Responses to the comments of referee#2

Interactive comment on "Fine particulate matter associated with monsoonal effect and the responses of biomass fire hotspots in the tropical environment" *by* M. F. Khan et al.

Anonymous Referee #2

Received and published: 13 September 2015

The manuscript of Khan et al. focuses on the health implications of fine particulate matter ($PM_{2.5}$) and its main constituents in the western part of Malaysia. The study period covers two monsoonal regimes, one coming from the south-west and one from the north-east and levels of PM, heavy metals and main ions are determined for both regimes. Overall it has been found that 48% of the samples were 4 times or more than guideline values, with the north-east monsoon regime exhibiting somewhat higher values. Based on the enrichment factor of metals it occurred that the majority of heavy metals were attributed to anthropogenic sources, while arsenic was identified as a potentially significant health concern as its concentrations were nearly equal to the WHO and US EPA guideline values, posing an exposure risk for inhabitants in the specific location. Using a mass closure model a mineral component was found to comprise 35% of the $PM_{2.5}$ concentration, followed by 11% by secondary inorganic aerosol, while 45% was unidentified, possibly a large part of it being the organic aerosol fraction. Using positive matrix factorization (PMF) analysis as a source apportionment tool, motor vehicle and biomass burning emissions were the dominant sources, followed by marine and sulfate aerosol, coal burning, nitrate aerosol and mineral dust. Finally, based on the health risk assessment and the PMF-identified sources, the non- carcinogenic risk posed by exposure of PM was at a safer level than the respective one in the South and East Asian region while the cancer risk posed by the exposure to toxic metals was 3 to 4 in 1 million people in the specific location. Motor vehicle emissions and trans-boundary pollution were the major identified reasons for change in the chemical composition of PM in tropical Peninsular Malaysia.

The manuscript is well written and interesting, with an added value of the presented results being from an area of the globe that is not very well documented. It is a pity that analysis of the organic fraction is not available, as it is expected that a large portion of the unidentified mass from the mass closure model will be the organic component. There are several details missing and more thorough discussion should be made in specific sections. Other than that the paper can be recommended for publication after addressing the issues listed below.

1) One of the features of the manuscript that the authors draw our attention to is the comparison

between the $PM_{2.5}$ from the PMF and from the high volume samplers (HVS) which was found to have a slope of 0.91 and a very good correlation. It appears somewhat strange that even though 45% of the $PM_{2.5}$ mass remains unidentified, the comparison of the mass concentrations from the PMF and the HVS results in a slope of 0.91. Please comment. Also, do the authors believe that the remaining 45% of the unidentified mass, with the organics possibly being a large part of this mass, will be part of the already identified components? Please clarify in the text that the PMF analysis results are based on the obtained filter analyses results.

Authors' response

We understand the reviewer's concern and thus add the following explanation in the text as follows (Page 22232, lines 22-27; Page 22233; lines 1-2):

"The reported PMF analysis is based on the chemical components of filter samples. As described in the mass closure, a large portion of the $PM_{2.5}$ mass fraction (about 45%) was not apportioned. In the PMF 5.0 procedure, the contributions of five factors were estimated and then the integrated contribution of the five factors was regressed over the measured $PM_{2.5}$ (HVS). The regression fit line was forced through the origin. Thus, our regression of the $PM_{2.5}$ (PMF) and $PM_{2.5}$ (HVS) showed that the $PM_{2.5}$ had been reproduced by PMF 5.0 with an error of less than 10% and the correlation of $PM_{2.5}$ (PMF) and $PM_{2.5}$ (HVS) showed a strong and significant correlation (slope = 0.91, r^2 = 0.88, $p < 0.01$) (Fig. 6b). To evaluate the results of the PMF model, the regression between predicted and observed data for each variable is shown during the operation. A linear correlation between the predicted and measured mass represents the goodness-of-fit of linear regression. Our values strongly suggested that the five identified sources could be readily interpreted."

Comment to "slope of 0.91 regression result of PMF-HVS"

We acknowledge the reviewer's concern regarding the PMF-MLR results. However, we would like to inform that we did follow all the crucial and necessary steps in running the PMF tools as per mentioned in section 2.7. The mass contribution was calculated following procedure as per mentioned in Ke et al.

(2008) where first, regressing the factor scores obtained from the PMF using multi linear regression against the $PM_{2.5}$ measured mass concentration of each sample; and secondly, the regression coefficients were used to convert the contributions of each factor score into a physical mass.

2) Authors mention that the K^+ ion has been widely used in the literature as an excellent tracer representing wood burning, and authors examined the correlation between K^+ concentrations and MODIS fire counts. To my opinion, and correlation coefficient of 0.36 does not suggest that K^+ can be used as a biomass tracer. I would propose to differentiate between nss-K^+ and total K^+ and check if the correlation is stronger. ss-K^+ can be calculated using Na as a reference and the K/Na ratio in bulk seawater.

Authors' response

We agree with the reviewer's suggestions. We have revised Fig. 5, included Fig. 5b and 5c and annotated in the text as below (Page 22235; lines 19-26):

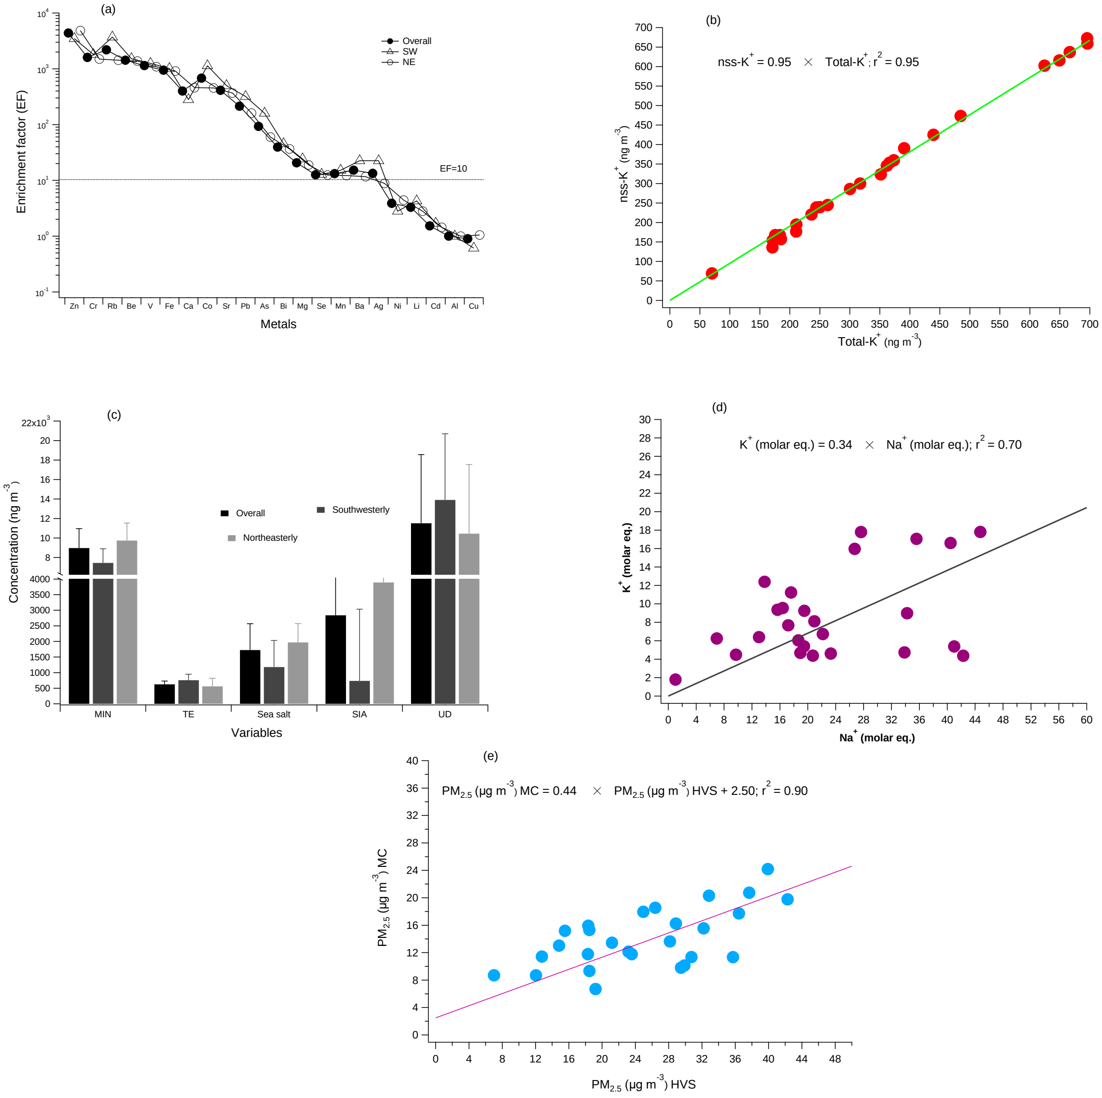

Figure 5 (a) Enrichment factor (EF) of heavy metals in $PM_{2.5}$. (b) correlation plot of nss-K^+ and total-K^+ (r^2 = 0.95), (c) correlation plot of K^+ and Na^+ and (d) reconstructed mass concentration of $PM_{2.5}$ by mass closure (MC) model and (e) correlation plot of $PM_{2.5}$ (µg m^{-3}) HVS and $PM_{2.5}$ (µg m^{-3}) MC

"Further, a comparison of nss-K^+ with the respective total K^+ is shown in Fig. 5b. The correlation of nss-K^+ as a function of total K^+ showed a strong correlation coefficient (r^2 = 0.95) which suggests that K^+ can be used as a biomass tracer. K^+ may also be emitted from local fire sources. Additionally, the molar equivalent of K^+ and Na^+, as shown in Fig 5c, demonstrated significant correlation (r^2 = 0.70) with a slope value of 0.34 which is much higher compared to 0.0225-0.230 and 0.0218, reported by Wilson (1975) and Hara et al. (2012), respectively. The higher molar ratio of K^+ and Na^+ indicates that at the current location, Na^+ depletion was high and the K^+ might also release from other dominant sources. Additional significant sources of K^+ which may attribute to the mass are soil dust, sea salt, vegetation and meat cooking (Zhang et al., 2010)."

3) Based on the presented biomass fire hotspots, it is clear that from December 2013 to March 2014, the hotspots are a lot more compared to the respective ones from June to September 2013. Maybe authors should consider adding a comment of why this is the case. Is December-March the dry season? Is this period of intense biomass fire hotspots present every year or was the presented year uncharacteristic?

Authors' response

We have revised our text as the reviewer suggested (Page 22229; lines 1-3):

"The back trajectory plots showed that there were high numbers of biomass fire hotspots during both seasons but from different regions (Fig. 3). The period of June to September is the dry season each year in Malaysia and Sumatra of Indonesia. During this dry season, biomass fire hotspots are densely located in this area due to the burning of agricultural waste and forest fires. Several other researchers also reported the high number of biomass fire - related hotspots to these regions (Khan et al., 2015; Sahani et al., 2014). On the other hand, December to March is usually the wet season in Malaysia. However, the backward trajectories showed that air masses were transported from Mainland China and neighbouring regions. In Mainland China and neighbouring regions, this is dry season. During the dry season in this region there are a lot of fires, as reported by Zhang et al. (2015) and Ho et al. (2014), and this influences the pollution of air masses transported to the present location. This scenario of biomass fire hotspots is commonly noticed in these two seasons. In past years Malaysia and Singapore have experienced intensified haze episodes in this particular season, e.g. 1997, 2005, 2013 and 2015."

4) In the enrichment factor section (2.5) in the whole paragraph EFs of two, five or even 10 are cited from the bibliography as thresholds for anthropogenic sources. Nevertheless authors choose a cut-off of EF=1. Please comment.

