Response to Reviewer #2

The authors would like to thank both reviewers for their comments and suggestions, which have helped to improve the quality of the manuscript. Please, find below a detailed response to the reviewer's comments.

Comment:

The manuscript titled "Profiling of aerosol microphysical properties at several EARLINET/AERONET sites during 2012 ChArMEx/EMEP campaign" intends to analyze the microphysical properties of aerosols at five different lidar ground-based stations, and to use the results obtained for the validation of different mineral dust models.

The paper addresses and interesting and sound topic related to the aims of the ChArMEx campaign. The English language and presentation are very clear and up to the standard of an international journal. The figures and tables in the manuscript are also relevant.

The paper is well organised and detailed. I strongly appreciate the effort of the authors to compile different ground-based observations and models. In this sense, the authors present a nice description of the state of the atmosphere during the ChArMEx campaign (9-11 July 2012). This technical work is noticeable; but somehow does not importantly contribute to science. After having read carefully the paper, I am not feeling having learnt a lot, for the following reasons.

Most of the paper is devoted to the description of aerosol optical properties, aerosol must and layering at different stations. The processes involved in the dynamics of transport of dust to the Mediterranean are widely known (as also stated by the authors in the references included). These processes were largely studied in a number of publications, such as Pey et al., 2013; Salvador et al., 2014; Gkikas et al., 2013 and 2015, Sicard et al., 2015; just to cite some recent papers. The models used (BSC-DREAM8b, NMMB/BSC-Dust, DREAM8-NMME, COSMO-MUSCAT) are not new either, and have been extensively validated in other studies (e.g. Perez et al., 2008; Pérez et al., 2011a, 2011b; Basart et al., 2012; Haustein et al., 2012; Mona et al., 2014, and especially, in Binietoglou et al., 2015, among many others). Also, using GARRLIC and LIRIC for retrieving microphysical properties is not a new contribution either.
Therefore, the authors should clarify which part of the manuscript is innovative and how this paper contributes to an advancement of the scientific knowledge.

Response:

The main contribution of this manuscript is the analysis of the microphysical properties, which has not been presented in the previous studies mentioned by the reviewer, mostly based on the analysis of the optical properties.
As far as LIRIC is concerned, results presented here follow a whole event during a continuous period of time in different stations operating simultaneously and thus providing vertical, horizontal and temporal coverage. Up to our knowledge, only the study by Chaikovsky et al. (2016) provides information about different lidars measuring simultaneously. However, those lidars were located at the same site for inter-

comparison purposes and the temporal evolution of the aerosol microphysical properties was not considered either. In studies other than Chaikovsky et al. (2016), LIRIC was applied to single sites with a single lidar and for specific selected case studies. In this sense, we show the capability of LIRIC to provide information about aerosol microphysical properties with a high vertical and temporal resolution in a simple, automated and robust way within a network such as EARLINET, providing regional coverage. The easy implementation of LIRIC in EARLINET/AERONET stations and the quality of the results obtained make it very suitable this kind of analysis within networks and during special campaigns. Additionally, information provided by LIRIC in such scenarios could be used to test and improve the performance of dust and aerosol forecast models.

In previous studies, models have been mostly validated using optical and column-integrated properties, but not many validations of the microphysical properties profiles are available, except for the study by Binietoglou et al. (2015). Our study goes one step further than the one by Binietoglou in the sense that the same dust event is evaluated regionally and we include also an evaluation of the temporal evolution at Granada station. Binietoglou et al. (2015) is a comprehensive analysis but applied to independent case studies at different stations. The addition of COSMO-MUSCAT in our study with respect to the one by Binietoglou et al. (2015) it is also worthy to point out. The comparison between COSMO-MUSCAT and the other three analyzed models is in our opinion quite interesting, since COSMO-MUSCAT is based in a different philosophy.

Comment:

Also, the authors have to further improve the discussion on the skills of the models. The authors calculate the relative bias (what the authors call the Relative Differences); but is this figure good enough to characterize the models? The bias may largely compensate with the layers where under- and overestimations are produced. In other words, a "zero" bias can come from very large absolute errors that compensate. The authors may use the US EPA (1991; 2005) indicators of those statistical figures coming from FAIRMODE initiative in order to have an idea of the ability of the models for reproducing dust must concentration. It would also be desirable to find some information related to the temporal skills: correlation coefficients, variability, etc.
Moreover, the authors do not provide any insight on the differences between the models (for instance, why some models indicate dust and some do not) or their skill. This has to be extended in the manuscript.

Response:
We agree with the reviewer that additional parameters are needed to better evaluate the model since the use of a single parameter can lead to misleading conclusions. Additional parameters from the documentation suggested by the reviewer have been included in the analysis, namely the root mean square error, the normalized mean bias and the normalized mean standard deviation. The correlation is now also included to evaluate the temporal skills of the models together with the new statistical parameters. Figure13 have been modified including these parameters (see figure below). In order to avoid confusion, some parameters presented in the previous version have now been removed since they do not provide additional information. Discussion has been

modified according to the results observed using the new parameters and extended where necessary.

Additionally, the results section has been reorganized in order to make it easier to follow and try to emphasize the main findings and conclusions inferred from the present study.

