19th-century surface ozone measurements exist but their accuracy has been debated (Pavelin et al., 1999). Atmospheric oxidants, except for H_2O_2 , are not directly preserved in the ice-core record. Even for H_2O_2 , however, post-depositional processes impede quantitative interpretation of this record (Hutterli et al., 2002). As summarized in Murray et al. (2014), Table 1, prior modeling studies that investigated past changes in the abundance of tropospheric oxidants disagree on the magnitude and even the sign of change. Such discrepancies call into question our ability to quantify the relative roles of sources and sinks in driving past variations in atmospheric methane ~~concentration~~concentrations. Previous studies attributed these variations to changes in wetland emissions, the dominant natural source of methane to the atmosphere (e.g., Khalil and Rasmussen, 1987; Brook et al., 2000). However, more recent modeling studies suggested that potential variations in OH – the primary sink for methane – may be larger than previously thought, driven by changes in biogenic VOC emissions (e.g., Kaplan, 2002; Valdes, 2005; Harder et al., 2007). This issue remains an ongoing debate (e.g., Levine et al., 2011c; Quiquet et al., 2015).

Tropospheric oxidants are strongly coupled through atmospheric photochemical reactions, and their abundances respond to meteorological conditions, changes in surface and stratospheric boundary conditions, and changes in emissions of key chemical species such as reactive nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) and VOCs. Present-day natural emissions of VOCs, which far exceed those from anthropogenic sources on a global scale, are dominated by plant isoprene emissions, which have an estimated global source ranging from approximately 500 to 750 Tg yr^{-1} (Lathière et al., 2005; Guenther et al., 2006). This large emission burden is accompanied by high reactivity; isoprene has an atmospheric chemical lifetime on the order of minutes to hours (Pike and Young, 2009). Isoprene and its oxidation products react with OH, ozone, and the nitrate radical, and are thus major players in the oxidative chemistry of the troposphere (Beerling et al., 2007). The oxidation products of isoprene also substantially contribute to secondary organic aerosol (SOA) formation (Henze and Seinfeld, 2006). Biogenic SOA, like other aerosols, affects climate by scattering and absorbing solar ra-

diation and by altering the properties and lifetimes of clouds, but the net climate effect is poorly characterized (Scott et al., 2014). Therefore, uncertainties in the preindustrial-to-present day changes in biogenic VOC emissions, and subsequently in SOA burdens, lead to large uncertainties in the anthropogenic indirect radiative forcing estimates over the industrial period (e.g., Carslaw et al., 2013; Scott et al., 2014).

5 Results from the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) demonstrate that uncertainties remain in our understanding of the long-term trends in OH and methane lifetime, and that these uncertainties primarily stem from a lack of adequate constraints on natural precursor emissions and on the
10 chemical mechanisms in the current generation of chemistry-climate models (Naik et al., 2013). Recent field and laboratory findings have called into question prior estimates of global burdens of isoprene for the past and future atmospheres, and have revealed new details of the isoprene photo-oxidation mechanism. First, isoprene emission from plants is well known to be strongly dependent on plant species and, for a given species, on environmental factors including temperature, light availability, and leaf age (Guenther et al., 2012). However, recent empirical studies have shown that isoprene emission by several plant taxa is also inversely correlated with atmospheric CO₂ levels, but this relationship is not yet well-constrained (e.g., Wilkinson et al., 2009; Possell and Hewitt, 2011). The biochemical mechanism for this effect remains
15 unresolved, but evidence suggests that CO₂ concentration plays a role in partitioning carbon-substrate availability between the chloroplast and cytosol of a plant cell, and in mobilizing stored carbon sources (Trowbridge et al., 2012). Such bio-mechanisms involving a CO₂-dependence of isoprene emissions may have evolved in plants long ago.

20 Second, recent field studies in major isoprene-emitting regions, such as the Amazon forest (Lelieveld et al., 2008), South East Asia (Hewitt et al., 2010), and China (Hofzumahaus et al., 2009), reported large discrepancies between measured and modeled HO_x (OH + HO₂) concentrations, suggesting that VOC oxidation under low-NO_x conditions may recycle OH more efficiently than previously understood. These findings
25

motivated numerous theoretical and experimental studies, which in turn led to extensive updates in the gas-phase isoprene photo-oxidation mechanism, in which there is greater regeneration and recycling of HO_x and NO_x under high- NO_x conditions, and of HO_x under low- NO_x conditions (e.g., Paulot et al., 2009a, b). In general, greater OH-recycling enhances the efficiency of atmospheric oxidation, while greater NO_x -recycling enhances the efficiency of ozone production. However, the improved mechanism is still unable to fully reconcile measured and modeled OH concentrations (Mao et al., 2012). Moreover, global and regional modeling studies indicate that the heterogeneous HO_2 uptake by aerosols presents a potentially important HO_x sink. There remains, however, considerable uncertainty in the magnitude of this sink and its impact on tropospheric chemistry (Thornton et al., 2008). Mao et al. (2013a) proposed a new scheme in which HO_2 uptake by aerosols leads to H_2O rather than H_2O_2 formation, via coupling of $\text{Cu}(\text{I})/\text{Cu}(\text{II})$ and $\text{Fe}(\text{II})/\text{Fe}(\text{III})$ ions. Since H_2O_2 can be readily photolyzed to regenerate OH, this new mechanism provides a more efficient HO_x removal pathway. Cu and Fe are ubiquitous components of crustal and combustion aerosols (Mao et al., 2013a). Observations and model studies suggest that during the LGM and preindustrial, natural dust distributions were higher than that in the present day (Mahowald et al., 2006). In particular, during the LGM, $\text{Fe}(\text{II})$ and $\text{Fe}(\text{III})$ ion concentrations in dust increased by at least two times relative to interglacial levels (Spolaor et al., 2013). Likewise, positive Cu anomalies during the last glacial period have been measured in ice cores (Oyarzun et al., 2005).

In support of the ICE age Chemistry And Proxies (ICECAP) project, Murray et al. (2014) developed a new climate-biosphere-chemistry modeling framework for simulating the chemical composition of the present and past tropospheres, focusing on preindustrial-to-present and glacial-interglacial transitions. The Last Glacial Maximum (LGM, ~ 19 –23 kyr) spans the coldest interval of the last glacial period (~ 11.5 –110 kyr) and is relatively well recorded in ice-core and sediment records, making the LGM-to-preindustrial transition a convenient glacial-interglacial analogue. Disparities in existing model studies of past tropospheric oxidant levels are partly due to differences in the

model components of the Earth system allowed to vary with climate, and the differing degrees of complexity in the representation of those components (Murray et al., 2014). The ICECAP project is the first 3-D model framework to consider the full suite of key factors controlling the oxidative capacity of the troposphere at and since the LGM, including the effect of changes in the stratospheric column ozone on tropospheric photolysis rates. Murray et al. (2014) found that: (1) the oxidative capacities of the preindustrial and LGM atmospheres were both lower than that of the present day; (2) tropospheric mean OH levels appear to be well buffered in the LGM-to-preindustrial transition – a result at odds with most prior studies; (3) past changes in atmospheric methane concentrations were predominantly source-driven; and (4) the key parameters controlling the oxidative capacity over LGM-present day timescales are tropospheric mean ozone photolysis rates, water vapor abundance, and total emissions of NO_x and reactive carbon.

In light of recent developments in our understanding of the isoprene photo-oxidation mechanism and of the sensitivity of plant isoprene emissions to atmospheric CO_2 levels, we build on the model study by Murray et al. (2014) to explore the sensitivity of the simulated tropospheric oxidative capacity at and since the LGM, and the ramifications for our understanding of the factors controlling the oxidative capacity. We also discuss the implications for changes in short-lived climate forcers and for interpreting the ice-core methane record. We examine, in a systematic manner, the effects of all of the above developments on the chemical composition of the troposphere over the last glacial-interglacial time interval and the industrial era.

2 Method: model framework, model developments, and project description

2.1 The ICECAP model framework

Figure 1 illustrates the stepwise, offline-coupled climate-biosphere-chemistry model framework of the ICECAP project. This setup relies on four global models. GEOS-

Chem is a global 3-D chemical transport model (CTM) with a long history in simulating present-day tropospheric ozone- NO_x -CO-VOC- BrO_x -aerosol chemistry (<http://www.geos-chem.org>; Bey et al., 2001; Park et al., 2004; Parrella et al., 2012). The version used here includes online linearized stratospheric chemistry (McLinden et al., 2000), which allows for calculation of photolysis rates more consistent with changing climate and chemical conditions. We use version 9-01-03 with modifications as described in Murray et al. (2014) and below. ICECAP is driven by meteorological fields from ModelE, a climate model developed at the NASA Goddard Institute of Space Studies (GISS). ModelE and related models at GISS have been used extensively in paleo-climate studies (e.g., LeGrande et al., 2006; Rind et al., 2001, 2009). Here we use the ModelE version with a horizontal resolution of 4° latitude by 5° longitude, and 23 vertical layers extending from the surface to 0.002 hPa in the atmosphere. Climate in ModelE is forced by prescribed greenhouse gas levels, orbital parameters, topography, and sea ice and sea surface temperatures (SSTs) relevant to each time slice of interest. The final components are the BIOME4-trace gas (BIOME4-TG) equilibrium terrestrial biosphere model (Kaplan et al., 2006) and the Lund-Potsdam-Jena Lausanne-Mainz fire (LPJ-LMfire) dynamic global vegetation model (Pfeiffer et al., 2013). BIOME4-TG is used to determine static vegetation distributions, while LPJ-LMfire simulates biomass burning regimes. Meteorology from ModelE drives both these models, and the resulting land-cover characteristics and dry matter burned are implemented into GEOS-Chem. The basal biogenic emission factors per plant functional types used in the BIOME4-TG model, which do not change between the climate scenarios, can be found in Murray et al. (2014), Table 5.