Authors' response

We understand and accept the reviewer's concern. Therefore, we have revised the cut-off point with explanation pertaining to that as follows (Page 22223; lines 11-24):

"Chester et al. (2000); Cheung et al. (2012); Khan et al. (2010); Mohd Tahir et al. (2013); Torfs and Van Grieken (1997) proposed a EF cut-off of ten to differentiate between crustal and natural and anthropogenic origins of heavy metals. Thus, we consider EF = 10 as the cut-off point. Therefore, a good number of the metals (Zn, Cr, Rb, Be, V, Fe, Ca, Co, Sr, Pb, As and Bi) in $PM_{2.5}$ in this study can be assumed to originate from anthropogenic sources; Fig. 5a. These heavy metals were not natural or from the Earth's crust. No seasonal differences were observed in the EF of the heavy metals."

Technical corrections:

P22217, L15-18: Not clear, especially the part ". . .with respect to inhalation follows the order. . .". Also in PMF 5.0 delete the ">".

Authors' response

We agree with the suggestion. We have revised the sentences as below (Page 22217; lines 14-17):

"The hazard quotient (HQ) for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in $PM_{2.5}$ mass from the coal burning source and least in $PM_{2.5}$ mass originating from the mineral/road dust source. The main carcinogenic heavy metal of concern to health at the current location was As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk in $PM_{2.5}$ mass concentration."

P22219, L17: . . ..a period from July to September

Authors' response

We have revised the sentence as below (Page 22219; lines 17-18):

Sampling was carried out on a 24 h basis for a period from July to September 2013 and January to February 2014 for a total of 27 samples.

P22220, L27: . . .ionic composition was determined

Authors' response

We have corrected the error (Page 22220, line 27):

"the water-soluble ionic composition (Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^- and SO_4^{2-}) was determined"

P22221, L18: Replace "fresh" for the calibration curves. Maybe use "updated" instead.

Authors' response

We have revised the sentence as below (Page 22221, line 18):

"During the trace element analysis by ICP-MS, two modes of analysis were applied with updated calibration curves each time."

P22223, L14: . . .metals in $PM_{2.5}$ originated from. . . (delete "had")

Authors' response

We have updated the sentence as below (Page 22223, line 14):

"Therefore, a good number of the metals (Zn, Cr, Rb, Be, V, Fe, Ca, Co, Sr, Pb, As and Bi) in $PM_{2.5}$ in this study can be assumed to originate from anthropogenic sources; Fig. 5a"

P22227, L18: . . .classified by the International Agency. . .

Authors' response

We have corrected the sentence as below (Page 22227, line 18):

"Further, we examined the non-carcinogenic risk (presented by the hazard quotient (HQ)) and lifetime carcinogenic risk (LCR) of selected heavy metals as classified by the International Agency for Research on Cancer (IARC)."

P22230, L28: Boreddy et al. (2014) also notice a chlorine depletion due to atmospheric processing in the western north Pacific.

Authors' response

We have added the new reference suggested by the reviewer as below (Page 22230, line 28):

"Boreddy et al. (2014) also noticed a chlorine depletion due to atmospheric processing in the western north Pacific."

P22233, L1: Based on Figure 6a the slope is 0.91 and R^2=0.88 and not the other way round.

Authors' response

We have corrected the typo errors as below (Page 22233, Line 1):

"the correlation of $PM_{2.5}$ (PMF) and $PM_{2.5}$ (HVS) showed a strong and significant correlation (slope = 0.91, $r^2 = 0.88$, $p < 0.01$) (Fig. 6b)"

P22235, L8: Zhang et al. (2015) demonstrate that during the dry season there is an important biomass burning activity in the Pearl River Delta (China), which can result in trans-border transport and a regional scale character of biomass burning. Therefore under the north-east monsoonal regime it is possible that outflow from that area can maybe influence the specific area.

Authors' response

We are thankful to the reviewer suggesting the reference as below (Page 22235, line 8):

"However, the backward trajectories showed that air masses were transported from Mainland China and neighbouring regions. In Mainland China and neighbouring regions, this is dry season. During the dry season in this region there are a lot of fires, as reported by Zhang et al. (2015) and Ho et al. (2014), and this influences the pollution of air masses transported to the present location."

P22235, L22: An r=0.36 does not suggest that K^+ can be used as a biomass tracer.

Authors' response

We have revised the text as the reviewer suggested. Please find the revised text as shown below (Page 22235, line 22):

"Further, a comparison of nss-K^+ with the respective total K^+ is shown in Fig. 5b. The correlation of nss-K^+ as a function of total K^+ showed a strong correlation coefficient ($r^2 = 0.95$) which suggests that K^+ can be used as a biomass tracer. K^+ may also be emitted from local fire sources. Additionally, the molar equivalent of K^+ and Na^+, as shown in Fig 5c, demonstrated significant correlation ($r^2 = 0.70$) with a slope value of 0.34 which is much higher compared to 0.0225-0.230 and 0.0218, reported by Wilson (1975) and Hara et al. (2012), respectively. The higher molar ratio of K^+ and Na^+ indicates that at the current location, Na^+ depletion was high and the K^+ might also release from other dominant sources. Additional significant sources of K^+ which may attribute to the mass are soil dust, sea salt, vegetation and meat cooking (Zhang et al., 2010)."

P22238, L17: . . . ..follows the following order: As > Ni . . . ..Also "follows" and "following" is a repetition, maybe replace one of the two

Authors’ response

We have corrected and re-worded the sentences as shown below (Page 22238, line 17):

“the lifetime carcinogenic risk level is estimated for $PM_{2.5}$ mass concentration and may be contributed to by several heavy metals from different sources: mineral/road dust, motor vehicle emissions/biomass burning and coal combustion.”

L18: . . .$PM_{2.5}$ concentration and As > Pb. . . (delete “;”)

Authors’ response

We have re-worded the sentences as below (Page 22238, line 18):

“The main carcinogenic heavy metal of concern to the health of people at the current location is As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk.”

Responses to the comments of referee#3

Interactive comment on* "Fine particulate matter associated with monsoonal effect and the responses of biomass fire hotspots in the tropical environment"** ***by **M. F. Khan et al.**

Anonymous Referee #3

Received and published: 13 September 2015

1. The title is not appropriate. Title should include the terms "source apportionment" and also "health effect". As, authors one of the main conclusion is on the health impact. Overall, the associated cancer risk posed by the exposure of toxic metals in $PM_{2.5}$ is three to four in 1 000 000 people in this location.

Authors' response

We do agree with the review's suggestion and have revised the title as shown below:

"Fine particulate matter in the tropical environment: monsoonal effects, source apportionment and health risk assessment"

2. Authors used quartz microfiber filters for trace metals analyzer. Quartz microfiber filters are not the great filters for trace metals. They may have some influences on the trace metals content. Though they did blank correction for the filters.

Authors' response

We agree with the reviewer's observation. Despite possible influence of trace metal content, several researchers still use the microfiber quartz filter but with strict QA/QC and blank corrected to account for possible interferences. Taking into account the reviewer's comment, we have included in the text several references to corroborate our choice of filter. The QA/QC aspect has been mentioned in the text (page 22221, line 8)

3. Authors measured only water-soluble inorganic ions and trace metals in $PM_{2.5}$. But the main component of $PM_{2.5}$ is organic (OC) and black carbon (BC or EC) and also water-soluble organic ions are missing. Trace metals may be up to 1% and water-soluble inorganic ions may be up to 20% but carbonaceous species may be up to 50% of the fine particles are missing in this chemical composition.

Authors' response

We acknowledge reviewer's concern and we will definitely take this into consideration in future studies. At this stage, we added an explanation highlighted in turquoise color as follows (page 22232, line 3):

"The reported result of the mass closure model is based on the analyzed chemical components of filter samples (~ 55%). As described in the mass closure, a large portion of $PM_{2.5}$ mass (~ 45%) was left unidentified; this unidentified component is believed to be the organics or carbonaceous species. Elemental carbon (EC), organic carbon (OC) and water-soluble organics were not measured due to the lack of instrumentation. Other possible reasons for the un-identified portion are: i) unaccounted for mineral oxides as they are abundant in $PM_{2.5}$, and ii) water associated with salts."

4. Author cut off point for EF is 1. Whereas Sun et al. (2006) suggested the threshold of EF > 5 to differentiate between sources from the Earth's crust and from anthropogenic sources. In contrast, Mohd Tahir et al. (2013) proposed the EF cut-off of ten to identify crustal and natural origin of heavy metals. What is the basis of their cut off point???

How did thy calculate EF? I mean whish for formula please refer that not my reference like Taylor (1964) but with formula or equation.

Authors' response

We understand and accept the reviewer's concern. We also made similar answer to the comments of previous reviewer#2. We acknowledge that the use of EF is subjected to variation depending on the reference crustal values. A larger margin is more often used for atmospheric samples (EF >10) to account for this uncertainty and also possible regional variation and the conservation of crustal element ratios through various environmental compartments. Therefore, we have revised the cut-off point to 10 with explanation pertaining to that highlighted in turquoise color as follows (Page 22223; lines 11-24):

"Chester et al. (2000); Cheung et al. (2012); Khan et al. (2010); Mohd Tahir et al. (2013); Torfs and Van Grieken (1997) proposed a EF cut-off of ten to differentiate between crustal and natural and anthropogenic origins of heavy metals. Thus, we consider EF = 10 as the cut-off point. Therefore, a good number of the metals (Zn, Cr, Rb, Be, V, Fe, Ca, Co, Sr, Pb, As and Bi) in $PM_{2.5}$ in this study can be assumed to originate from anthropogenic sources; Fig. 5a. These heavy metals were not natural or from the Earth's crust. No seasonal differences were observed in the EF of the heavy metals."

The manuscript has been revised with following equation of EF (page 22223, line 9):

"The EF of each element can be defined using the following equation:

$$EF = \frac{\left(\frac{E}{Al}\right)_{PM\,2.5}}{\left(\frac{E}{Al}\right)_{Crust}} \qquad (1)$$

where, E/Al is the concentration ratio of element, E, to the reference metal, Al."

5. Figure caption is inadequate. e.g., Figure 3 should have the source (e.g., HYSPLIT,), backward or forward, starting and ending time etc. Though authors mentioned them in the text. They should also write

in the figure caption.

Authors' response

Revised caption of Figure 3 as shown below:

"Figure 3 The location of biomass fire hotspots and the monthly mean cluster of backward trajectories by HYSPLIT 4.9 model for 120 h and 500 m releasing height starting from 16:00 UTC during the south-westerly and the north-easterly monsoon"

6. Authors are using $PM_{2.5}$ MC with equation 4. It would be great if they can discussion $PM_{2.5}$ MC and $PM_{2.5}$ mass.

Authors' response

We agree with the reviewer's suggestion. We have added an explanation and a correlation plot of $PM_{2.5}$ (HVS) and $PM_{2.5}$ (MC) highlighted in turquoise color as bellows (page 22232, line 3):

"The average value of reconstructed $PM_{2.5}$ by mass closure (MC) is 14.12±4.32 µg m^{-3} with a minimum of 6.70 µg m^{-3} and a maximum of 24.19 µg m^{-3}. On the other hand, the measured $PM_{2.5}$ determined gravimetrically by HVS was 25.13±9.21 µg m^{-3} with a range of 7.01 to 42.78 µg m^{-3}. A correlation plot of $PM_{2.5}$ (MC) and measured $PM_{2.5}$ (HVS) is shown in Fig. 5e. The correlation shows a good fit (r^2 = 0.98) with a slope of 0.46 and an intercept of 1.93. The results of the fit parameters suggest that the $PM_{2.5}$ mass (MC) concentration was underestimated compared to $PM_{2.5}$ (HVS). The reported result of the mass closure model is based on the analyzed chemical components of filter samples (~ 55%). As described in the mass closure, a large portion of $PM_{2.5}$ mass (~ 45%) was left unidentified; this unidentified component is believed to be the organics or carbonaceous species. Elemental carbon (EC), organic carbon (OC) and water-soluble organics were not measured due to the lack of instrumentation. Other possible reasons for the un-identified portion are: i) unaccounted for mineral oxides as they are abundant in $PM_{2.5}$, and ii) water associated with salts."

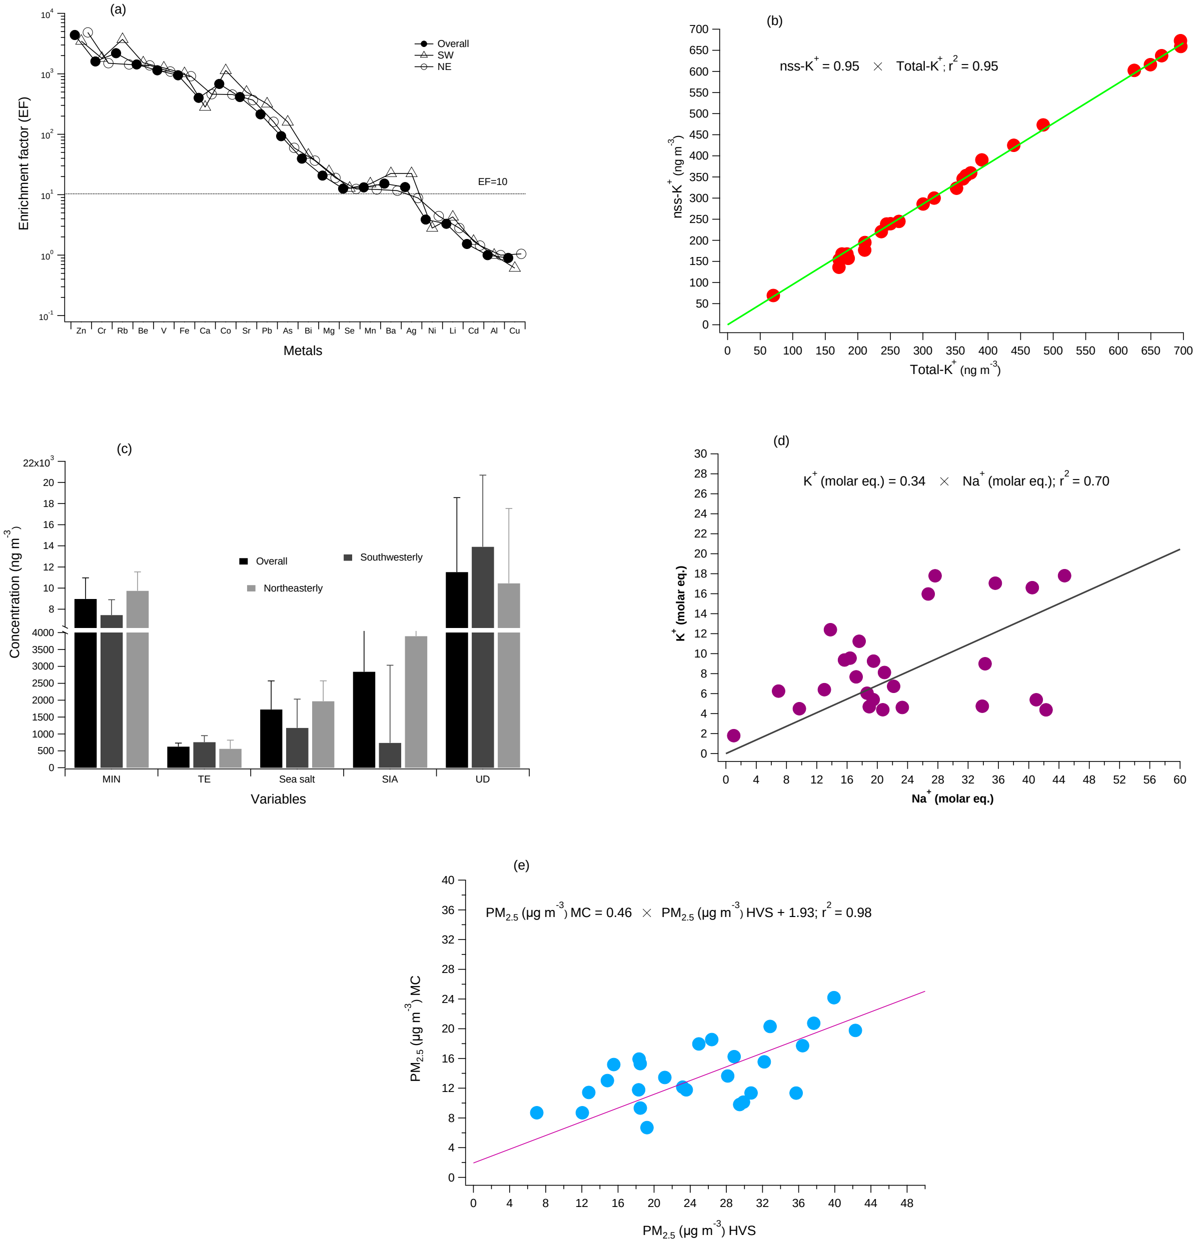

Figure 5 (a) Enrichment factor (EF) of heavy metals in $PM_{2.5}$, (b) correlation plot of nss-K^+ and total-K^+, (c) reconstructed mass concentration of $PM_{2.5}$ by mass closure model, (d) correlation plot of K^+ and Na^+, and (e) correlation plot of estimated $PM_{2.5}$ (MC) and measured $PM_{2.5}$ (HVS)

7. It is kind of weird to discuss the carcinogenicity on the basis on of sources. E.g., if a metal Ni came from coal may be more carcinogen than if it is came from traffic. Please try to rewording then section Table 3 and discussion 3.4.

Authors' response

We agreed with the reviewer's comment; we did not mean to say that metals in one source are more carcinogenic than the same metals in other sources. We apologies for the confusion and we have re-worded our discussion to reflect that carcinogenic effects are due to metals present in $PM_{2.5}$ that are associated with that particular source (pages 22237-22239):

"Table 3. Hazard quotient (HQ) and lifetime carcinogenic risk (LCR) for selected heavy metals in $PM_{2.5}$ associated with sources"

Revised Table 3

Table 3. Hazard quotient (HQ) and lifetime carcinogenic risk (LCR) for selected heavy metals in $PM_{2.5}$ associated with sources

Inhalation	Mineral/road dust		Motor vehicle/biomass		Coal burning		$PM_{2.5}$	
	HQ	LCR	HQ	LCR	HQ	LCR	HQ	LCR
Pb	-	4.0×10^{-8}	-	1.0×10^{-7}	-	4.1×10^{-8}	-	2.5×10^{-7}
As	1.8×10^{-3}	1.1×10^{-7}	4.9×10^{-2}	1.1×10^{-6}	6.6×10^{-2}	1.5×10^{-6}	15.9×10^{-2}	3.5×10^{-6}

Pb*: pb (acetate), As*: As (Inorganic), Cd*: Cd (Diet), Mn*: Mn (Diet), Zn*: Zn (Metallic), Ni*: Ni (Refinery Dust), ”-”: no data, THR: Total Health Risk, HI: Hazard Index, HQ: Hazard quotient (non-cancer risk); LCR: Lifetime Cancer Risk

"Table 3 shows the non-carcinogenic (represented as HQ) and carcinogenic risks posed by several selected metals (Pb, As, Cd, Cu, Mn, Zn and Ni) in $PM_{2.5}$ mass concentration through inhalation exposure associating with sources. The HQ values for As and Ni in $PM_{2.5}$ mass concentration are 15.9×10^{-2} and 14.3×10^{-2}, respectively, suggesting the non-carcinogenic health risks posed by these metals might be higher compared to other metals. The HQ for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in the $PM_{2.5}$ mass originating from the coal burning source and least in $PM_{2.5}$ originating from the mineral/road dust source. The cut-off point for significant health risks or the safe level to the exposed population is HQ > 1. Our results showed that the sum of HQ for each metal are lower than the safe level (= 1) in $PM_{2.5}$ mass concentration originating from each source. The sum of HQ for $PM_{2.5}$ is 35.7×10^{-2}, which is lower than the HQs of $PM_{2.5}$ reported by Hu et al. (2012) in Nanjing, China (2.96); Cao et al. (2014) in Shanxi Province, China ($1.06\times10^{+1}$); and Taner et al. (2013) in a non-smoking restaurant in Turkey (4.09). A study by Hu et al. (2012), reported HQ values for As and Ni in $PM_{2.5}$ as 4.14×10^{-1} and 1.73×10^{-1}, respectively, in Nanjing, China. However, the HQs of $PM_{2.5}$ estimated after inhalation at two sites in Nanjing City, China (0.88 (Xianlin) and 0.79 (Gulou)) were close to the safe level (= 1) according to a study by Li et al. (2015). At two urban locations in Yangtze River Delta, China, the HQ for Cr in $PM_{2.5}$ was within the acceptable limit but higher for Mn (Niu et al., 2015). Although the HQ calculated for As was the highest, it was below 1, thus the non-carcinogenic health risk was estimated to be at a safelevel. In addition, the hazard index (total - hazard quotient) of $PM_{2.5}$ calculated for the four heavy metals (As, Cd, Mn, Ni) from the different sources (Table 3) showed an insignificant health risk.

The carcinogenic risks from the carcinogenic heavy metals Pb, As, Cd and Ni in $PM_{2.5}$ are shown in Table 3. Similar to the non-carcinogenic risks, the lifetime carcinogenic risk level is estimated for $PM_{2.5}$ mass concentration and may be contributed to by several heavy metals from different sources: mineral/road dust, motor vehicle emissions/biomass burning and coal combustion. The total life-time cancer risk (LCR) from heavy metals in the $PM_{2.5}$ mass concentration was calculated at 3.9×10^{-6} which is a significant cancer risk. The main carcinogenic heavy metal of concern to the health of people at the current location is As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk. Thus, the LCR from the $PM_{2.5}$ mass concentration originating from motor vehicle/biomass and coal burning sources showed a value of 1×10^{-6}, slightly above the acceptable cancer risk level as recommended by USEPA, while the total LCR from $PM_{2.5}$ mass concentration from all sources was estimated to be 4×10^{-6} which is also slightly above the acceptable cancer risk. The carcinogenic risk posed by As (3.66×10^{-3}) in $PM_{2.5}$ in Shanxi Province, China (Cao et al., 2014) was higher than the guideline value set by USEPA. A study by Niu et al. (2015) of $PM_{2.5}$-bound metals showed a high cancer risk in Yangtze River Delta, China (2.47×10^{-4}). A study by Pandey et al. (2013) conducted in the vicinity of human activities observed that the concentrations of Cd, Cr, Ni and Pb in $PM_{2.5}$ showed higher excess cancer risk (ECR) due to those particle-bound metals compared to guideline level set by USEPA. Satsangi et al. (2014) also reported a higher cancer risk from Cr, Ni and Cd in $PM_{2.5}$ compared to the USEPA guideline. The integrated carcinogenic risk of six metals (Cr, As, Co, Pb, Ni and Cd) in $PM_{2.5}$ in Tianjin, China were in the range 3.4×10^{-3} – 4.1×10^{-3} which is reportedly beyond the tolerance level (Zhang et al., 2014). The total ECRs based on the average values of As, Cd, Cr, Ni and Pb in $PM_{2.5}$ is 4.34×10^{-5} in Delhi, India, implying that four or five people might get cancer out of 100,000 people after exposure to toxic metals in $PM_{2.5}$ (Khanna et al., 2015). Our findings showed that the life-time cancer risk posed by the exposure of heavy metals in $PM_{2.5}$ mass concentration is three to four per 1,000,000 people at this location. This significant cancer risk warrants further investigation. Our findings showed that an insignificant non-carcinogenic risk and significant cancer risk is posed to the population from exposure to $PM_{2.5}$ at this location. Detailed exposure assessment of the $PM_{2.5}$ at the specific sources and the health risks posed by individual hazardous elements of concern may help to improve understanding about the exposure pathways as well as the detailed risk factors involved in both carcinogenic and non-carcinogenic risk."