A detailed description of the ICECAP model framework and its evaluation against observations can be found in Murray et al. (2014). The present-day simulation has been evaluated against a suite of sonde, aircraft, satellite, and surface measurements of trace gases, aerosols, and radionuclides. The simulated LGM climate scenarios have also been evaluated against pollen-based climate reconstruction from Bartlein et al. (2011). The ICECAP model overestimates transport from the stratosphere due to

an overly vigorous Brewer-Dobson circulation (Murray et al., 2014). Rather than fixing the transport fluxes to better match present-day values, we accept this bias in order to allow the stratospheric columns of ozone to adjust freely to different climate scenarios. For example, Murray et al. (2014) found that reductions in greenhouse gases weakens the stratospheric residual circulation and leads to an increase in tropical stratospheric ozone columns.

As in Murray et al. (2014), we perform simulations for four different climate scenarios: present day (ca. 1990s); preindustrial (ca. 1770s); and two different representations of the LGM ($\sim 19\text{--}23$ kyr) to span the range of likely conditions. The simulated average global surface air temperatures are 14.9°C for the present day, 14.3°C for the preindustrial, 10.7°C for the warm LGM, and 6.1°C for the cold LGM (Murray et al., 2014, Table 4). The two LGM scenarios differ in the degree of cooling of tropical SSTs. Such differences have implications for LGM dynamics because of the influence of tropical SSTs on meridional temperature gradients and low-latitude circulation (Rind et al., 2009). The “warm LGM” uses SST reconstructions from the Climate: Long range Investigation, Mapping, and Prediction project (CLIMAP, 1976), with an average change in SST within 15° of the equator relative to the preindustrial ($\Delta\text{SST}_{15^\circ\text{S--N}}$) of -1.2°C . The “cold LGM” uses SSTs from Webb et al. (1997) who found $\Delta\text{SST}_{15^\circ\text{S--N}}$ of -6.1°C . By imposing an ocean heat transport flux in an earlier version of the GISS model, Webb et al. (1997) achieved a better match with certain paleo-proxies of temperature such as corals (Guilderson et al., 1994; Stute et al., 1995). The warm LGM SSTs yields a change of mean global surface air temperature of -3.6°C relative to the preindustrial, while the cold LGM SSTs yields a change of -8.2°C . These values lie within the range of temperature changes reported by Holden et al. (2010), and they span the approximately -7°C change inferred from Gildor et al. (2014) for the LGM relative to the present day. A more recent estimate from the MARGO project, [which is the current best assumption of tropical SSTs at the LGM](#), found $\Delta\text{SST}_{15^\circ\text{S--N}}$ of $-1.7 \pm 1.0^\circ\text{C}$ (Waelbroeck et al., 2009), [which is more](#). [These estimates are more](#) [more](#) similar to the warm LGM than the cold LGM [scenario scenarios](#) used in this study.

Murray et al. (2014) also tested the sensitivity of their model results to uncertainties in lightning and fire emissions. Comparison with paleo-observations suggests that their “low-fire, variable-lightning, warm LGM” scenario was the best representation of the LGM atmosphere, in which lightning NO_x emissions are parameterized to reflect changes in convective cloud top heights, and the LPJ-LMfire fire emissions are scaled to match observational records inferred from the Global Charcoal Database (Power et al., 2007, 2010). The model simulations in this study are performed using the Murray et al. (2014) “best estimate” fire and lightning emission scenarios relevant for each climate.

10 2.2 Uncertainties in biogenic isoprene emissions

Biogenic VOC emissions in GEOS-Chem are calculated interactively by the Model of Emissions of Gases and Aerosols from Nature (MEGAN v2.1) (Guenther et al., 2012). The canopy-level flux of isoprene is computed as a function of plant function type (PFT)-specific basal emission rate, scaled by activity factors (γ_i) to account for environmental controlling factors including temperature, light availability, leaf age, and leaf area index (LAI). Tai et al. (2013) recently implemented an additional activity factor, γ_C , to account for the effect of atmospheric CO₂ concentrations. They used the empirical relationship from Possell and Hewitt (2011): $\gamma_C = a / (1 + abC)$, where the fitting parameters a and b have values of 8.9406 and 0.0024 ppm⁻¹, respectively, and C represents the atmospheric CO₂ concentration ($\gamma_C = 1$ at $C = 370$ ppm). To date, Possell and Hewitt (2011) studied the widest range of plant taxa and atmospheric CO₂ concentrations. Their CO₂-isoprene emission response curve shows a higher sensitivity at CO₂ concentrations below present-day levels than others from similar studies (e.g., Wilkinson et al., 2009), likely providing an upper limit of this effect for past climates. We have not considered the effect of CO₂-sensitivity on other plant VOC emissions, such as monoterpenes and sesquiterpenes, due to lack of conclusive evidence of this effect (Penuelas and Staudt, 2010). In all four climate scenarios, isoprene constitutes more than 60 % of total biogenic VOC emissions.

In this study, we follow the Tai et al. (2013) implementation, which uses the empirical relationship from Possell and Hewitt (2011). Table 1 summarizes the prescribed CO₂ mixing ratios, and the estimated total annual isoprene burdens with and without consideration of the CO₂-sensitivity of plant isoprene emissions, for each climate scenario.

5 When the CO₂-sensitivity is considered, we find relative increases in the total biogenic isoprene source of 4 % for the present day, 28 % for the preindustrial, 78 % for the warm LGM, and 77 % for the cold LGM scenarios.

2.3 Uncertainties in the fate of the oxidation products of isoprene

2.3.1 Isoprene photo-oxidation mechanism

10 Murray et al. (2014) used the original GEOS-Chem isoprene photo-oxidation mechanism which is largely based on Horowitz et al. (1998). Here we apply recent updates to the mechanism by Mao et al. (2013c) and Paulot et al. (2009a, b), which Mao et al. (2013c) evaluated in GEOS-Chem through comparison with present-day observations of ozone, isoprene, and oxidation products. Daytime oxidation of isoprene by OH leads to the formation of hydroxyl-peroxy radicals (ISOPO₂). The new scheme includes a more explicit treatment of the production and subsequent reactions of organic nitrates, acids, and epoxides from reactions of the ISOPO₂ radicals. Such reactions lead to greater HO_x- and NO_x-regeneration and recycling than in the original mechanism, especially under low-NO_x conditions, which is of particular relevance for past atmospheres (Mao et al., 2013c). The new scheme also includes an update for the aerosol reactive uptake coefficient of NO₃ radicals, in which the value is increased from 10⁻⁴ to 0.1 (Mao et al., 2013c). Beyond Mao et al. (2013c), we also change the stoichiometry of the (ISOPO₂ + HO₂) reaction to that recommended by the laboratory study of Liu et al. (2013), which has smaller uncertainties and leads to relatively smaller yields (by ~50 %) of HO_x, methyl vinyl ketone (MVK), and methacrolein (MACR) from this pathway. Our work tests the sensitivity of model results to these updates in the isoprene photo-oxidation mechanism.

2.3.2 Heterogeneous HO₂ uptake by aerosols

As parameterized in the standard GEOS-Chem model, gaseous HO₂ uptake by aqueous aerosols leads to H₂O₂ formation and has a $\gamma(\text{HO}_2)$ value typically less than 0.1, where $\gamma(\text{HO}_2)$ is a measure of the efficacy of uptake, defined as the fraction of HO₂

5 collisions with aerosol surfaces resulting in reaction. (Note that γ traditionally refers to both the aerosol uptake efficiency and biogenic emissions flux activity factor.) Atmospheric observations, however, suggest that HO₂ uptake by aerosols may in fact not produce H₂O₂ (de Reus et al., 2005; Mao et al., 2010). In light of these findings, Mao et al. (2013a) implemented a new uptake scheme in GEOS-Chem, in which HO₂ 10 uptake yields H₂O via coupling of Cu(I) / Cu(II) and Fe(II) / Fe(III) ions, and we follow that approach here. As in Mao et al. (2013a), we use the upper limit of $\gamma(\text{HO}_2) = 1.0$ for all aerosol types to evaluate the implications of this uptake for the HO_x budgets and for the fate of the oxidation products of isoprene.

2.4 Outline of model sensitivity experiments

15 Table 2 summarizes the different climate, chemistry and plant isoprene emission scenarios tested in this model study. For each climate scenario, we apply to GEOS-Chem the archived meteorology and land cover products from the “best estimate” fire and lightning emission scenarios from Murray et al. (2014). We test three different chemistry schemes in GEOS-Chem: C1 uses the original isoprene chemistry and original HO₂ uptake; C2 uses the new isoprene chemistry and original HO₂ uptake; and C3 20 uses the new isoprene chemistry and new HO₂ uptake mechanisms. Each chemistry scheme is tested either with (w) or without (wo) inclusion of the CO₂-sensitivity of biogenic isoprene emissions, except for the present day. As Table 1 shows, consideration of the CO₂-sensitivity for the present day results in only a 4 % change in the global isoprene burden ($\gamma_C = 1$ at $C = 370$ ppm), and so we assume that the present-day model simulations with consideration of the CO₂-sensitivity of biogenic isoprene emissions 25 are representative of their respective “without” scenarios. Our “C1-wo” model simula-

tions match the isoprene emissions and photochemistry schemes used by Murray et al. (2014). We perform 21 simulations in total.