8. Overall: Abstract is not well written. Conclusion is okay. Authors spent more times on methodology not on the results and discussions.

Author's responses

We appreciate reviewer's observation. We have already modified our abstract. We have revised the Health risk part in the "Results and Discussion". Based on the comments from reviewer#2, we also have enriched our "Results and Discussion" in the revised manuscript file highlighted in turquoise color. The revised version of the abstract is shown below (page 22217, lines 2-20):

"The health implications of $PM_{2.5}$ in the tropical region of Southeast Asia (SEA) are significant as $PM_{2.5}$ can pose serious health concerns. $PM_{2.5}$ concentration and sources here are strongly influenced by changes in the monsoon regime from the southwest quadrant to the northeast quadrant in the region. In this work, $PM_{2.5}$ samples were collected at a semi-urban area using a high volume air sampler at different seasons on 24 h basis. Analysis of trace elements and water-soluble ions was performed using inductively coupled plasma mass spectroscopy (ICP-MS) and ion chromatography (IC), respectively. Apportionment analysis of $PM_{2.5}$ was carried out using the United States Environmental Protection Agency (US EPA) positive matrix factorization (PMF) 5.0 and a mass closure model. We quantitatively characterized the health risks posed to human populations through the inhalation of selected heavy metals in $PM_{2.5}$. 48% of the samples collected exceeded the World Health Organization (WHO) 24 h $PM_{2.5}$ guideline but only 19% of the samples exceeded 24 h US

EPA National Ambient Air Quality Standard (NAAQS). The $PM_{2.5}$ concentration was slightly higher during the north-east monsoon compared to south-west monsoon. The main trace metals identified were As, Pb, Cd, Ni, Mn, V and Cr while the main ionsn were SO_4^{2-}, NO_3^-, NH_4^+ and Na. The mass closure model identified four major sources of $PM_{2.5}$ that accounts for 55% of total mass balance. The four sources are mineral matter (MIN) (35%), secondary inorganic aerosol (SIA) (11%), sea salt (SS) (7%), and trace elements (TE) (2%). PMF 5.0 elucidated five potential sources: motor vehicle emissions coupled with biomass burning (31%) were the most dominant, followed by marine/sulfate aerosol (20%), coal burning (19%), nitrate aerosol (17%), and mineral/road dust (13%). The hazard quotient (HQ) for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in $PM_{2.5}$ mass from the coal burning source and least in $PM_{2.5}$ mass originating from the mineral/road dust source. The main carcinogenic heavy metal of concern to health at the current location was As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk in $PM_{2.5}$ mass concentration. Overall, the associated lifetime cancer risk posed by the exposure of hazardous metals in $PM_{2.5}$ is three to four in 1,000,000 people at this location."

Abstract

The health implications of $PM_{2.5}$ in the tropical region of Southeast Asia (SEA) are significant as $PM_{2.5}$ can pose serious health concerns. $PM_{2.5}$ concentration and sources here are strongly influenced by changes in the monsoon regime from the southwest quadrant to the northeast quadrant in the region. In this work, $PM_{2.5}$ samples were collected at a semi-urban area using a high volume air sampler at different seasons on 24 h basis. Analysis of trace elements and water-soluble ions was performed using inductively coupled plasma mass spectroscopy (ICP-MS) and ion chromatography (IC), respectively. Apportionment analysis of $PM_{2.5}$ was carried out using the United States Environmental Protection Agency (US EPA) positive matrix factorization (PMF) 5.0 and a mass closure model. We quantitatively characterized the health risks posed to human populations through the inhalation of selected heavy metals in $PM_{2.5}$. 48% of the samples collected exceeded the World Health Organization (WHO) 24 h $PM_{2.5}$ guideline but only 19% of the samples exceeded 24 h US EPA National Ambient Air Quality Standard (NAAQS). The $PM_{2.5}$ concentration was slightly higher during the north-east monsoon compared to south-west monsoon. The main trace metals identified were As, Pb, Cd, Ni, Mn, V and Cr while the main ionsn were SO_4^{2-}, NO_3^-, NH_4^+ and Na. The mass closure model identified four major sources of $PM_{2.5}$ that accounts for 55% of total mass balance. The four sources are mineral matter (MIN) (35%), secondary inorganic aerosol (SIA) (11%), sea salt (SS) (7%), and trace elements (TE) (2%). PMF 5.0 elucidated five potential sources: motor vehicle emissions coupled with biomass burning (31%) were the most dominant, followed by marine/sulfate aerosol (20%), coal burning (19%), nitrate aerosol (17%), and mineral/road dust (13%). The hazard quotient (HQ) for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in $PM_{2.5}$ mass from the coal burning source and least in $PM_{2.5}$ mass originating from the mineral/road dust source. The main carcinogenic heavy metal of concern to health at the current location was As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk in $PM_{2.5}$ mass concentration. Overall, the associated lifetime cancer risk posed by the exposure of hazardous metals in $PM_{2.5}$ is three to four per 1,000,000 people at this location.

1 Introduction

Atmospheric fine particles ($PM_{2.5}$, dP ≤ 2.5 µm), a mixture of many inorganic and organic components, reside for a long time in the atmosphere and can penetrate deep into the lung. Prolonged exposure to $PM_{2.5}$ can cause adverse health impacts and premature mortality in humans (Betha et al., 2014). Potential health benefits and an improvement in general mortality could be expected if the control policies were implemented (Boldo et al., 2011). The adverse effects of $PM_{2.5}$ can reach intercontinental scales (Anenberg et al., 2014) due to the potential transport of $PM_{2.5}$ over hundreds to thousands of kilometers (Seinfeld and Pandis, 2012). The sources of $PM_{2.5}$, particularly motor vehicle emissions, are associated with an increase in hospital admissions (Kioumourtzoglou et al., 2014). A study by Bell et al. (2014) suggested that controlling some of the sources of $PM_{2.5}$ could protect public health more efficiently than the regulation of particle concentration. Thus, the possible reduction in health risks from the predominant sources of $PM_{2.5}$ is desired as part of the mitigation strategy. Diesel emissions and biomass burning, as the primary risk sources of $PM_{2.5}$, should be closely monitored and regulated (Wu et al., 2009).

The identification of $PM_{2.5}$ sources is becoming a widely-recognized way to protect human health as well as the environment. Multivariate receptor models are very useful in the source apportionment of $PM_{2.5}$. Widely used multivariate methods are: a) a chemical mass balance model (CMB) (Watson et al., 1990), b) positive matrix factorization (PMF) (Paatero, 1997; Paatero and Tapper, 1994), c) Unmix (Henry, 1987), d) principal component analysis coupled with absolute principal component score (PCA/APCS) (Thurston and Spengler, 1985), e) pragmatic mass closure (PMC) (Harrison et al., 2003) and f) a new source-type identification method for $PM_{2.5}$ known as Reduction and Species Clustering Using Episodes (ReSCUE) (Vedantham et al., 2014). PMF is the most reliable method for source-type identification for the following reasons: i) it uses a weighted least-squares fit and estimates error of the measured data and can impose non-negativity constraints weighing each data point individually (Paatero, 1997; Paatero and Tapper, 1994), ii) *a priori* knowledge of pollutants is not necessary and iii) it is able to deal with missing values, noisy data, outliers, and values below detection limit (Baumann et al., 2008; Khan et al., 2012; Khan et al., 2015b; Polissar et al., 1998a; Polissar et al., 1998b). A recent study by Gibson et al. (2014) suggested that PMF can resolve $PM_{2.5}$ concentrations even below 2 µg m^{-3} more accurately compared to PMC and CMB.

Source apportionment studies of $PM_{2.5}$ based on monsoonal seasonal changes in Malaysia are of widespread interest due to the influence of local sources as well as trans-boundary haze pollution. This haze pollution reaches its worst level during the south-west (SW) and north-east (NE) monsoons each year. Therefore, the main objectives of this work are to investigate a) the monsoonal effect on the variability of $PM_{2.5}$ and its chemical composition, b) factors influencing the sources of $PM_{2.5}$ and c) to quantitatively characterize the non-carcinogenic and carcinogenic risks to the potentially-exposed human populations by selected heavy metals in $PM_{2.5}$ released from the particular sources. The $PM_{2.5}$ mass concentration contributed by each source will be calculated using PMF 5.0.

2 Methodologies

2.1 Description of the study area

Figure 1 shows the sampling location which is on the roof top of the Biology Building of the Faculty of Science and Technology (FST), University Kebangsaan Malaysia (UKM), Malaysia (2° 55' 31.91" N, 101° 46' 55.59" E, about 65 m above sea level). This site is less than 1 km from the main Bangi road.

2.2 Sampling and analysis of $PM_{2.5}$ samples

Sampling was carried out on a 24 h basis for a period from July to September 2013 and January to February 2014 for a total of 27 samples. The $PM_{2.5}$ samples were collected on quartz microfiber filters (203 mm×254 mm, Whatman^{TM}, UK) through a $PM_{2.5}$ high volume sampler (HVS, Tisch, USA) at a flow rate of 1.13 m^3 min^{-1}. Several others researchers also conducted sampling using the quartz microfiber filters for the analysis of trace metals (Li et al., 2015a; Martins et al., 2016; Kholdebarin et al., 2015; Cusack et al., 2015; Sánchez-Soberón et al., 2015). Prior to use, the filters were preheated at 500 °C for 3 h to remove any deposited organic compounds. All filter papers either blank or exposed were conditioned in a desiccator for 24 h before and after sampling prior to weighing using a 5-digit high-resolution electronic balance (A&D, GR-202, Japan) with a 0.01 mg detection limit. The filter samples were then stored at -18 °C until the extraction procedure. A microwave-assisted digestion system (Start D, Milestone, Germany) was employed for the preparation of the trace element samples. The microwave was operated at two temperature stages, 180 °C for 20 min and ramping to 220 °C for 15 min. The power was set at 500 watts during the procedure when the number of samples ≤ three. However, the power was set at 1000 watts if the number of samples exceeded three. A 4:1 ratio of 12 mL nitric acid (65%, Mark KGaA, Germany) and 3 mL hydrogen peroxide (40%, Mark KGaA, Germany) was used as the reagent in this digestion process. A portion of the filter was soaked in the tetrafluoromethaxil (TFM) vessels (SK-10, Milestone, Germany) of the microwave where total mass of the sample and reagent was maintained below 0.25 g for quality assurance purposes. Upon completion, the samples were filtered using a syringe filter (Acrodisc®, 0.2 µm, Pall Gelman Laboratory, MI, USA) with a 50 cc/mL Terumo syringe (Terumo®, Tokyo, Japan) before dilution to 25 mL using ultrapure water (UPW, 18.2 MΩ cm, Easypure® II, Thermo Scientific, Canada). For the preparation of samples for water-soluble ion analysis, a portion of the filter samples was cut into small pieces and placed directly into 50 mL centrifuge tubes with UPW. For this extraction, a combination of ultrasonic vibration, centrifuge and mechanical shaking were applied. The samples were first sonicated in an ultrasonic bath (Elmasonic S70H, Elma, Germany) for 20 min. Then, the extraction solutions were centrifuged at 2500 rpm (Kubota 5100, Japan) for 10 min before shaken using a vortex mixer for 10 min. The sonication and centrifuged steps were repeated for two more times before the extract was filtered through glass microfiber filters (Whatman™, UK). Both the trace elements and water-soluble ion extracts were refrigerated at 4 °C until further analysis. The trace elements (Al, Ba, Ca, Fe, Mg, Pb, Zn, Ag, As, Cd, Cr, Li, Be, Bi, Co, Cu, Mn, Ni, Rb, Se, Sr and V) were determined by Inductively Coupled Plasma Mass Spectroscopy (ICP-MS, PerkinElmer ELAN 9000, USA) while the water-soluble ionic composition (Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^- and SO_4^{2-}) was determined using Ion Chromatography (Metrohm 850 model 881 Compact IC Pro, Switzerland). Metrosep A-Supp 5-150/4.0 and C4-100/4.0 columns were used in the determination of cations and anions, respectively. 1.7 mmol L^{-1} nitric and 0.7 mmol L^{-1} dipicolinic acid (Merck KGaA, Germany) were prepared to be used as eluents for cations. Eluents of 6.4 mmol L^{-1} sodium carbonate (Na_2CO_3) (Merck KGaA, Germany) and 2.0 mmol L^{-1} sodium bicarbonate ($NaHCO_3$) (Merck KGaA, Germany) were prepared and used to measure anions (Cl^-, NO_3^- and SO_4^{2-}) with a flow rate of 0.7 mL min^{-1}. 100 mmol L^{-1} Suprapur® sulfuric acid (H_2SO_4) (Merck KGaA, Germany) was also prepared to use as a suppressor regenerant and ions were detected by a conductivity detector.