For each climate scenario, we use four subsequent years of archived meteorology from the GISS climate model. Each GEOS-Chem simulation is initialized with a 10-year spin-up, repeatedly using the first year of archived meteorology, to reach equilibrium with respect to stratosphere-troposphere exchange. We then perform three more years of simulations for analysis, using the three subsequent years of archived meteorology. All of the quantities considered here are global means or averages over large spatial regions. We find that the inter-annual variability of such quantities is small compared to the differences between the climate scenarios, and that three years is sufficient for our analysis.

In GEOS-Chem, atmospheric methane concentrations are prescribed with imposed meridional gradients derived from observations, except for the tropical LGM in which model results are used (Murray et al., 2014, Table 3). The tropospheric mean values are 1743 ppbv for the present day, 732 ppbv for the preindustrial, and 377 ppbv for the LGM scenarios.

3 Results

3.1 Tropospheric mean oxidant burdens

Figure 2 shows the simulated tropospheric mean mass-weighted burdens of OH, ozone, H_2O_2 , and NO_3 for each combination of climate, chemistry and plant isoprene emission scenarios. The dotted orange line represents results using the “best estimate” lightning and fire emission scenarios of Murray et al. (2014). The plots show the varying sensitivity of oxidant levels to assumptions about the tropospheric chemical mechanism and the global isoprene burden.

Consideration of the CO_2 -sensitivity of plant isoprene emissions yields larger isoprene emissions for the preindustrial and LGM scenarios (Table 1). For a given chem-

istry scheme and climate scenario, this leads to a decrease in the tropospheric mean OH burden, an increase in H_2O_2 , and small changes in ozone and NO_3 . This result can be understood by considering the classical tropospheric ozone- HO_x - NO_x -CO catalytic cycle (e.g., Rohrer et al., 2014, Fig. 1). In general, daytime oxidation of VOC by reaction with OH leads to formation of oxidized organic products and HO_2 . Efficient HO_x -cycling depends on the presence of NO_x . Since low- NO_x conditions prevail in past atmospheres, an increased isoprene burden represents a net OH sink but an HO_2 source. The self-reaction of HO_2 leads to H_2O_2 formation. Under low- NO_x conditions, tropospheric ozone production is relatively insensitive to changes in the reactive carbon burden. The tropospheric NO_3 burden also shows little change since the abundances of its precursors ($\text{NO}_2 + \text{O}_3$) hardly vary with the global isoprene burden.

Implementation of the new isoprene oxidation mechanism leads to large changes in tropospheric oxidant burdens of OH, O_3 , but not H_2O_2 and NO_3 , for the past atmospheres. For a given climate scenario, the largest source of uncertainties in global mean OH arises from differences between the original and new isoprene photo-oxidation mechanisms. Increases in the tropospheric mean OH burdens result from greater HO_x -regeneration in the new isoprene photo-oxidation cascade (Mao et al., 2013c). The ozone production efficiency – the number of ozone molecules produced per molecule of NO_x consumed (Liu et al., 1987) – is greater in the new isoprene mechanism, leading to increases in the tropospheric ozone burdens. This is because the newly added reactions of recycling of isoprene nitrates, formed in the ($\text{ISOP}\text{O}_2 + \text{NO}$) reaction pathway, can lead to NO_x -regeneration, thereby representing a less permanent NO_x sink than nitric acid (Paulot et al., 2012). The present-day burden of NO_3 shows a large decrease in response to the new isoprene oxidation scheme, while those of the past atmospheres show little change. The muted NO_3 response for the past atmospheres is due to two competing effects in the new scheme: (1) an increased aerosol reactive uptake coefficient of NO_3 radicals (from 10^{-4} to 0.1) leading to greater NO_3 depletion (Mao et al., 2013c); and (2) increased abundances in both NO_3 precursors ($\text{NO}_2 + \text{O}_3$) enhancing its formation. The latter effect is due to greater

NO_x-recycling and regeneration in the new scheme through isoprene nitrate recycling, and hence greater ozone production efficiency and increased lifetime of NO_x reservoir species. For the present-day, the increased abundances of NO₃ precursors are smaller than those of the past atmospheres. Finally, implementation of the new scheme of HO₂ uptake by aerosols leads to significant decreases in the tropospheric mean OH and H₂O₂ burdens in all simulations. This is due to both the higher efficacy of uptake than previously assumed and the formation of H₂O, instead of H₂O₂, as a by-product of the uptake, yielding a more efficient HO_x removal pathway.

Despite uncertainties in the isoprene emissions and photochemistry, we find reduced levels of ozone, H₂O₂, and NO₃ in each combination of chemistry and isoprene emission scenarios for the past atmospheres relative to the present-day, a result consistent with Murray et al. (2014). However, their conclusion that OH is relatively well buffered on glacial-interglacial timescales relative to other tropospheric oxidants does not hold for some of the uncertainties explored in this study. Figure 3 shows the simulated percent changes in the tropospheric mean OH burden for the present-day, warm LGM, and cold LGM scenarios, relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). Consideration of the CO₂-sensitivity of plant isoprene emissions alone (C1-w) leads to 23 and 29 % reductions in the tropospheric mean OH burden in the warm and cold LGM scenarios, relative to that of the preindustrial, while the present-day burden is 17 % greater than that of the preindustrial. When the new chemistry schemes are applied without consideration of the CO₂-sensitivity, the modeled changes in OH relative to the preindustrial are less dramatic but have opposite signs to those calculated under the C1-w scenarios for the present day and warm LGM. When all effects are considered (C2-w and C3-w), changes in the tropospheric mean OH burden across the warm LGM-to-preindustrial and preindustrial-to-present day transitions do not exceed 5 %, a result consistent with Murray et al. (2014). The varying sensitivity of the tropospheric mean OH burden to assumptions about the isoprene photochemistry and emissions has implications for our understanding of

past methane and SOA burdens and radiative forcing calculations, as discussed in Sects. 3.3–3.4.

3.2 Comparison with observations

We evaluate the results of the model sensitivity experiments against four different categories of observations. First, Table 3 compares the simulated methyl chloroform (CH_3CCl_3) and methane lifetimes against loss from tropospheric OH under different chemistry schemes with observations for the present day. The global lifetimes of methyl chloroform and of methane against oxidation by tropospheric OH are calculated as the global burden divided by the total loss rate summed over all grid boxes in the troposphere:

$$\tau_{X,\text{OH}} = \frac{\int_{\text{surface}}^{\text{TOA}} [X] \, dx \, dy \, dz}{\int_{\text{surface}}^{\text{tropopause}} k_{X+\text{OH}}(T) [\text{OH}] [X] \, dx \, dy \, dz}, \quad (1)$$

where X represents either methyl chloroform or methane, and $k_{X+\text{OH}}(T)$ is the temperature-dependent rate constant of the reaction. We assume that the mixing ratio of methyl chloroform is uniform throughout the troposphere and is 92 % lower than the total atmospheric concentration (Bey et al., 2001; Prather et al., 2012). For methane, the global burden is calculated from the mean surface concentration using a conversion factor of $2.75 \text{ Tg CH}_4 \text{ ppbv}^{-1}$ from Prather et al. (2012). In our present-day simulations (ca. 1990s), we prescribe the mean surface concentration as 1743 ppbv.

The combination of new isoprene and original HO_2 uptake chemistry (C2) has the largest simulated tropospheric mean OH burden (Fig. 2) and so yields the shortest methyl chloroform and methane lifetimes: 4.1 and 8.9 years, respectively. Prinn et al. (2005) inferred an average methyl chloroform lifetime of $6.0^{+0.5}_{-0.4}$ years for the years

1978–2004 based on observations of methyl chloroform and knowledge of its emissions. Our present-day model results range between 4.1–4.8 years, which are all lower than the range derived from observations, but comparable to recent multi-model estimates of 5.7 ± 0.9 years for 2000 (Naik et al., 2013). Based on observations and emission estimates, the mean methane lifetime against loss from tropospheric OH is estimated to be $10.2^{+0.9}_{-0.7}$ years between 1978–2004 by Prinn et al. (2005), and 11.2 ± 1.3 years for 2010 by Prather et al. (2012). The values given by the C1 (10.3 years) and C3 (9.6 years) chemistry schemes fall within these ranges. The lowest value given by C2 (8.9 years) does not fall within the ranges derived from observations, but is still within the range of estimates reported by recent multi-model studies: 10.2 ± 1.7 years (Fiore et al., 2009), 9.8 ± 1.6 years (Voulgarakis et al., 2013) and 9.7 ± 1.5 years (Naik et al., 2013). Reconciling the magnitude of the inferred OH burden with modeled results remains an ongoing challenge (Holmes et al., 2013).

Second, we also assess our model results for present-day OH by evaluating the simulated inter-hemispheric ratios (N / S) of tropospheric mean OH. Estimates of this ratio based on methyl chloroform measurements from 1980–2000 range between 0.85–0.98 (Montzka et al., 2000; Prinn et al., 2001; Krol and Lelieveld, 2003; Bousquet et al., 2005), whereas the recent ACCMIP multi-model study finds a mean ratio of 1.28 ± 0.10 for 2000 (Naik et al., 2013). In our present-day sensitivity experiments, we calculate ratios of 1.20 for C1, 1.11 for C2, and 1.07 for C3. The C1 value falls within the ACCMIP range, but the C3 value best matches the ratio inferred from observations. Models participating in the ACCMIP study did not consider HO_x -recycling pathways through reactions of peroxy and HO_2 radicals (Naik et al., 2013). As previously described, HO_x -recycling in the absence of NO_x can occur in our new isoprene photochemistry scheme (C2), which leads to a lower present-day N / S ratio of tropospheric mean OH. The ratio decreases further and becomes more comparable with the observations when the upper limit of efficacy of HO_2 uptake by aerosols is considered (C3). This result is due to the large anthropogenic aerosol loadings in the Northern Hemisphere.

Third, we compare modeled CO for the preindustrial and present-day simulations against observed CO surface concentrations over Antarctica (Fig. 4). CO influences the oxidative capacity of the troposphere through reaction with its primary sink, OH, which can subsequently affect the ozone budget (Fiore et al., 2012). In this context, 5 CO can thus be a useful tool for evaluating the ability of chemistry transport models to simulate the tropospheric oxidative capacity (Haan and Raynaud, 1998). CO has a tropospheric lifetime of ~2 months (Novelli et al., 1998), and CO surface concentrations over Antarctica are thus influenced by oxidation processes throughout much of the Southern Hemisphere (Haan and Raynaud, 1998; van der Werf et al., 2013) 10. The NOAA Global Monitoring Division measured a mean CO surface concentration of 49 ± 2 ppbv for the 1990s, which is matched by all of our present-day simulations tested with different chemistry schemes. Wang et al. (2010) recently provided a 650-year Antarctic ice-core record of concentration and isotopic ratios of atmospheric CO. They measured CO surface concentrations at the South Pole of 48 ± 4 ppbv for the 15 year 1777 (± 110 years). Only one (C1-w) out of the six preindustrial simulations tested with different chemistry and isoprene emission schemes falls within the range of the observed value. However, in situ production of CO from organic substrates trapped within the ice may complicate the comparison between ice-core CO and preindustrial model results (Faïn et al., 2014; Guzmán et al., 2007; Haan and Raynaud, 1998). 20 Finally, we compare our preindustrial and LGM model results to isotopic signatures in the ice-core record. Oxidants transfer unique isotopic signatures to the oxidation products, and we can take advantage of these signatures in our model evaluation if they are preserved in the ice-core record. The $\Delta^{17}\text{O}$ ($= \delta^{17}\text{O} - 0.52 \times \delta^{18}\text{O}$) of sulfate, known as $\Delta^{17}\text{O}(\text{SO}_4^{2-})$, and of nitrate, $\Delta^{17}\text{O}(\text{NO}_3^-)$, measure the departure from mass-dependent fractionation in its oxygen isotopes and reflect the relative importance of different oxidants in their atmospheric production pathways (Savarino et al., 2000). 25 Sulfate formation primarily involves ozone, H_2O_2 , and OH, while the main oxidants relevant to nitrate formation are ozone, RO_2 ($\text{R} = \text{H atom or organic group}$), OH, and BrO (Sofen et al., 2014). Such oxygen triple-isotope measurements have been used

to infer the atmospheric formation pathways of sulfate and nitrate in the present from atmospheric sulfate and nitrate (e.g. Lee et al., 2001; Michalski, 2003), and in the past from ice-core sulfate and nitrate (e.g., Alexander et al., 2002, 2004). The dominant source region for Antarctic sulfate is the Southern Ocean marine boundary layer (MBL) (Sofen et al., 2011), while that for Antarctic nitrate is extra-tropical South America (Lee et al., 2014). We thus qualitatively compare our model results for these respective regions with Antarctic ice-core measurements of $\Delta^{17}\text{O}(\text{SO}_4^{2-})$ and $\Delta^{17}\text{O}(\text{NO}_3^-)$.

Table 4 lists the simulated percent changes in surface $[\text{O}_3]/[\text{OH}]$ and $[\text{O}_3]/[\text{RO}_2]$ in the present day scenarios relative to their respective preindustrial scenarios. Measurements of $\Delta^{17}\text{O}(\text{SO}_4^{2-})$ from the WAIS Divide ice core imply that the $[\text{O}_3]/[\text{OH}]$ ratio in the Southern ocean MBL may have increased by 260 % since the early 19th century. Our model results greatly underestimate the values inferred from observations, with values ranging from 35 % to 42 %. Measurements of $\Delta^{17}\text{O}(\text{NO}_3^-)$ suggest that the $[\text{O}_3]/[\text{RO}_2]$ ratio in the Southern Hemisphere extratropical troposphere may have decreased by 60-90 % between the 1860s and 2000, assuming no change ($\leq 5\%$) in OH (Sofen et al., 2014). As with the $[\text{O}_3]/[\text{OH}]$ ratio, the model cannot capture the sensitivity of $[\text{O}_3]/[\text{RO}_2]$ to recent climate change, with changes in the ratio ranging from -0.4% to $+5.1\%$, depending on the scenario. These mismatches may be due to deficiencies in our current understanding and model representation of remote marine boundary layer sulfate formation, as suggested by Sofen et al. (2014), and potential model underestimates of the sensitivity of oxidant abundances to climate change (Alexander and Mickley, 2015).

On glacial-interglacial timescales, measurements of $\Delta^{17}\text{O}(\text{SO}_4^{2-})$ from the Vostok ice core imply that gas-phase oxidation by OH contributed up to 40 % more to sulfate production during the last glacial period relative to the interglacial periods before and after (Alexander et al., 2002). Our simulated percent changes in surface OH concentrations over the Southern Ocean between the LGM and preindustrial scenarios range from 68 % to 120 % for the warm LGM and 87 % to 117 % for the cold LGM scenarios (Table 4). Given the uncertainties in the model, these values are remarkably consis-

tent with those inferred from the $\Delta^{17}\text{O}(\text{SO}_4^{2-})$ measurements, both in terms of sign and magnitude.

In summary, we find that all three chemistry schemes yield present-day methyl chloroform lifetimes 24–35 % shorter than that inferred from observations (Prather et al., 2012). For methane, the C1 and C3 lifetimes fall within the range inferred from observations (Prinn et al., 2005; Prather et al., 2012), while the C2 chemistry scheme yields a value 21 % too short compared to the value from Prather et al. (2012). For the OH N / S ratio, the C3 chemistry falls closest to the observations (Montzka et al., 2000; Prinn et al., 2001; Krol and Lelieveld, 2003; Bousquet et al., 2005). Compared to preindustrial ice-core measurements of CO, application of the C1 scheme with CO_2 sensitivity yields the best match, with the other scenarios underestimating CO by 16–33 %. Slow, in situ production of CO in ice cores may, however, inflate the observed CO values. Isotopic signatures in sulfate and nitrate provide a means to test the preindustrial and LGM model estimates of the oxidation capacity. For example, for all scenarios, we find relatively good agreement of the modeled change in OH since the LGM compared to that derived from measured $\Delta^{17}\text{O}(\text{SO}_4^{2-})$.

3.3 Implications for the methane budget

The global methane lifetime against oxidation by tropospheric OH, $\tau_{\text{CH}_4, \text{OH}}$, is calculated as defined by Eq. (1). In GEOS-Chem, atmospheric methane concentrations are prescribed from observations – the tropospheric mean concentrations are 1743 ppbv for the present day, 732 ppbv for the preindustrial, and 377 ppbv for the LGM scenarios (Murray et al., 2014, Table 3). The approximately doubled methane concentration across the LGM-to-preindustrial transition implies an increase in methane emissions or in its lifetime against oxidation, or some combination of both factors.

Table 5 and the left panels of Fig. 5 show the global methane lifetimes against oxidation by tropospheric OH for each combination of climate, chemistry, and isoprene emission scenarios. In Fig. 5, the dotted orange line represents results using the “best

estimate” lightning and fire emission scenarios of Murray et al. (2014). Consideration of the CO₂-sensitivity of plant isoprene emissions alone leads to large increases in the past global isoprene emissions, which in turn depress the tropospheric mean OH burden, thereby lengthening the methane lifetimes by 1.2 years for the preindustrial, 5 5.3 years for the warm LGM, and 5.9 years for the cold LGM. Conversely, implementation of the new isoprene photo-oxidation scheme leads to larger OH burdens, resulting in decreases in the methane lifetimes – by 1.4 years for the present day, 2.6 years for the preindustrial, 3.3 years for the warm LGM, and 3.9 years for the cold LGM. Implementation of the new HO₂ uptake scheme dampens the OH burden, which in turn 10 slightly increases the methane lifetimes for each climate scenario.

We compare the sensitivity of changes relative to the preindustrial in the global methane lifetimes and in the implied emissions in the right panels of Fig. 5. The values shown are relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). Results from the “best estimate” scenarios of Murray et 15 al. (2014) suggest that relative to the preindustrial, the global methane lifetime is reduced by 0.7 years in the present, and is increased by 0.5 years at the warm LGM. (As discussed in Sect. 2.1, comparison with paleo-observations suggests that their “low-fire, variable-lightning, warm LGM” scenario was the best representation of the LGM atmosphere.) This minimal increase in the lifetime at the LGM puts a higher burden on 20 sources in explaining the glacial-interglacial variability of atmospheric methane concentration. Assuming no large changes occurred in the minor loss mechanisms, methane emissions scale with changes in its loss by OH in the troposphere (Table 5). As defined in Sect. 3.2, the total loss rate of methane with respect to OH oxidation in the trop-

tropopause

sphere (Tg yr⁻¹) is calculated from the integral: $\int_{\text{surface}} k_{\text{CH}_4+\text{OH}}(T)[\text{OH}][\text{CH}_4] \, dx \, dy \, dz$.