2.3 Quality assurance and quality control (QA/QC)

As part of QA/QC, the concentrations of the composition of $PM_{2.5}$ were corrected from the reagent and filter blanks samples, which were treated with a similar procedure to the exposed filters. To determine the recovery (%) of the heavy metals, a standard reference material (SRM), Urban Particulate Matter SRM 1648a obtained from the National Institute of Standards and Technology (NIST), USA, was treated using the procedures outlined above. The method detection limit (MDL) for trace elements is calculated as three times the standard deviation of ten replicates of the reagent blank. Three samples of filter blanks were used to calculate the MDL of water-soluble ions. Overall MDL were as reported in Table 1. During the trace element analysis by ICP-MS, two modes of analysis were applied with updated calibration curves each time. Based on trial runs and SRM1648a, the elements were initially screened for concentration levels which resulted in two modes analysis: (a) a set of metals (Al, Ca, Fe, Mg, Zn and Mn) with high concentrations (with several dilution factors); and (b) a set of metals (Ba, Pb, Ag, As, Cd, Cr, Li, Be, Bi, Co, Cu, Ni, Rb, Se, Sr and V) with low concentrations.

2.4 Local circulation of wind and biomass fire hotspots

Each year, Peninsular Malaysia experiences two monsoon regimes, the south-west (SW) monsoon (June-September) and the north-east (NE) monsoon (December-March). During the SW monsoon, south-west winds dominate the wind pattern in Peninsular Malaysia, inducing drier weather. During the NE monsoon, strong north-east winds dominate over the Peninsular Malaysia, bringing more rainfall to the east coast. To investigate this, the regional synoptic wind field 10 m above the surface and resolution of 0.25 × 0.25° ranging from latitude: -10°, 25° N, longitude: 85°, 125° E was plotted using Open Grid Analysis and Display System (GrADS version 2.0.2). The wind field used to demonstrate the monsoon regimes in this study is a gridded product produced by the global atmospheric reanalysis known as ERA-Interim, by the European Centre for Medium-Range Weather Forecasts (ECMWF) (Dee et al., 2011).

The ERA-Interim 10 m surface wind vectors (January 2004 to June 2014) show the two opposite monsoon regimes experienced by Peninsular Malaysia (Fig. 2). It can be seen that the south-west wind, from June to August, blew from Sumatra Island, Indonesia to Peninsular Malaysia was generally weaker with wind speed around 1-2 m s^{-1}. Whereas the north-east wind, from November to January, was much stronger, with wind speeds of around 5-7 m s^{-1} (Fig. 2).

Biomass fire hotspots and the travel path of the monthly back trajectories of each season were also plotted (Fig. 3). The mean clusters of back trajectories were produced using the Hybrid Single-Particle Lagrangian Integrated Trajectory Model (HYSPLIT 4.9), and were re-plotted using the graphical software, IGOR Pro 6.0.1 (WaveMetrics, OR, USA). A release height of about 500 m for 120 h back trajectories with 6 h intervals was chosen. Trajectory start time was chosen at 16:00 (UTC) to represent 24:00 (local time). The cluster mean of trajectories was regarded by numeral number and colour (1-red, 2-green, 3-turquoise, and 4-purple). The fire hotspot data of the Moderate Resolution Imaging Spectroradiometer (MODIS) was used to investigate the biomass burning hotspots in the specific area of interest. The data was downloaded from the National Aeronautics and Space Administration (NASA)-Land Atmosphere near Real-Time Capability for Earth Observing System (EOS)-Fire Information for Resource Management System (NASA LANCE FIRMS) fire archive covering an area from 15°S to 30°N and 80°W to 130°E. In addition, to investigate the variability of the boundary layer height around the region of Peninsular Malaysia, ERA-Interim boundary layer height (BLH) gridded data from January 2000 to December 2014 was downloaded from the European Centre for Medium-Range Weather Forecasts (ECMWF). The resolution of this data was 0.5° × 0.5°, covering the domain of the Peninsular Malaysia (lat: 99 – 105°; lon: 0 – 9°). Yearly daily means of the ERA-Interim BLH data were calculated using the Climate Data Operators (CDO) version 1.6.9 software (https://code.zmaw.de/projects/cdo) developed by the Max-Plank-Institute, by first calculating the area mean.

2.5 Enrichment Factor (EF)

The EF of the heavy metals was calculated based on the abundance of elements in the Earth's crust published by Taylor (1964). The EF of each element can be defined using the following equation:

$$EF = \frac{\left(\frac{E}{Al}\right)_{PM\,2.5}}{\left(\frac{E}{Al}\right)_{Crust}} \qquad (1)$$

where E/Al is the concentration ratio of element, E, to the reference metal, Al. Al was selected as the reference element to calculate the annual and seasonal EF. Several other researchers also used Al as the reference element (Birmili et al., 2006; Khan et al., 2010a; Sun et al., 2006). Chester et al. (2000); Cheung et al. (2012); Khan et al. (2010a); Mohd Tahir et al. (2013); Torfs and Van Grieken (1997) proposed a EF cut-off of ten to differentiate between crustal and natural and anthropogenic origins of heavy metals. Thus, we consider

EF = 10 as the cut-off point. Therefore, a good number of the metals (Zn, Cr, Rb, Be, V, Fe, Ca, Co, Sr, Pb, As and Bi) in $PM_{2.5}$ in this study can be assumed to originate from anthropogenic sources; Fig. 5a. These heavy metals were not natural or from the Earth's crust. No seasonal differences were observed in the EF of the heavy metals.

2.6 Mass closure model

A study by Harrison et al. (2003) introduced a PMC model for the source apportionment of particulate matter, which is the basis for this study. The variables were grouped into the following four sub-classes: i) mineral matter (MIN), ii) sea salts (SS), iii) secondary inorganic aerosol (SIA), iv) trace elements (TE) and v) undefined (UD). MIN is derived from the sum of Al, Mg, K, Ca, and Fe multiplied by the appropriate factors to convert them into their corresponding oxides as described by the following Eq. (2). Ca was multiplied by a factor of 1.95 to account for CaO and $CaCO_3$ as this metal is assumed to be present in these two forms (Remoundaki et al., 2013; Sillanpää et al., 2006; Terzi et al., 2010)

$$MIN = 1.89Al + 1.66Mg + 1.21K + 1.95Ca + 1.43Fe \qquad (2)$$

The contribution of SS was estimated by assuming that soluble Na^+ in $PM_{2.5}$ samples originated solely from the marine source and is based on the composition of seawater, ignoring potential atmospheric transformation (Seinfeld and Pandis, 2012). Following Terzi et al. (2010), the composition of sea salt comprised of the following Eq. (3)

$$SS = [Na^+] + [ss\text{-}Cl^-] + [ss\text{-}Mg^{2+}] + [ss\text{-}K^+] + [ss\text{-}Ca^{2+}] + [ss\text{-}SO_4^{2-}] \quad (3)$$

where, ss-Cl^- = 1.8*Na^+, ss-Mg^{2+} = 0.12*Na^+, ss-K^+ = 0.036*Na^+, ss-Ca^{2+} = 0.038*Na^+ and ss-SO_4^{2-} = 0.252*Na^+. Meanwhile, SIA can be estimated by the sum of non-sea salt-sulfate (nss-SO_4^{2-}), NO_3^- and NH_4^+ as explained by Remoundaki et al. (2013); Terzi et al. (2010) with the following Eq. (4)

$$SIA = [nss\text{-}SO_4^{2-}] + [NO_3^-] + [NH_4^+] \qquad (4)$$

Finally, TE is calculated by the sum of rest of the metals analysed in this study and UD represents unidentified gravimetric mass of $PM_{2.5}$. Therefore, the overall mass closure equation applied in this work can be expressed as the following Eq (5)

$$PM_{2.5}\,MC = MIN(1.89Al + 1.66Mg + 1.21K + 1.95Ca + 1.43Fe) +$$
$$SS(\,[Na^{+}] + [ss\text{-}Cl^{-}] + [ss\text{-}Mg^{2+}] + [ss\text{-}K^{+}] + [ss\text{-}Ca^{2+}] + [ss\text{-}SO_4^{2-}]) +$$
$$SIA([nss\text{-}SO_4^{2-}] + [NO_3^{-}] + [NH_4^{+}]) + TE + UD \quad (5)$$

2.7 Source Apportionment of $PM_{2.5}$ using PMF

Source apportionment of $PM_{2.5}$ was conducted using the US EPA PMF 5.0 model of the United States Environmental Protection Agency (US EPA) as suggested by Norris et al. (2014). The PMF model is a mathematical factor-based receptor model that interprets source types with a robust uncertainty estimate. Two sets of data were run through the PMF model: i) concentration and ii) uncertainty. The concentration of each element was pretreated and validated based on the outliers, missing values and/or values below MDL. In particular, variables with outliers were excluded. Species with concentrations below MDL were replaced with the half of the MDL (Baumann et al., 2008; Polissar et al., 1998a; Polissar et al., 1998b). The uncertainty value of each variable of each sample was calculated following the empirical formula Eq. (6):

$$\sigma_{ij} = 0.01(X_{ij} + \overline{X}_j) \quad (6)$$

Where $\boldsymbol{\sigma_{ij}}$ is the estimated measurement error for j^{th} species in the i^{th} sample, $\boldsymbol{X_{ij}}$ is the observed elements concentration and $\boldsymbol{\overline{X_j}}$ is the mean value. The factor 0.01 was determined through trial and error procedures following by Ogulei et al. (2006a). Thus, the measurement of uncertainty ($\boldsymbol{S_{ij}}$) can be computed with Eq. (7) as applied by Chueinta et al. (2000):

$$S_{ij} = \sigma_{ij} + \mathrm{C}X_{ij} \quad (7)$$

Where $\boldsymbol{\sigma_{ij}}$ the estimation of measurement error (Eq. 6) and C is a constant. In this study, we used a value of 0.4 for C which, according to Ogulei et al. (2006b), produced the best Q value as it is the closest to theoretical value and physically interpretable results. Other main researchers have also applied this procedure for the calculation of uncertainty (Harrison et al., 2011; Hedberg et al., 2005; Khan et al., 2015b). An additional 5% uncertainty was added to cover any methodological errors during the preparation of filter papers, gravimetric mass measurements and preparing the calibration curves.

Initially, PMF factors were resolved using the numbers of 20 runs with a seed value of 9. The number of factors was changed to optimize the goodness-of-fit parameter of Q over the theoretical Q. Five factors were decided upon based on the lowest Q (Robust) and Q (True) value of 180.26 with the Q (true)/Q_{exp} value of 0.50 after 604 computational steps and the convergence of the PMF results. The Q/Q_{exp} ratio for most of the variables was < 5 to 0.92 which indicates that the Q values were very similar to the expected value. Some of the variables, however, showed a ratio of 0.5 because the computed Q value were smaller than the expected Q value. A study by Brown et al. (2012) described this discrepancy as contributing to the increase of global uncertainty. However, the sharp drop for $PM_{2.5}$ mass ratio (0.03) was due to the down-weighting of the signal to noise (S/N) values. To show the stability of the results, we estimated the error of the concentration for each variable using bootstrap, displacement (DISP) and a combination of BS-DISP. A comparison of the error estimates with base model runs are demonstrated in the supplementary Fig. S1. The five-factor results were relatively stable with meaningful physical interpretation and satisfactorily comparable with the bootstrap analysis. Fe and Cr were reported as outliers and therefore excluded in the calculation. Referring to Table 2, the overall $PM_{2.5}$ concentration is well explained within ±10% by the PMF 5.0 considering the Fpeak = 0.