25 For their “best estimate” scenarios, Murray et al. (2014) reports that total methane emissions are 150 % higher in the present relative to the preindustrial and are reduced by 50 % at the warm LGM.

Consideration of the CO₂-sensitivity of plant isoprene emissions alone results in the global methane lifetime being reduced by 1.9 years in the present, and increased by 4.6 years in the warm LGM, relative to the respective preindustrial scenario. This result suggests that methane emissions are reduced by 62 % at the warm LGM relative to the preindustrial, which places an even larger burden on sources than in Murray et al. (2014) in explaining the glacial-interglacial variability of atmospheric methane concentration. On the other hand, implementation of the new isoprene photo-oxidation scheme, either with or without consideration of the CO₂-sensitivity of plant isoprene emissions, results in relatively small changes in methane lifetimes across the glacial-interglacial or preindustrial-to-present day timescales. The resulting estimates of the reductions in methane emissions at the warm LGM relative to the preindustrial (between 46–62 %) are consistent with the Murray et al. (2014) “best estimate” of 50 %.

In summary, we find little variability in the implied relative LGM-preindustrial difference in methane emissions with respect to the uncertainties in isoprene photochemistry and emissions tested in this study. However, the range of values derived from the loss of methane by OH across our sensitivity simulations exceeds the 29–42 % decrease in wetland emissions simulated by the PMIP2 ensemble members (Weber et al., 2010), and the 16 and 23 % decreases in natural methane emissions simulated by Kaplan et al. (2006) and Valdes (2005), respectively.

3.4 Implications for SOA burdens and radiative forcing

Isoprene oxidation products substantially contribute to SOA formation (Henze and Seinfeld, 2006), and so our results have implications for past changes in SOA burdens. Increasingly cooler global temperatures relative to the present day in the preindustrial, warm LGM, and cold LGM scenarios are expected to decrease biogenic isoprene emissions. However, such reductions are damped or offset when the sensitivity to atmospheric CO₂ is also considered, since biogenic isoprene emissions are enhanced at CO₂ concentrations below present-day levels. The left panel of Fig. 6 shows the global SOA burdens for each combination of climate, chemistry, and isoprene emis-

sion scenarios. The dotted orange line represents results using the “best estimate” lightning and fire emission scenarios of Murray et al. (2014). Consideration of the CO₂-sensitivity of plant isoprene emissions alone leads to large increases in the past global isoprene burdens, which subsequently increases SOA at the preindustrial and LGM. 5 For example, when the CO₂-sensitivity is considered under the C1 chemistry scheme (i.e. C1-w compared to C1-wo), the relative increases in the simulated SOA burden are 24 % for the preindustrial, 93 % for the warm LGM, and 80 % for the cold LGM scenarios , as shown in the left panels of Fig. 6. Conversely, for a given isoprene emission 10 scenario, changes to the isoprene photo-oxidation and HO₂ uptake schemes lead to much smaller changes in the SOA burdens in each climate scenario.

The right panel of Fig. 6 shows the percent changes in tropospheric mean SOA burdens relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). The “best estimate” scenarios of Murray et al. (2014) – represented by our “C1-wo” simulations – suggest that relative to the preindustrial, the total 15 SOA burden is 5 % lower in the present, 42 % lower at the warm LGM, and 50 % lower at the cold LGM. These values, while relatively robust to variations in the isoprene photo-oxidation and HO₂ uptake schemes, are sensitive to estimates of the global isoprene burdens for the past atmospheres; consideration of the CO₂-sensitivity of plant isoprene emissions enhances the present-to-preindustrial difference but reduces the 20 LGM-to-preindustrial differences in the global SOA burden. For example, under the C1 chemistry scheme, consideration of the CO₂-sensitivity of plant isoprene emissions leads to decreases of 23 % in the total SOA burden in the present, but only of 10 and 28 % in the warm and cold LGM scenarios, relative to the preindustrial.

3.5 Implications for tropospheric ozone and radiative forcing

25 Isoprene and its oxidation products influence the formation and loss of tropospheric ozone (Beerling et al., 2007). As in Murray et al. (2014), we find decreasing tropospheric mean ozone burdens in each progressively colder scenario for each combination of isoprene photochemistry and emissions scenarios. The “best estimate” scenario

ios of Murray et al. (2014) – represented by our “C1-wo” simulations – suggest that relative to the preindustrial, the tropospheric mean ozone burden is 33 % higher in the present, 27 % lower at the warm LGM, and 19 % lower at the cold LGM. These values do not vary more than 8 % for the present day and 5 % for the LGM when the isoprene photochemistry and/or emission schemes are varied.

We can estimate what these changes imply in terms of radiative forcing from tropospheric ozone using the relationship of 0.042 W m^{-2} per DU change in the mean tropospheric column ozone (Stevenson et al., 2013). Averaging across our sensitivity simulations, changes in the mean tropospheric column ozone relative to their respective preindustrial scenarios lead to forcing contributions of $+0.3 \text{ W m}^{-2}$ for the present day, -0.3 W m^{-2} for the warm LGM, and -0.2 W m^{-2} for the cold LGM, relative to the preindustrial.

Using the multi-model estimate of 0.042 W m^{-2} per DU change in the mean tropospheric column ozone across the preindustrial-present day transition (Stevenson et al., 2013), we estimate that across our sensitivity simulations, changes in the mean tropospheric column ozone relative to their respective preindustrial scenarios lead to forcing contributions of $+0.3 \text{ W m}^{-2}$ for the present day. If we extrapolate this relationship to the LGM-preindustrial transition, we estimate values of -0.3 W m^{-2} for the warm LGM and -0.2 W m^{-2} for the cold LGM. However, accurate quantification of the tropospheric ozone forcing at the LGM relative to the preindustrial would require the use of an online radiative transfer model that convolves changes in the ozone distribution with other radiatively active climate processes.

3.6 Factors controlling variability in the tropospheric oxidative capacity

Murray et al. (2014) identified the key parameters that appear to control global mean OH levels on glacial-interglacial timescales. In this section, we explore the robustness of their result to the uncertainties in isoprene photochemistry and emissions tested in this study. Using the steady-state equations of the ozone- NO_x - HO_x -CO system, Wang and Jacob (1998) derived a linear relationship between the global mean OH burden and

the ratio $S_N / (S_C^{3/2})$, where S_N and S_C are the tropospheric sources of reactive nitrogen (Tmol N yr^{-1}) and of reactive carbon (Tmol C yr^{-1}), respectively. Murray et al. (2014) found that on glacial-interglacial timescales, the linear relationship can be maintained if two additional factors, which Wang and Jacob (1998) had assumed constant in their derivation, are also considered: (1) the mean tropospheric ozone photolysis frequency, J_{O_3} (s^{-1}) and (2) the tropospheric water vapor concentration, represented by the specific humidity, q ($\text{g H}_2\text{O kg air}^{-1}$). In other words,

$$[\text{OH}] \propto J_{O_3} q S_N / (S_C^{3/2}) \quad (2)$$

Figure 7 shows a plot of the tropospheric mean OH burden for each simulation as a function of $J_{O_3} q S_N / (S_C^{3/2})$, divided into panels according to the chemistry scheme. As in Murray et al. (2014), S_C is calculated as the sum of emissions of CO and NMVOCs and an implied source of methane equal to its loss rate by OH. While Murray et al. (2014) assumed that each molecule of isoprene yields an average 2.5 carbons that go on to react in the gas phase, this assumption has been found to not be robust for different isoprene oxidation schemes, and so we assume that each isoprene molecule undergoes 100 % gas-phase oxidation for all of the three chemistry schemes tested in this study.

Only the C1 data subset shows a statistically significant correlation coefficient ($r = 0.87$, $n = 7$, $p < 0.01$); a reduced major axis regression fit is shown by the orange line in Fig. 7. The breakdown in linearity for the C2 ($r = 0.36$) and C3 ($r = 0.34$) subsets can be explained by examining the classical tropospheric NO_x - HO_x -CO-ozone chemistry, upon which the linear relationship is derived. In this classical chemistry system, HO_x -cycling is coupled to NO_x -cycling. However, the new isoprene photo-oxidation mechanism includes additional pathways for HO_x -regeneration and recycling in the absence of NO_x . The new mechanism thus permits HO_x -cycling to occur without subsequent production of ozone through NO_2 photolysis, thereby weakening the sensitivity

of OH to each of the individual components of $J_{O_3} q S_N / (S_C^{3/2})$. For example, Murray et al. (2014) found that the global mean OH independently varied weakly but most strongly with the photolysis component (J_{O_3}) in their simulations. In this study, the only subset of simulations exhibiting a statistically significant correlation between OH and J_{O_3} is C1-wo ($r = 0.98$, $n = 4$, $p = 0.02$). Note that we are assuming the present-day C1-w simulation to be representative of the C1-wo scenario. This scheme employs the original isoprene and HO_2 uptake schemes without consideration of the CO_2 -sensitivity of plant isoprene emissions – i.e., the same as that used by Murray et al. (2014).