2.8 Health risk assessment (HRA) of $PM_{2.5}$ and associated various sources

The human health risk posed by heavy metals may occur through inhalation of $PM_{2.5}$. We applied the US EPA supplemented guidance to estimate the risk posed by heavy metals in $PM_{2.5}$ mass concentration and their various sources. As part of the HRA, we considered lifetime non-carcinogenic and carcinogenic risk. USEPA (2011) describes the exposure concentration (EC) by the following equation:

$$EC_{inh} = C \times \frac{ET \times EF \times ED}{ATn} \qquad (8)$$

Where *C* is the concentration of metals in $PM_{2.5}$ estimated for each source with µg m^{-3} unit for the estimation of EC_{inh}; EF is the exposure frequency (151 days $year^{-1}$) representing July, August, September, January and February; ED is exposure duration (24 years for adult); BW is the average body weight (70 kg for adult); ET is the exposure time (h/day); ATn is the average time (ATn = ED × 365 days × 24 h/day for non-carcinogenic and ATn = 70 year × 365 days/year × 24 h/day for carcinogenic risk). ED, BW and AT values are based on the study by Hu et al. (2012).

Further, we examined the non-carcinogenic risk (presented by the hazard quotient (HQ)) and lifetime carcinogenic risk (LCR) of selected heavy metals as classified by the International

Agency for Research on Cancer (IARC). The following equations were involved for the calculation of HQ and LCR:

$$HQ = \frac{EC}{(RfCi \times 1000\ \mu g\ m^{-3})} \qquad (9)$$

$$LCR = IUR \times EC \qquad (10)$$

Where, RfC_i is the inhalation reference concentration (mg m^{-3}); IUR is the inhalation unit risk ((μg $m^{-3})^{-1}$). The non-carcinogenic risk or HQ represents the observable health effects from exposure to the $PM_{2.5}$ based on the dose-response relationship principles. The cut-off point for significant health risks to the exposed population is HQ > 1. The carcinogenic risk refers to a person's chance of developing cancer from exposure to any carcinogenic agent. LCR represents the **e**xcess lifetime cancer risk is described in terms of the probability that an exposed individual will develop cancer because of that exposure by age 70 as defined by US EPA Risk Communication (http://www.epa.gov/superfund/community/pdfs/toolkit/risk_communicati-onattachment6.pdf). The carcinogenic risk from the lifetime exposure of those hazardous metals is regulated by the acceptable or tolerance level (1×10^{-6}) set by the US EPA which corresponds to lifetime exposure to an unpolluted environment (Satsangi et al., 2014).

3 Results and Discussions

3.1 Concentration of $PM_{2.5}$ and its chemical composition

Table 1 summarizes the statistics from the SW monsoon, the NE monsoon and overall concentrations of $PM_{2.5}$, heavy metals and major ions. Overall, the 24 h average values of $PM_{2.5}$ (avg = 25.13 µg m^{-3}) in the study area are slightly higher than that of the WHO 24 h guideline (25 µg m^{-3}) but lower than that of 24 h US EPA National Ambient Air Quality Standard (NAAQS) (35 µg m^{-3}). Of the samples taken during the day, 48% exceeded the WHO 24 h guideline while 19% of them exceeded the US EPA 24 h NAAQS for $PM_{2.5}$ (Currently Malaysia has no set guidelines for $PM_{2.5}$). If we compare the $PM_{2.5}$ overall value of 25.13 µg m^{-3} with yearly mean of US EPA NAAQS (15 µg m^{-3}), WHO (10 µg m^{-3}), European Union (EU) (25 µg m^{-3}), DoE (Australia) (8 µg m^{-3}), the concentration of $PM_{2.5}$ is much higher with respect the guideline set by all regulatory bodies. The average value of $PM_{2.5}$ during the NE monsoon was slightly higher than the SW monsoon. During the southwest monsoon season, $PM_{2.5}$ was mainly carried by the prevailing southwest wind from the Sumatra Island of Indonesia which is located at the Southwest quadrant of the SEA region. On the other hand, during the northeast monsoon season, the $PM_{2.5}$ sources can be traced back to the Chinese mainland, Indochina region and the Philippines. This is due to the prevailing northeast wind transporting $PM_{2.5}$ from these locations to the tropical region of SEA. The *Student T-test* for paired independent samples showed that the mean during these two monsoons varies insignificantly ($t = 1.19, p > 0.05$). However, the monsoonal changes in this region as displayed in Fig. 3, showed that air masses of different origins transport different pollutants to the area. The back trajectory plots showed that there were high numbers of biomass fire hotspots during both seasons but from different regions (Fig. 3). The period of June to September is the dry season each year in Malaysia and Sumatra of Indonesia. During this dry season, biomass fire hotspots are densely located in this area due to the burning of agricultural waste and forest fires. Several other researchers also reported the high number of biomass fire - related hotspots to these regions (Khan et al., 2015c; Sahani et al., 2014). On the other hand, December to March is usually the wet season in Malaysia. However, the backward trajectories showed that air masses were transported from Mainland China and neighbouring regions. In Mainland China and neighbouring regions, this is dry season. During the dry season in this region there are a lot of fires, as reported by Zhang et al. (2015) and Ho et al. (2014), and this influences the pollution of air masses transported to the present location. This scenario of biomass fire hotspots is commonly noticed in these two seasons. In past years Malaysia and Singapore have experienced intensified haze episodes in this particular season, e.g. 1997, 2005, 2013 and 2015. A study of this area by Kanniah et al. (2014) observed that during the dry season (June to September) aerosols mainly originated from the west and south-west (i.e. Sumatra, Indonesia), while during the wet season (November to March), aerosols were mostly associated with the NE monsoon winds coming from the South China Sea. Also, the variability of BLH and WS were able to influence the concentration of the pollutants at a particular location. Fig. 4 shows the day to day variation of BLH and WS with respect to the 24 h average of $PM_{2.5}$ concentration. From the plot, it is revealed that the daily average $PM_{2.5}$ concentration is inversely proportional to the BLH. Therefore, while factors such as traffic volume, industrial emissions, power plants, land use and population size can alter the concentration of $PM_{2.5}$, meteorological factors which govern the day to day variation of BLH in Peninsular Malaysia might play a crucial role too. These meteorological factors can include strong local convection, which is a very common meteorological feature in this region, and also the movement of air via a land-sea breeze due to the sea surrounding Peninsular Malaysia. A study by Lelieveld et al. (2001) reported that strong convection can ventilate the daily BLH. The small expansion of BLH that was observed during NE monsoon was most likely due to the higher magnitude of WS to Peninsular Malaysia during this season, as demonstrated in Fig. 2.

In comparison, our results of $PM_{2.5}$ here on the west coast of Peninsular Malaysia (avg = 25.13 µg m^{-3}) are higher compared to the east coast of Peninsular Malaysia at 14.3 µg m^{-3} (Mohd Tahir et al., 2013). This $PM_{2.5}$ concentration in this study area was similar to the annual concentration of $PM_{2.5}$ measured in Petaling Jaya, Kuala Lumpur (26.85 µg m^{-3}) by Rahman et al. (2011), Petaling Jaya (33 µg m^{-3}) and Gombak (28 µg m^{-3}) by Keywood et al. (2003) and Singapore (27.2 µg m^{-3}) as reported by Balasubramanian et al. (2003). The yearly mean value of $PM_{2.5}$ in the Bandung urban area and suburban location in Lembang of Indonesia are 14.03 and 11.88 µg m^{-3}, respectively (Santoso et al., 2008), which are much lower concentration compared to the this study. However, Lestari and Mauliadi (2009) reported that the $PM_{2.5}$ concentration of 43.5 µg m^{-3} in the Bandung city, Indonesia, was about 1.7 times larger than that of the current location and by Budhavant et al. (2015) showed 19 µg m^{-3} in Male, Maldives (urban) which is lower as well compared to this study. A comparative study conducted in Bangkok (34 µg m^{-3}), Beijing (136 µg m^{-3}), Chennai (44 µg m^{-3}), Bandung (45.5 µg m^{-3}), Manila (43.5 µg m^{-3}) and Hanoi (78.5 µg m^{-3}) showed consistently higher $PM_{2.5}$ pollution in the Southeast and South Asian cities as compared to this study (Kim Oanh et al., 2006). From Table 1, it can be seen that the highest concentration of anions species was found for SO_4^{2-} followed by NO_3^-. A study by Zhang et al. (2012) suggested that the photochemical conversion of SO_2 to H_2SO_4 is the main reason for the changes of sulfate concentration in $PM_{2.5}$ and that higher temperatures reduce the nitrate concentration by the partitioning of nitrate into the gas phase. However, lower temperatures and a stable atmosphere favours the formation of NO_3^- aerosol reacting with NH_4^+, i.e. shifting the gas phase nitrate into the particle phase (Mariani and de Mello, 2007). The formation of NH_4NO_3 normally occurs at high humidity with lower temperatures (Morales and Leiva, 2006). The average molar ratios of SO_4^{2-} to NO_3^- were 6.0 with a range of 0.16 – 38.24 which suggests that the sulfate aerosol is more dominant over the nitrate aerosol and may have been transported from trans-boundary sources. A similar observation was found in a study in the UK by Abdalmogith and Harrison (2006). This ion balance ratio indicates the possible sources of aerosol, and stationary sources dominate over the mobile sources as explained by Arimoto et al. (1996). The average ratio of SO_4^{2-} to NH_4^+ was 1.28 which is much higher than the ratio of NO_3^- to NH_4^+ (0.63), confirming that the sulfate aerosol is more stable in tropical conditions as compared to the nitrate aerosol. A study by Maenhaut et al. (2008) described a similar observation. The formation of ammonium sulfate is favoured in the fine fraction (Khan et al., 2010b). For the cations, the highest concentration was NH_4^+ followed by Na^+. However, the average molar ratio of Cl^- to Na^+ did not reflect the seawater ratio. “Cl loss” may be the cause of the drop in Cl^- to Na^+ ratio. Boreddy et al. (2014) also noticed a chlorine depletion due to atmospheric processing in the western north Pacific. According to Finlayson-Pitts and Pitts Jr. (2000), sulfuric and nitric acids have a tendency to react rapidly with NaCl, the major component of sea salt particles, to produce gaseous HCl under 50–100% relative humidity conditions. For heavy metals, the predominant metal reported was Fe with concentrations in the range 2171 - 4567 ng m^{-3}. Ca showed the second-highest concentrations with the concentration range of below MDL - 3149 ng m^{-3}. A study by Yin and Harrison (2008) suggested that Fe originates from non-traffic sources and that iron and calcium are released into ambient air through the resuspension of surface dust. Among other heavy metals of particular health concern, the average concentrations of As, Pb, Cd, Ni, Mn, V and Cr were 5.76, 21.84, 0.54, 4.03, 17.24, 5.13 and 107.68 ng m^{-3}, respectively. The As concentration was nearly equal to the WHO and US EPA guideline values of 6.6 and 6 ng m^{-3}, respectively. Therefore, As may be of significant health concern. The concentrations of other hazardous metals were well below the WHO and European commission guidelines. The EF reveals that all metals of $PM_{2.5}$ can be assumed to originate from anthropogenic sources with no seasonal differences observed (Fig. 5a).