As can be seen by inspection of Fig. 7, the relationship between OH and $J_{O_3} q S_N / (S_C^{3/2})$ differs between the LGM-to-preindustrial and preindustrial-to-present day transitions for all of the three data subsets. With the present-day values excluded, we test whether the slope and intercept values are significantly different between the chemistry schemes by fitting a multiple regression model with $J_{O_3} q S_N / (S_C^{3/2})$ as a continuous explanatory variable and chemistry scheme as a categorical explanatory variable. We find that the three correlations have different values for the intercepts whereas the values for the slopes do not significantly differ (Fig. 7, dashed grey lines). The value of the intercept is largest for the C2 ensemble, followed by C3, and then C1. This sequence follows from our finding in Fig. 2, described in Section 3.1, that the new isoprene photo-oxidation mechanism leads to larger tropospheric mean OH burdens for each climate scenario compared to those simulated by the original mechanism. Implementation of the new HO_2 uptake scheme dampens this increase, but values remain above those from the C1 ensemble. We postulate two main reasons why the slope of OH to $J_{O_3} q S_N / (S_C^{3/2})$ appears to be lower across the industrial era than across the glacial-interglacial period. First, it is likely that heterogeneous reactions that can also act as HO_x sinks but are not considered in the derivation of the linear relationship, such as N_2O_5 hydrolysis and HO_2 uptake by aerosols, become more important under present-day conditions. In the present day, tropospheric aerosol mass loading is

17–20 % higher than the preindustrial, and 36–52 % higher than the warm and cold LGM scenarios. Second, there is a dramatic shift in the altitudinal distribution of tropospheric NO_x emissions. The ratio of lightning to surface NO_x emissions is 0.16 for the present day, 0.50 for the preindustrial, 0.73 for the warm LGM, and 0.79 for the cold LGM. The much lower present-day ratio is primarily due to large anthropogenic surface NO_x emissions, especially in the Northern Hemisphere (Murray et al., 2014, Fig. 5). This could lead to relatively more efficient NO_x removal by wet and dry deposition, and by formation of organic nitrates, which would both reduce primary and secondary OH production. However, these hypotheses need to be examined in greater detail, and an evaluation of potential weaknesses of the linear relationship between OH and $J_{O_3} q S_N / (S_C^{3/2})$ that operate independently of the classic photo-oxidation mechanism is described by Murray et al. (2015).

4 Discussion and conclusions

Using a detailed climate-biosphere-chemistry framework, we evaluate the sensitivity of modeled tropospheric oxidant levels to recent advances in our understanding of biogenic isoprene emissions and of the fate of isoprene oxidation products in the atmosphere. We focus on this sensitivity for the present day (ca. 1990s), preindustrial (ca. 1770s), and the Last Glacial Maximum (LGM, ~19–23 kyr). The 3-D global ICECAP model employed here considers the full suite of key factors controlling the oxidative capacity of the troposphere, including the effect of changes in the stratospheric column ozone on tropospheric photolysis rates (Murray et al., 2014). Our study, which revisits Murray et al. (2014), takes into account the sensitivity of plant isoprene emissions to atmospheric CO₂ levels, and considers the effects of a new isoprene photo-oxidation mechanism (Paulot et al., 2009a, b) and a potentially larger role for heterogeneous HO₂ uptake Mao et al., 2013a). We perform a systematic evaluation of the sensitivity of the chemical composition of past atmospheres to these developments.

We simulate two possible realizations of the LGM, one significantly colder than the other, to bound the range of uncertainty in the extent of tropical cooling at the LGM. For each climate scenario, we test three different chemistry schemes: C1, the original isoprene chemistry and original HO_2 uptake; C2, the new isoprene chemistry and original HO_2 uptake; and C3, the new isoprene chemistry and new HO_2 uptake mechanisms. Each chemistry scheme is tested with or without inclusion of the CO_2 -sensitivity of biogenic isoprene emissions, except for the present day for which consideration of the CO_2 -sensitivity results in only a 4 % change in the global isoprene burden. We find that consideration of the CO_2 -sensitivity of biogenic emissions enhances plant isoprene emissions by 27 % in the preindustrial and by 77–78 % at the LGM, relative to respective estimates that do not take into account the CO_2 -sensitivity. This implementation increases global isoprene emissions in the warm LGM scenario by 15 % relative to the preindustrial. At the LGM, lower sea levels expose extensive land area in equatorial Asia and Australia, which leads, in turn, to large regional increases in plant isoprene emissions (Murray et al., 2014, Figure 7). When we account for the potential increase in biogenic isoprene emissions at low CO_2 concentrations, this implementation swamps the effect of cooler temperatures in the warm LGM scenario.

We find that different oxidants have varying sensitivity to the assumptions tested in this study, with OH being the most sensitive. Although Murray et al. (2014) estimated that OH is relatively well buffered on glacial-interglacial timescales, we find that this result is not robust to all of the assumptions tested in this study, especially with respect to uncertainties in the isoprene photo-oxidation mechanism. Changes in the global mean OH levels for the LGM-to-preindustrial transition range between –29 and +7 %, and those for the preindustrial-to-present day transition range between –8 and +17 %, across our sensitivity simulations. However, consistent with Murray et al. (2014), we find reduced levels of ozone, H_2O_2 , and NO_3 for the past atmospheres relative to the present-day in our ensemble of sensitivity simulations. That study also reported a linear relationship between OH and tropospheric mean ozone photolysis rates, water vapor, and total emissions of NO_x and reactive carbon ($J_{\text{O}_3} q S_{\text{N}} / (S_{\text{C}}^{3/2})$) on LGM-to-present

day timescales. We find that the new isoprene photo-oxidation mechanism causes a breakdown in this linear relationship across the entire period, as the new mechanism permits HO_x -cycling to occur without subsequent production of ozone through NO_2 photolysis, thereby weakening the feedback on OH production per RO_2 consumed. We

5 propose that the sensitivity of OH to changes in $J_{\text{O}_3} q S_{\text{N}} / (S_{\text{C}}^{3/2})$ may be lower for the preindustrial-to-present day than the LGM-to-preindustrial transition. This is most likely because NO_x and HO_x loss processes not considered in the classical $\text{NO}_x\text{-HO}_x\text{-CO}$ -ozone system (from which the linear relationship is derived) become more important under present-day conditions.

10 We find little variability in the implied relative LGM-preindustrial difference in methane emissions with respect to the uncertainties in isoprene photochemistry and emissions tested in this study. The resulting estimates of the reductions in methane emissions at the warm LGM relative to the preindustrial (between 46–62 %) are comparable to the Murray et al. (2014) “best estimate” of 50 %. However, the range of our implied values

15 exceed those derived from prior model studies of wetland emission changes (Valdes et al., 2005; Kaplan et al., 2006; Weber et al. 2010). Our findings also have implications for radiative forcing estimates of SOA on preindustrial-present and glacial-interglacial timescales. For example, the “best estimate” scenarios of Murray et al. (2014) suggest that relative to the preindustrial, the total SOA burden is 5 % lower in the present

20 and 42 % lower at the LGM. Here, we find decreases ranging between 2–23 % in the present and 10–44 % at the LGM relative to the preindustrial across our sensitivity experiments. The climate effects of biogenic SOA are not well characterized, but are thought to provide regional cooling (Scott et al., 2014). Our work thus suggests that SOA reductions may have amplified regional warming in the present but minimized

25 regional cooling at the LGM, relative to the preindustrial. Results from ~~this~~these sensitivity studies, however, underscore the large uncertainties in current model estimates of SOA radiative forcing across long time scales (e.g., Scott et al., 2014; Unger and Yue, 2014; Unger, 2014a). Unlike SOA, we find that changes in tropospheric mean ozone burdens relative to the preindustrial are insensitive to the uncertainties in iso-

prene emissions and photochemistry tested in this study. Relative to the preindustrial, the absolute magnitude of the radiative forcing from the change in tropospheric ozone at the LGM may be comparable to that of the present day. However, most climate simulations of the LGM still use preindustrial ozone values as boundary conditions, including this study and the Paleoclimate Modelling Intercomparison Project 2 (PMIP2, Braconnot et al., 2012). Accurate quantification of the tropospheric ozone forcing at the LGM relative to the preindustrial requires the use of an online radiative transfer model that convolves changes in the ozone distribution with other radiatively active climate processes.

5 Besides SOA, changes in biogenic VOC emissions also affect the atmospheric concentrations of other climate forcing agents. Recent studies have demonstrated the importance of considering the net effect of human-induced changes in biogenic VOC emissions on global climate forcing over the industrial period (e.g., Unger, 2014a, b; Heald et al., 2014; Heald and Spracklen, 2015). Unger (2014a) quantified the global radiative impact of changes to the atmospheric concentrations of ozone, methane, and SOA due to a reduction in the emission of biogenic VOCs resulting from global cropland expansion between the 1850s and 2000s. She estimated a net cooling of $-0.11 \pm 0.17 \text{ W m}^{-2}$, which is comparable in magnitude but opposite in sign to the net forcing from the changes in surface albedo and land carbon release associated 15 with cropland expansion. When other known anthropogenic influences on biogenic VOC emissions are also considered, the net global climate forcing is estimated to be -0.17 W m^{-2} (Unger 2014b). Our work demonstrates that reducing the uncertainties on such an estimate will require improvements in our knowledge of isoprene photochemistry and CO_2 -sensitivity, as well as reconciling model estimates of land cover 20 change over the industrial period.