3.2 Mass closure model

The $PM_{2.5}$ was reconstructed by the use of a PMC model (Harrison et al., 2003). Employing the mass closure model outlined in the previous section, the four major classes of chemical components contributing to $PM_{2.5}$ were: i) MIN, ii) SIA, iii) SS, iv) TE and UD. As shown in Fig. 5c, the overall reconstructed masses of MIN, SIA, SS, TE and UD were 8970, 2841, 1727, 626.2 and 11511 ng m^{-3}, respectively. MIN is released from soil or crustal sources and represents the oxide form of the metals (Remoundaki et al., 2013; Sillanpää et al., 2006; Terzi et al., 2010). The MIN component comprises 35% of the $PM_{2.5}$ concentration. SIA, which accounts for 11%, is comprised of the most abundant secondary ions (nss-SO_4^{2-}, NO_3^- and NH_4^+). These are formed in the atmosphere from the precursor gases (SO_2, NH_3 and NO_x)

through a gas-to-particle conversion (Sillanpää et al., 2006) and therefore are assumed to be in the form of $(NH_4)_2SO_4$ and NH_4NO_3 in the aerosol phase (Joseph et al., 2012). It is important to mention that the behaviour of the formation pattern of the SIA in this South East Asia region may differ from other regions due to the nearly constant temperature throughout the year. SS and TE accounted for 7% and 2% of the $PM_{2.5}$. The UD, undefined fraction, accounted for 45% of $PM_{2.5}$.

The average value of reconstructed $PM_{2.5}$ by mass closure (MC) is 14.12±4.32 μg m^{-3} with a minimum of 6.70 μg m^{-3} and a maximum of 24.19 μg m^{-3}. On the other hand, the measured $PM_{2.5}$ determined gravimetrically by HVS was 25.13±9.21 μg m^{-3} with a range of 7.01 to 42.78 μg m^{-3}. A correlation plot of $PM_{2.5}$ (MC) and measured $PM_{2.5}$ (HVS) is shown in Fig. 5e. The correlation shows a good fit ($r^2 = 0.98$) with a slope of 0.46 and an intercept of 1.93. The results of the fit parameters suggest that the $PM_{2.5}$ mass (MC) concentration was underestimated compared to $PM_{2.5}$ (HVS). The reported result of the mass closure model is based on the analyzed chemical components of filter samples (~ 55%). As described in the mass closure, a large portion of $PM_{2.5}$ mass (~ 45%) was left unidentified; this unidentified component is believed to be the organics or carbonaceous species. Elemental carbon (EC), organic carbon (OC) and water-soluble organics were not measured due to the lack of instrumentation. Other possible reasons for the un-identified portion are: i) unaccounted for mineral oxides as they are abundant in $PM_{2.5}$, and ii) water associated with salts.

During the SW monsoon, the UD showed the higher concentrations; this can be explained by the annual biomass haze episodes experienced in this area. Thus, a large proportion of the UD of $PM_{2.5}$ is probably formed from the organic fraction. Such findings are consistent with a study conducted by Abas and Simoneit (1996) which also found that the concentrations of organic compounds observed were greater during the haze episodes than any other periods in a year, and that some of them are suspected to be transported from trans-boundary sources.

The seasonal variability of the results obtained from the mass closure model is shown in Fig. 5c. The reconstructed masses of MIN, SIA and SS were higher in the NE than the SW monsoon. These haze events were very likely caused by the slash-and-burn activities practiced by the agriculture industries, and the occurrence of forest fires during this dry season. The regional trans-boundary pollution during the NE and SW monsoon is the underlying reason for the change in the chemical component concentrations as well as the overall $PM_{2.5}$.

3.3 Identification and apportionment of $PM_{2.5}$ sources

Using US EPA PMF 5.0, the five identified sources of $PM_{2.5}$ were i) mineral and road dust, ii) motor vehicle emissions and biomass burning, iii) nitrate aerosol, iv) coal burning and v) marine and sulfate aerosol. Each of the source profiles is shown in Fig. 6a which demonstrates the concentration and percentage of the variables to each factor. The reported PMF analysis is based on the chemical components of filter samples. As described in the mass closure, a large portion of the $PM_{2.5}$ mass fraction (about 45%) was not apportioned. In the PMF 5.0 procedure, the contributions of five factors were estimated and then the integrated contribution of the five factors was regressed over the measured $PM_{2.5}$ (HVS). The regression fit line was forced through the origin. Thus, our regression of the $PM_{2.5}$ (PMF) and $PM_{2.5}$ (HVS) showed that the $PM_{2.5}$ had been reproduced by PMF 5.0 with an error of less than 10% and the correlation of $PM_{2.5}$ (PMF) and $PM_{2.5}$ (HVS) showed a strong and significant correlation (slope = 0.91, $r^2 = 0.88$, $p < 0.01$) (Fig. 6b). To evaluate the results of the PMF model, the regression between predicted and observed data for each variable is shown during the operation. A linear correlation between the predicted and measured mass represents the goodness-of-fit of linear regression. Our values strongly suggested that the five identified sources could be readily interpreted.

Factor component one: the predominant tracers are Mg, Zn, Cu, Ni and Ca^{2+}. The mineral or natural fugitive dust component is identified based on the presence of Mg (52% of the Mg mass), Ca^{2+} (42% of Ca^{2+} mass), Ca (28% of Ca mass) and Al (19% of Al mass), as shown in Table 2. Many other researchers cite these metals as markers for a mineral dust source (Dall'Osto et al., 2013; Moreno et al., 2013; Mustaffa et al., 2014; Viana et al., 2008; Waked et al., 2014). The possible cause of the mineral dust is the rapid development activities such as construction, renovation of road surface etc, around this suburban region. Airborne soil and construction material are the key sources of mineral dust (Dai et al., 2013; Gugamsetty et al., 2012; Huang et al., 2014). Cu, Zn and Ba are associated with road dust due to the release of these metal markers from cars from non-exhaust sources (Amato et al., 2011). Several studies identified that Cu is released from brake wear or the brake pads/tailpipes of cars (Wåhlin et al., 2006) while Zn originates from tire wear (Dall'Osto et al., 2013) and additives in cars as lubricant (Ålander et al., 2005). A study by Wang and Hopke (2013) suggested that Ni was emitted from gasoline engine and road dust sources. Ni (18% of Ni mass) and V (20% of V mass) are moderately presented in this factor component which shows the existence of heavy lubricating oil combustion (Amato et al., 2011). The average contribution of mineral or natural fugitive and road dust sources to the $PM_{2.5}$ was 3.17 µg m^{-3} or 13%.

Factor component two: contains substantial Pb, NH_4^+ and K^+. Motor vehicle emissions and biomass burning sources accounted for 7.47 µg m^{-3} or 31% of the total $PM_{2.5}$ concentration, which makes these the largest sources contributing to the $PM_{2.5}$ concentration. Pb along with the moderately enriched metals As, Cd, Zn, Ni and V (Fig. 5a, refer to previous section for detail), represents a motor vehicle emission source (Wu et al., 2007). The brake wear dust of motor vehicles contains Pb (Garg et al., 2000). A study by Begum et al. (2010) conducted in Dhaka and by Santoso et al. (2013) at roadsides in Jakarta defined Pb in $PM_{2.5}$ releasing from the pre-existing road dust by PMF. Choi et al. (2013) also introduced Pb in $PM_{2.5}$ as a tracer for the motor vehicle source. Zn is released from the wear and tear of tyres (Srimuruganandam and Shiva Nagendra, 2012). Further, Zn in $PM_{2.5}$ appeared to have a motor vehicle source as resolved by PMF, due to its use as fuel detergent and anti-wear additive (Brown et al., 2007). Ni and V were widely reported in the literature as markers for the combustion of engine oil or residual oil combustion (Gugamsetty et al., 2012; Han et al., 2006; Huang et al., 2014; Yu et al., 2013). Pb is no longer used as an additive in gasoline fuel. Thus, the Pb does not reflect the emissions from engine combustion but does reflect those from a non-exhaust traffic source. A study conducted by Rahman et al. (2011) in Kuala Lumpur investigating Pb in $PM_{2.5}$ found that it originated from the soil dust source, indicating the influence of road dust. Also, coal combustion is a predominant source of Pb (Tao et al., 2014). The K^+ ion has been widely cited in the literature as an excellent tracer representing a wood or biomass burning source (Dall'Osto et al., 2013; Kim and Hopke, 2007; Mustaffa et al., 2014; Wahid et al., 2013). The biomass burning source is generally comprised of either wood burning as residential fuel, agriculture residue/waste, and/or wild forest fires. In Kuala Lumpur, the biomass burning source was described due to the presence of K from $PM_{2.5}$ measured by Particle Induced X-ray Emission (Rahman et al., 2011). During the episode of biomass burning in Chengu, China, K^+ and other related tracers in $PM_{2.5}$ were increased by a factor of 2 -7. In this suburban region, the smoke emissions released due to the burning of wheat straw, rape straw and other biomass fuel for domestic cooking or heating purposes (Tao et al., 2013). K^+ is also mainly emitted from biomass burning in the suburb of Shenzhen, China (Dai et al., 2013), Beijing, China (Yu et al., 2013; Zhang et al., 2013) and Colombo, Sri Lanka (Seneviratne et al., 2011). In Seoul, Korea, biomass burning is characterised by the presence of K and other related markers in $PM_{2.5}$. The character of burning in this East Asian city is typically post-harvest field burning, biofuel burning for heating and cooking as well as forest fire from the outside of the city (Heo et al., 2009). Thus, the local and regional transport of smoke from the burning sources contribute to this factor. Hong Kong experiences the influence of biomass burning in $PM_{2.5}$ due to its transboundary origin (Huang et al., 2014). During the sampling period in the SW monsoon, the MODIS detected a very high number of fire counts over the Sumatra Island. In this monsoon season, the wind will consistently travel from the southwest direction, bringing air masses from these burning areas to Peninsular Malaysia. During the NE monsoon, on the other hand, the wind will travel from the northeast direction, bringing air masses from the China mainland, Indochina and the Philippines to Peninsular Malaysia. In this period of time, a high density of fire locations were found on the Indo-China and China mainland. Zhang et al. (2015) demonstrate that during the dry season there is important biomass burning activity in the Pearl River Delta (China), which can result in trans-border transport and a regional scale character of biomass burning. Therefore under the north-east monsoonal regime it is possible that outflow from that area can maybe influence the specific area. A study by Streets et al. (2003) estimated that China contributes 25% to the total biomass burning in Asia and showed a good agreement between national estimate of biomass burning and adjusted fire count. Yang et al. (2013) applied spatial-temporal features of fire counts and observed that the study area of Heilongjiang Province, China was seriously affected by forest fires during 2000-2011. Reid et al. (2013) reported a high intensity of fire counts in Vietnam/China region in April and in Indonesia during September. Khan et al. (2015a) also reported a high density of fire locations in Thailand, Vietnam and Laos during February and Sahani et al. (2014) reported many in the same regions during June-September. The biomass burning is the dominant source of trace gas and particulate matter and the fire emissions are mainly concentrated in Indonesia, Thailand, Myanmar and Cambodia (Chang and Song, 2010). Further, a comparison of nss-K^+ with the respective total K^+ is shown in Fig. 5b. The correlation of nss-K^+ as a function of total K^+ showed a strong correlation coefficient ($r^2 = 0.95$) which suggests that K^+ can be used as a biomass tracer. K^+ may also be emitted from local fire sources. Additionally, the molar equivalent of K^+ and Na^+, as shown in Fig 5c, demonstrated significant correlation ($r^2 = 0.70$) with a slope value of 0.34 which is much higher compared to 0.0225-0.230 and 0.0218, reported by Wilson (1975) and Hara et al. (2012), respectively. The higher molar ratio of K^+ and Na^+ indicates that at the current location, Na^+ depletion was high and the K^+ might also release from other dominant sources. Additional significant sources of K^+ which may attribute to the mass are soil dust, sea salt, vegetation and meat cooking (Zhang et al., 2010).

Factor component three: this factor is mainly dominated by the concentration of the nitrate ion (75% of NO_3^- mass) suggesting that this source is strongly related to the formation of nitrate aerosol. NO_3^- is mainly formed from the conversion of NOx, which is emitted from the exhaust of motor vehicles (Dai et al., 2013). Huang et al. (2014) also identified a nitrate source in $PM_{2.5}$ by the use of PMF in suburban areas of Hong Kong. In Beijing, a nitrate source appeared in $PM_{2.5}$ when source apportionment performed by PMF (Song et al., 2006). This source is also contributed to by the small amount of Al, Mn and Ca^{2+}. Overall, it accounted for 4.11 μg m^{-3} or about 17% of the $PM_{2.5}$ concentration.

Factor component four: this fourth source has an abundance of As, Ba and Sr (Se moderately contributed) and thus is classified as coal burning source. As constitutes the most to this fourth component at 53% (of As mass), which gives an indication that this source is related to the coal combustion. In Malaysia, several power plants are operating on the west coast of Peninsular Malaysia, e.g. Port Dickson, Kapar and Manjung. The power plants located at Port Dickson and Kapar are about 50 km far from the sampling station. These plants use coal as the raw material to generate electric power. Other researchers have also used As a tracer for the coal burning source (Moreno et al., 2013) and As and Se by Meij and te Winkel (2007); Querol et al. (1995). As and Se are categorized as of great concern and Ba and Sr are of moderate environmental concern in the utilization of coal, as reported by Vejahati et al. (2010). However, Ba is an indicator of brake wear and tear from motor vehicles (Gietl et al., 2010). Overall, the coal burning source accounts for 4.60 μg m^{-3} or about 19% of $PM_{2.5}$.

Factor component five: this component features Na^+ (50% of Na^+ mass), Cl^- (46% of Cl^- mass) and sulfate (64% of SO_4^{2-} mass) suggesting the presence of marine as well as sulfate aerosol. Begum et al. (2010) identified sea salt in $PM_{2.5}$ by PMF in Dhaka, based on the appearance of Na and Cl. Choi et al. (2013) defined a sea salt source in Seoul, Korea due to the high contribution of Na^+ and Cl^- in $PM_{2.5}$. Several other studies in East, Southeast and South Asia assigned a sea salt source in $PM_{2.5}$ considering Na^+ and Cl^- from the model output of PMF (Lee et al., 1999; Santoso et al., 2008; Santoso et al., 2013; Seneviratne et al., 2011). For sulfate, it shows that nss-SO_4^{2-} contributed 93% to the total sulfate concentration while ss-SO_4^{2-} accounted for only 6%. Therefore, the sulfate aerosol in $PM_{2.5}$ is released as a product from the photochemical conversion of SO_2, which mainly originates from anthropogenic large point sources as observed by Heo et al. (2009) in Seoul, South Korea. A secondary sulfate source in $PM_{2.5}$ was also identified by Huang et al. (2014) in a suburban area of Hong Kong and by Song et al. (2006) in Beijing. The marine and sulfate aerosol, as the final identified source, accounts for 4.99 μg m^{-3} or about 20% of the total $PM_{2.5}$

concentration. A study by Kim and Hopke (2007) defined a sea salt source by the high concentration of Na^+ and Cl^-, while sulfate sources are based on the high concentration of sulfate. The secondary aerosol fraction is an important source worldwide, which is also the case here. It generally constitutes a predominant portion of $PM_{2.5}$, which splits into two modes i.e. the nitrate-rich and sulfate-rich factors. Studies by Chen et al. (2007) and McGinnis et al. (2014) also identified the major contribution of the secondary aerosol fraction to $PM_{2.5}$.

3.4 Health risk implications

Table 3 shows the non-carcinogenic (represented as HQ) and carcinogenic risks posed by several selected metals (Pb, As, Cd, Cu, Mn, Zn and Ni) in $PM_{2.5}$ mass concentration through inhalation exposure associating with sources. The HQ values for As and Ni in $PM_{2.5}$ mass concentration are 15.9×10^{-2} and 14.3×10^{-2}, respectively, suggesting the non-carcinogenic health risks posed by these metals might be higher compared to other metals. The HQ for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in the $PM_{2.5}$ mass originating from the coal burning source and least in $PM_{2.5}$ originating from the mineral/road dust source. The cut-off point for significant health risks or the safe level to the exposed population is HQ > 1. Our results showed that the sum of HQ for each metal are lower than the safe level (= 1) in $PM_{2.5}$ mass concentration originating from each source. The sum of HQ for $PM_{2.5}$ is 35.7×10^{-2}, which is lower than the HQs of $PM_{2.5}$ reported by Hu et al. (2012) in Nanjing, China (2.96); Cao et al. (2014) in Shanxi Province, China ($1.06\times10^{+1}$); and Taner et al. (2013) in a non-smoking restaurant in Turkey (4.09). A study by Hu et al. (2012), reported HQ values for As and Ni in $PM_{2.5}$ as 4.14×10^{-1} and 1.73×10^{-1}, respectively, in Nanjing, China. However, the HQs of $PM_{2.5}$ estimated after inhalation at two sites in Nanjing City, China (0.88 (Xianlin) and 0.79 (Gulou)) were close to the safe level (= 1) according to a study by Li et al. (2015b). At two urban locations in Yangtze River Delta, China, the HQ for Cr in $PM_{2.5}$ was within the acceptable limit but higher for Mn (Niu et al., 2015). Although the HQ calculated for As was the highest, it was below 1, thus the non-carcinogenic health risk was estimated to be at a safelevel. In addition, the hazard index (total - hazard quotient) of $PM_{2.5}$ calculated for the four heavy metals (As, Cd, Mn, Ni) from the different sources (Table 3) showed an insignificant health risk.

The carcinogenic risks from the carcinogenic heavy metals Pb, As, Cd and Ni in $PM_{2.5}$ are shown in Table 3. Similar to the non-carcinogenic risks, the lifetime carcinogenic risk level is estimated for $PM_{2.5}$ mass concentration and may be contributed to by several heavy metals from different sources: mineral/road dust, motor vehicle emissions/biomass burning and coal combustion. The total life-time cancer risk (LCR) from heavy metals in the $PM_{2.5}$ mass concentration was calculated at 3.9×10^{-6} which is a significant cancer risk. The main carcinogenic heavy metal of concern to the health of people at the current location is As; the other heavy metals (Ni, Pb, and Cd) did not pose a significant cancer risk. Thus, the LCR from the $PM_{2.5}$ mass concentration originating from motor vehicle/biomass and coal burning sources showed a value of 1×10^{-6}, slightly above the acceptable cancer risk level as recommended by USEPA, while the total LCR from $PM_{2.5}$ mass concentration from all sources was estimated to be 4×10^{-6} which is also slightly above the acceptable cancer risk. The carcinogenic risk posed by As (3.66×10^{-3}) in $PM_{2.5}$ in Shanxi Province, China (Cao et al., 2014) was higher than the guideline value set by USEPA. A study by Niu et al. (2015) of $PM_{2.5}$-bound metals showed a high cancer risk in Yangtze River Delta, China (2.47×10^{-4}). A study by Pandey et al. (2013) conducted in the vicinity of human activities observed that the concentrations of Cd, Cr, Ni and Pb in $PM_{2.5}$ showed higher excess cancer risk (ECR) due to those particle-bound metals compared to guideline level set by USEPA. Satsangi et al. (2014) also reported a higher cancer risk from Cr, Ni and Cd in $PM_{2.5}$ compared to the USEPA guideline. The integrated carcinogenic risk of six metals (Cr, As, Co, Pb, Ni and Cd) in $PM_{2.5}$ in Tianjin, China were in the range 3.4×10^{-3} – 4.1×10^{-3} which is reportedly beyond the tolerance level (Zhang et al., 2014). The total ECRs based on the average values of As, Cd, Cr, Ni and Pb in $PM_{2.5}$ is 4.34×10^{-5} in Delhi, India, implying that four or five people might get cancer out of 100,000 people after exposure to toxic metals in $PM_{2.5}$ (Khanna et al., 2015). Our findings showed that the life-time cancer risk posed by the exposure of heavy metals in $PM_{2.5}$ mass concentration is three to four per 1,000,000 people at this location. This significant cancer risk warrants further investigation. Our findings showed that an insignificant non-carcinogenic risk and significant cancer risk is posed to the population from exposure to $PM_{2.5}$ at this location. Detailed exposure assessment of the $PM_{2.5}$ at the specific sources and the health risks posed by individual hazardous elements of concern may help to improve understanding about the exposure pathways as well as the detailed risk factors involved in both carcinogenic and non-carcinogenic risk.

4 Conclusions

$PM_{2.5}$ samples were collected using a high volume sampler in a semi-urban site on Peninsular Malaysia. The results obtained for $PM_{2.5}$ showed that 48% of the samples exceeded the WHO 24 h guideline and 19% exceeded the US EPA 24 h NAAQS for $PM_{2.5}$. The average value of $PM_{2.5}$ is higher than a previous study carried out on the east coast of Peninsular Malaysia. $PM_{2.5}$ concentration during the NE monsoon was slightly higher than the SW monsoon with air masses from different origins. For the SW monsoon the air masses originated from Sumatera, Indonesia and for the NE monsoon from Southern China. Major carcinogenic metals, namely As, Pb, Cr, Ni and Cd, have contributed to $PM_{2.5}$ by a significant portion. Of all carcinogenic metals, As was close to the values set by the WHO and EU guidelines.

Results of the EF analysis suggested that a large number of the heavy metals in $PM_{2.5}$ were emitted from anthropogenic sources. No seasonal differences were found in the EF of the heavy metals. The mass closure model results showed higher MIN, SIA and SS in the NE than the SW monsoon. Further analysis revealed that sulfate is relatively more stable in tropical climates compared to nitrate aerosol, indicating the dominance of static sources over mobile sources. However, the average molar ratio of Cl^- to Na^+ does not reflect the seawater ratio. "Cl loss" may be the cause of the drop in Cl^- to Na^+ ratio. The five sources of $PM_{2.5}$ obtained by the PMF 5.0 model were dominated by motor vehicle emissions/biomass burning (7.47 $\mu g\ m^{-3}$, 31%). The other four sources were mineral/road dust; nitrate aerosol; coal burning; and marine-sulfate aerosol with an overall contribution of 3.17 $\mu g\ m^{-3}$ (13%), 4.11 $\mu g\ m^{-3}$ (17%), 4.60 $\mu g\ m^{-3}$ (19%), and 4.99 $\mu g\ m^{-3}$ (20%), respectively.

Using the PMF-identified sources as the basis, the hazard quotient (HQ) for four selected metals (Pb, As, Cd and Ni) in $PM_{2.5}$ mass was highest in $PM_{2.5}$ originating from a coal burning source and least in that originating from a mineral/road dust source. The non-carcinogenic cancer risk posed by the exposure of $PM_{2.5}$ was at a considerably safer level compared to the South and East Asian region. The lifetime cancer risk (LCR) followed the order of As > Ni > Pb > Cd for mineral/road dust, coal burning sources and $PM_{2.5}$ mass concentration, and As > Pb > Ni > Cd for motor vehicle/biomass burning. Among the trace metals studied, As predominantly showed the largest LCR in $PM_{2.5}$ mass concentration as well as its associated sources, implying the largest risk after exposure of $PM_{2.5}$ to people at the current location. The associated LCR posed by the exposure of the hazardous metals in $PM_{2.5}$ mass concentration was three to four per 1,000,000 people at this location. This significant LCR warrants further investigation. Detailed exposure assessment of the $PM_{2.5}$ at the specific sources and the health risks posed by individual hazardous elements may help to improve understanding about the exposure pathways as well as the detailed risk factors involved in both carcinogenic and non-carcinogenic risk. Therefore, the motor vehicle emissions and regional trans-boundary pollution were the major underlying reasons for the change in the chemical component of $PM_{2.5}$ in tropical Peninsular Malaysia, which potentially leads to different health threats.