25 We find that biogenic VOC emissions decrease by 8 % in the present day relative to the preindustrial due to changing meteorology, redistribution of natural vegetation, and cropland expansion, and by 25 % when the CO_2 -sensitivity of isoprene emissions is also considered. The larger reduction is comparable to results from previous studies

that have estimated a 20-26 % reduction in biogenic VOC emissions from the late 19th century to the present day (Lathiere et al., 2010; Pacifico et al., 2012; Unger, 2013). Consistent with our study, Lathiere et al. (2010) determined that the CO₂-sensitivity effect dominates the change in isoprene emissions between 1901-2002, with the impact of land use change about half that of CO₂-sensitivity. In contrast, Pacifico et al. (2012) and Unger (2013) found cropland expansion to be the dominant driver of the reduction. This discrepancy likely arises for two reasons. First, our study applied an increase of approximately 10 % in global cropland expansion (Guenther et al., 2012), which is smaller than the 22 % change estimated by Unger (2013). Second, we apply a CO₂-sensitivity algorithm that most likely provides an upper limit of this effect for past climates (Possell and Hewitt, 2011).

The primary goal of this model study is to explore the sensitivity of the oxidative capacity of present and past atmospheres to assumptions about isoprene emissions and the fate of its oxidation products. We are reluctant to offer “best guess” estimates in large part because the uncertainty in the CO₂-isoprene interaction is substantial and our knowledge of the isoprene photo-oxidation mechanism is still evolving. Some studies have suggested that canopy-scale processes may complement or offset the leaf-scale response to atmospheric CO₂ levels (e.g., Sun et al., 2013). Also, it is likely that the application of the same CO₂-sensitivity parameterization to all PFTs leads to an overestimate of this effect. As discussed below, observations of the relevant chemical species that could constrain the oxidative capacity of past atmospheres are sparse. Laboratory and field measurements, however, strongly suggest that the C1 chemistry scheme is an inadequate representation of the isoprene photo-oxidation mechanism (Paultot et al., 2009a, b; Mao et al., 2013c). Therefore, model studies that depend on a simple, C1-like isoprene photo-oxidation scheme are likely outdated, particularly with respect to their ability to accurately simulate the tropospheric oxidative capacity. All of the models participating in the ACCMIP study in support of the IPCC AR5 used a C1-like isoprene photo-oxidation mechanism (Naik et al., 2013). Our results demonstrate that even under identical emission scenarios, the original and new isoprene

photo-oxidation mechanisms yield different interpretations of various parameters such as changes in global mean OH and methane lifetime across the preindustrial-present day transition.

Quantifying the oxidative capacity of past atmospheres remains an ongoing chal-

5 lenge because the oxidants are not directly preserved in the ice-core record, and paleo-
proxies that can provide a simple and robust constraint have not been readily identified
(Levine et al., 2011; Alexander and Mickley, 2015). Our results call for greater attention
10 and research efforts in the following measurements to help constrain model estimates
of the oxidative capacity of past atmospheres: (1) Ice-core CO. Quantifying the amount
of CO produced in situ from organic substrates trapped within the ice would facilitate
the use of ice-core CO measurements as constraints for model results; (2) Ice-core
15 $\Delta^{17}\text{O}(\text{NO}_3^-)$. Because of its greater sensitivity to oxidant abundances, ice-core mea-
surements of $\Delta^{17}\text{O}(\text{NO}_3^-)$ may in fact provide a more robust proxy than $\Delta^{17}\text{O}(\text{SO}_4^{2-})$ for
reconstructing the oxidation capacity of past atmospheres. For example, cloud amount
and pH do not influence the isotopic composition of nitrate as they do for sulfate (Levine
15 et al., 2011). In particular, measurements of $\Delta^{17}\text{O}(\text{NO}_3^-)$ in tropical ice cores, which are
so far sparse, may be highly valuable given that the dominant natural sources of NO_x
and production of OH are most prevalent in the tropics (Buffen et al., 2014); (3) Field
campaigns focused on measurements of oxidant cycling in high-isoprene, low- NO_x
20 environments. Such a suite of observations will help constrain the modeled sensitivity of
tropospheric oxidants to past climate changes.

The main scientific value of our study lies in its demonstration of the importance
of biogenic VOC emissions and the fate of their oxidation products in influencing
chemistry-climate interactions across the last glacial-interglacial time interval and the
25 industrial era. Because of existing uncertainties in isoprene emissions and photochem-
istry, there are larger uncertainties in model estimates of the oxidative capacity of
past atmospheres than previously acknowledged. These uncertainties For example,
Levine et al. (2011c) concluded that the effects of temperature and specific humidity
cancel out the effects of biogenic NMVOCs on OH across glacial timescales, with

or without consideration of OH-recycling in the isoprene photo-oxidation mechanism. However, using a more complex tropospheric chemical mechanism, including a more detailed representation of OH-recycling, as well as considering the effects of the CO₂-sensitivity of plant isoprene emissions and of changes in the stratospheric column ozone and tropospheric NO_x emissions, we demonstrate that uncertainties in the LGM-to-preindustrial change in OH remain substantial. Such uncertainties, in turn, limit our confidence in estimating radiative forcing due to changes in short-lived species such as SOA over time, as well as our ability to identify the factors controlling global mean OH levels between the LGM and the present day.

Constraining the anthropogenic radiative forcing over the industrial period inherently depends on our ability to quantify the chemical composition of the preindustrial atmosphere. In particular, assessing the radiative forcing from changes involving biogenic processes is an ongoing challenge in the modeling community, but has importance in the coming decades as policymakers face decisions that depend critically on accurate knowledge of the atmospheric oxidative capacity. For example, recent studies have demonstrated the importance of considering the net effect of human-induced changes in biogenic VOC emissions on global climate forcing over the industrial period (e.g., Unger, 2014a, b; Heald et al., 2014; Heald and Spracklen, 2015). Tackling the long-standing issue of the dynamics of future global methane sources and sinks is also crucial for the next generation of climate projections (Quiquet et al., 2015; Kirschke et al., 2013). However, including detailed photochemical mechanisms in chemistry-climate models is computationally expensive. In the ACCMIP models involved in the IPCC assessments of the preindustrial and present day, the tropospheric chemical mechanisms of non-methane hydrocarbons were represented in varying degrees of complexity (Lamarque et al., 2013), and the isoprene photo-oxidation mechanisms did not consider HO_x-recycling under low-NO_x conditions (Naik et al., 2013). Chemistry-climate models attempting to explain methane trends since the Last Glacial Maximum have also historically depended on relatively simple schemes for isoprene photo-oxidation (e.g., Valdes et al., 2005; Kaplan et al., 2006). Our work points to the value of

incorporating into such models both current knowledge and the associated uncertainties regarding biogenic isoprene emissions and photochemistry.

Author contributions. P. Achakulwisut and L. J. Mickley designed the experiments and P. Achakulwisut performed the model simulations and analysis. L. T. Murray, A. P. K. Tai, and

5 J. O. Kaplan developed the model code. P. Achakulwisut prepared the manuscript with contributions from all listed co-authors.

Acknowledgements. The authors would like to thank Mirjam Pfeiffer for performing the LPJ-LMfire simulations, John Mak for providing ice-core CO data, and Daniel Jacob, Karena McKinney, Fabien Poulton, and Malcolm Possell for stimulating discussions. This project was funded
10 by NSF grant AGS-1102880 to Harvard University and to the University of Washington.

Table 1. Atmospheric CO₂ concentrations and global annual terrestrial plant isoprene emissions for each climate scenario.

Climate Scenario	[CO ₂] (ppmv)	Global Annual Terrestrial Plant Isoprene Emissions		
		without CO ₂ -sensitivity (Tg C yr ⁻¹)	with ^a CO ₂ -sensitivity (Tg C yr ⁻¹)	Percent change with CO ₂ -sensitivity relative to without (%)
Present day	354	536	557	+3.9
Preindustrial	280	580	740	+28
Warm LGM	188	478	849	+78
Cold LGM	188	261	463	+77

* This study uses the empirical relationship from Possell and Hewitt (2011) to test the sensitivity of plant isoprene emissions to atmospheric CO₂ concentrations.

Table 2. Summary of the different climate, chemistry and plant isoprene emission scenarios tested in this model study. For each climate scenario except for the present day, all possible combinations of chemistry and emission schemes are tested (for the present day, only the “with” CO₂-sensitivity scheme is used). We perform 21 simulations in total.

Climate	Notes
Present day	ca. 1990s
Preindustrial	ca. 1770s
Warm LGM	19-23 ka; SSTs from CLIMAP Project Members(1967) with $\Delta\text{SST}_{15^\circ\text{S}-0^\circ\text{N}}^a$ of -1.2°C
Cold LGM	19-23 ka; SSTs from Webb et al. (1997) with $\Delta\text{SST}_{15^\circ\text{S}-0^\circ\text{N}}^a$ of -6.1°C
Chemistry	Notes (color scheme used in figures)
C1 ^b	Original isoprene chemistry and original HO ₂ uptake (orange)
C2	New isoprene chemistry and original HO ₂ uptake (green)
C3	New isoprene chemistry and new HO ₂ uptake (blue)
CO ₂ -sensitivity of plant isoprene emission	Notes
Without (wo) ^b	Controlling factors include temperature, light availability, leaf age, and leaf area index (LAI)
With (w)	Controlling factors include the above and atmospheric CO ₂ concentrations

^a The average change in sea surface temperature (SST) within 15 ° of the equator relative to the preindustrial.

^b The “C1-wo” combination corresponds to the schemes used by Murray et al. (2014) in their “best estimate” scenarios.

Table 3. Calculated present-day methyl chloroform (MCF) and methane lifetimes against tropospheric oxidation by OH ($\tau_{\text{MCF},\text{OH}}$, $\tau_{\text{CH}_4,\text{OH}}$), with consideration of CO_2 -sensitivity of plant isoprene emissions.

Lifetime	Model Chemistry Scheme ^a			Lifetimes inferred from observations
	C1	C2	C3	
$\tau_{\text{MCF},\text{OH}}$ [yr]	4.8	4.1	4.5	$6.0^{+0.5}_{-0.4}^{\text{b}}$
$\tau_{\text{CH}_4,\text{OH}}$ [yr]	10.3	8.9	9.6	$11.2 \pm 1.3^{\text{c}}$

^a See Table 2 for a full description of the different chemistry schemes tested in this study.

^b Inferred from observations (Prinn et al., 2005).

^c Inferred from observations (Prather et al., 2012).

Table 4. Modeled percent changes in the surface $[O_3]/[OH]$ and $[O_3]/[RO_2]$ ratios for the present day relative to the preindustrial, and in the surface $[OH]$ concentration for the warm and cold LGM relative to the preindustrial, for different model sensitivity experiments. Surface $[O_3]/[OH]$ and $[OH]$ values are averaged over the $46\text{--}66^\circ S$ latitude band to compare with values inferred from ice-core measurements of $\Delta^{17}O(SO_4^{2-})$ by Sofen et al. (2014) and Alexander et al. (2002). Surface $[O_3]/[RO_2]$ are averaged over the $34\text{--}54^\circ S$ and $62.5\text{--}72.5^\circ W$ (extratropical South America) to compare with values inferred from ice-core measurements of $\Delta^{17}O(NO_3^-)$ by Sofen et al. (2014), as described in Sect. 3.2.

Chemistry ^a Scheme	CO ₂ -sensitivity of plant isoprene emissions	Present day – Preindustrial	Present day – Preindustrial	Warm LGM – Preindustrial	Cold LGM – Preindustrial
		Percent change in surface $[O_3]/[OH]$ over $46\text{--}66^\circ S$ (%)	Percent change in surface $[O_3]/[RO_2]$ over S. America (%)	Percent change in surface $[OH]$ over $46\text{--}66^\circ S$ (%)	Percent change in surface $[OH]$ over $46\text{--}66^\circ S$ (%)
C1	without	35	2.3	68	87
	with	39	-0.3	105	106
C2	without	42	5.1	93	95
	with	42	2.8	105	101
C3	without	38	2.5	102	109
	with	40	-0.4	120	117
Observation-derived estimates		260	-60 to -90	40 ^b	40 ^b

^a See Table 2 for a full description of the different chemistry schemes tested in this study.

^b Percent increase in sulfate formed from gas-phase oxidation by OH

Table 5. Global methane burden and lifetime against tropospheric oxidation by OH ($\tau_{\text{CH}_4, \text{OH}}$).

Climate	Chemistry	CO ₂ -sensitivity	CH ₄ burden (Tg)*	Loss by OH in troposphere (Tg y ⁻¹)	$\tau_{\text{CH}_4, \text{OH}}$ (y)
Present day	C1	w	4790	465	10.3
	C2	w	4790	539	8.9
	C3	w	4790	497	9.6
Preindustrial	C1	wo	2010	184	11.0
		w	2010	165	12.2
	C2	wo	2010	238	8.4
		w	2010	230	8.7
warm LGM	C1	wo	2010	223	9.0
		w	2010	214	9.4
	C2	wo	1040	91	11.5
		w	1040	62	16.8
cold LGM	C1	wo	1040	127	8.2
		w	1040	112	9.3
	C2	wo	1040	120	8.7
		w	1040	102	10.2
	C3	wo	1040	66	15.8
		w	1040	48	21.7
	C2	wo	1040	87	11.9
		w	1040	79	13.1
	C3	wo	1040	81	12.9
		w	1040	72	14.5

* Global burden calculated from mean surface concentration using a conversion factor of 2.75 Tg CH₄ ppbv⁻¹ (Prather et al., 2012).

Figure 1. The ICE age Chemistry And Proxies (ICECAP) model framework consists of four global models, represented here by boxes with solid lines. The stratospheric and tropospheric chemistry schemes are coupled online in the GEOS-Chem Chemical Transport Model (CTM). Arrows indicate the flow of model output. The ICECAP model framework was especially designed for simulating the oxidative capacity of past atmospheres. (Adapted from Murray et al., 2014, Fig. 1.)

Figure 2. Simulated sensitivity of the tropospheric mean mass-weighted oxidant burdens of OH, O₃, H₂O₂, and NO₃ to each combination of climate, chemistry, and plant isoprene emission scheme. Simulations are as described in Table 2. The climate scenarios are present day, preindustrial, warm LGM, and cold LGM, with decreasing sea surface temperatures within 15° of the equator (SST_{15°S-N}), going from left to right along the abscissa. The chemistry schemes are C1 (orange curves), C2 (green), and C3 (blue). Plant isoprene emissions are modeled without (light-shaded) or with (dark-shaded) sensitivity to atmospheric CO₂ concentrations. The tropospheric burdens are calculated with the tropopause determined from the thermal lapse rate. The dotted light-orange line represents the results reported in Murray et al. (2014) for their “best estimate” lightning and fire emissions scenarios.

Figure 3. Percent changes (%) in the tropospheric mean mass-weighted OH burden for a range of scenarios relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). Simulations are as described in Table 2. The climate scenarios are present day, preindustrial, warm LGM, and cold LGM. The chemistry schemes are C1 (orange bars), C2 (green), and C3 (blue). Plant isoprene emissions are modeled without (light-shaded) or with (dark-shaded) sensitivity to atmospheric CO₂ concentrations. For the present day, test simulations with and without CO₂-sensitivity yield nearly identical isoprene emissions. We therefore perform all present-day simulations with CO₂-sensitivity turned on and assume that these model results apply to the respective present-day “without” scenarios. (Note: The percent change at the warm LGM relative to the preindustrial is very small when the C1 chemistry scheme is used without consideration of the CO₂-sensitivity (C1-wo), and so no light orange bar is apparent in the middle panel.)

Figure 4. Comparison of model results with observations of CO surface concentrations (ppbv) over Antarctica for the preindustrial (1770s) and present-day (1990s) simulations. Simulations are as described in Table 2; colors are as in Fig. 2. The maroon crosses represent observations from different sources for each time slice. Wang et al. (2010) measured ice-core CO concentrations at the South Pole of 48 ± 4 ppbv for the year 1777 (± 110 years); the associated errors represent analytical uncertainties. The mean CO surface concentration measured at the South Pole by the NOAA Global Monitoring Division for the 1990s is 49 ± 2 ppbv; the associated errors represent inter-annual variability. The squares represent values averaged over Antarctica from our model simulations tested with different chemistry and isoprene emission schemes for the preindustrial and present-day scenarios. Simulations are as described in Table 2; colors are as in Fig. 2. Error bars associated with the model results represent ± 1 standard deviation of the spatially-averaged mean value.

Figure 5. Left Panel: calculated global methane lifetime against oxidation by tropospheric OH for each combination of climate, chemistry and plant isoprene emission scenarios. Simulations are as described in Table 2; colors are as in Fig. 2. The dotted light-orange line represents the results reported in Murray et al. (2014) for their “best estimate” lightning and fire emissions scenarios. Right Panels: Changes in the global methane lifetimes (yr) and emissions (%) relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). Colors are as in Fig. 3. Changes in methane emissions are calculated by assuming that they scale with changes in methane loss by OH in the troposphere.

Figure 6. Left Panel: tropospheric mean mass-weighted secondary organic aerosol (SOA) burdens for each combination of climate, chemistry and plant isoprene emission scenarios. Simulations are as described in Table 2; colors are as in Fig. 2. The dotted light-orange line represents the results reported in Murray et al. (2014) for their “best estimate” lightning and fire emissions scenarios. Right Panel: Percent changes in tropospheric mean SOA burdens relative to their respective preindustrial scenarios (e.g., C1-w Present day relative to C1-w Preindustrial). Colors are as in Fig. 3.

Figure 7. Tropospheric mean mass-weighted OH burden in each simulation as a function of $J_{O_3} q S_N / (S_C^{3/2})$, where J_{O_3} is the tropospheric mean mass-weighted ozone photolysis frequency (s^{-1}), q is the tropospheric mean mass-weighted specific humidity ($g\,kg^{-1}$), and S_N and S_C are the tropospheric sources of reactive nitrogen ($Tmol\,Na^{-1}$) and of reactive carbon ($Tmol\,Ca^{-1}$), respectively. S_C is calculated as the sum of emissions of CO, NMVOCs, and an implied source of methane equal to its loss rate by OH. Model results for different chemistry schemes are separated into three subsets as follows. Top panel: original isoprene chemistry and original HO_2 uptake (C1). Middle panel: new isoprene chemistry and original HO_2 uptake (C2). Bottom panel: new isoprene chemistry and new HO_2 uptake (C3). Different symbols denote different climate scenarios (present day, preindustrial, warm LGM, cold LGM). Filled symbols represent simulations in which the CO_2 -sensitivity of plant isoprene emission is considered (w); unfilled symbols are those without (wo). All present-day simulations were performed with CO_2 -sensitivity turned on. The orange line shows a reduced major axis regression fit for the C1 subset, with the regression equation and correlation coefficient ($r = 0.87$, $p < 0.01$) inset. We do not find a statistically significant correlation between OH and $J_{O_3} q S_N / (S_C^{3/2})$ for the C2 ($r = 0.36$) and C3 ($r = 0.34$) subsets. When the present-day values are excluded and a multiple regression model is fitted to the remaining ensemble, we find that the three different chemistry schemes possess the same values for the slopes of the linear correlation but different values for the intercepts, as shown by the dashed grey lines (see text for details).