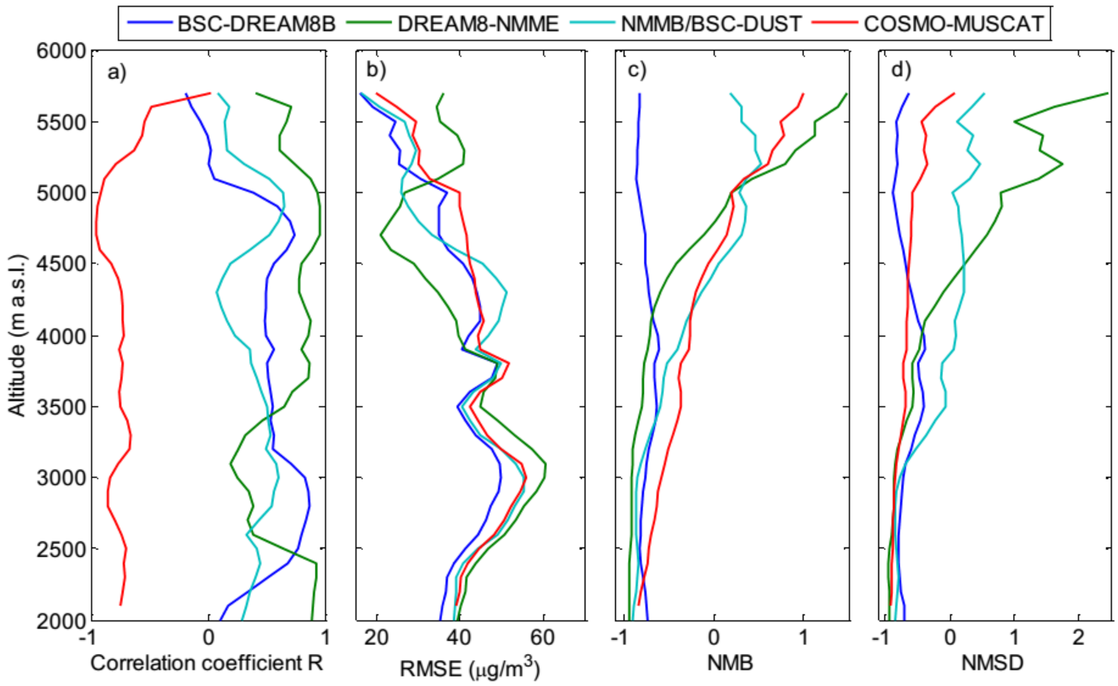

Figure 13. Vertical profiles of the correlation coefficient between LIRIC and the models time series for every altitude level, the root mean square error RMSE, the normalized mean bias NMB and the normalized mean standard deviation NMSD.

Other minor comments:
1. I cannot find the reference Gama et al. (2015) in the literature section.

Response:
The reference was not included in the references section. We apologize for the mistake and the reference is now added to the list.
"Gama, C., Tchepel, O., Baldasano, J. M., Basart, S., Ferreira, J., Pio, Cardoso, J., and Borrego, C.: Seasonal patterns of Saharan dust over Cape Verde-a combined approach using observations and modelling. Tellus B 2015, 67, 24410, [*http://dx.doi.org/10.3402/tellusb.v67.24410*](http://dx.doi.org/10.3402/tellusb.v67.24410)*, 2015."*

Response to Reviewer #3

The authors would like to thank both reviewers for their comments and suggestions, which have helped to improve the quality of the manuscript. Please, find below a detailed response to the reviewer's comments.

Comment:
The paper it is clearly written and the authors provide an overview on the dust event that mainly affected the western Mediterranean from 9 to 11 July 2012, without adding any new scientific insight on the spatial and temporal evolution of Mediterranean dust events. Therefore, the paper is not appropriate for the ACP journal, to my opinion.

Response:

The main focus of this paper is on the analysis of the microphysical properties during the ChArMEx campaign in 2012, which has not been presented in previous studies mostly based on the analysis of the aerosol optical properties. We show the utility and the potential of having synergies between lidar and sun/sky radiometer for the vertical profiling of microphysical properties during the day. For example, it is evidenced that the aerosol plume coming from the western Mediterranean area is not the one detected over the Balkan's stations, something that is shown using the synergy between active and passive lidar by applying the LIRIC retrieval algorithm. The study also shows the clear advantage of having additional information such as the data provided by the polarization channels to obtain information about aerosol typing. The simultaneous validation of the different models at different sites together with their temporal evaluation is also one of the main points of the study, since no validation of these characteristics has been presented before.

Comment:
The methodology applied in the paper is commonly used to analyse dust outbreaks and it was also used by Sicard et al., 2015 to characterize the same dust event at the same sites of this study.

Response:

Sicard et al. (2015) focuses on the optical properties derived from lidar profiles while this paper is focused on exploiting the synergies between active profiling and passive remote sensing to retrieve microphysical properties. In this sense, in this work we present atmospheric profiles of the aerosol concentration, including the splitting between spherical and non-spherical coarse mode particles, something that is really relevant in aerosol typing. Data presented in both studies are complementary of each other.

Comment:
The results referring to Evora should be taken away from the manuscript to my opinion. Note that Fig. 6a of the paper by Sicard et al., (2015) indicates that the Evora lidar signals around 1 km agl were likely affected by the lidar field of view. Note also the sentence at line 225 of the manuscript " the initial vertical resolution….was established to….100 m". The aerosol layer of Fig. 6 extends within 200-400 m.

Response:

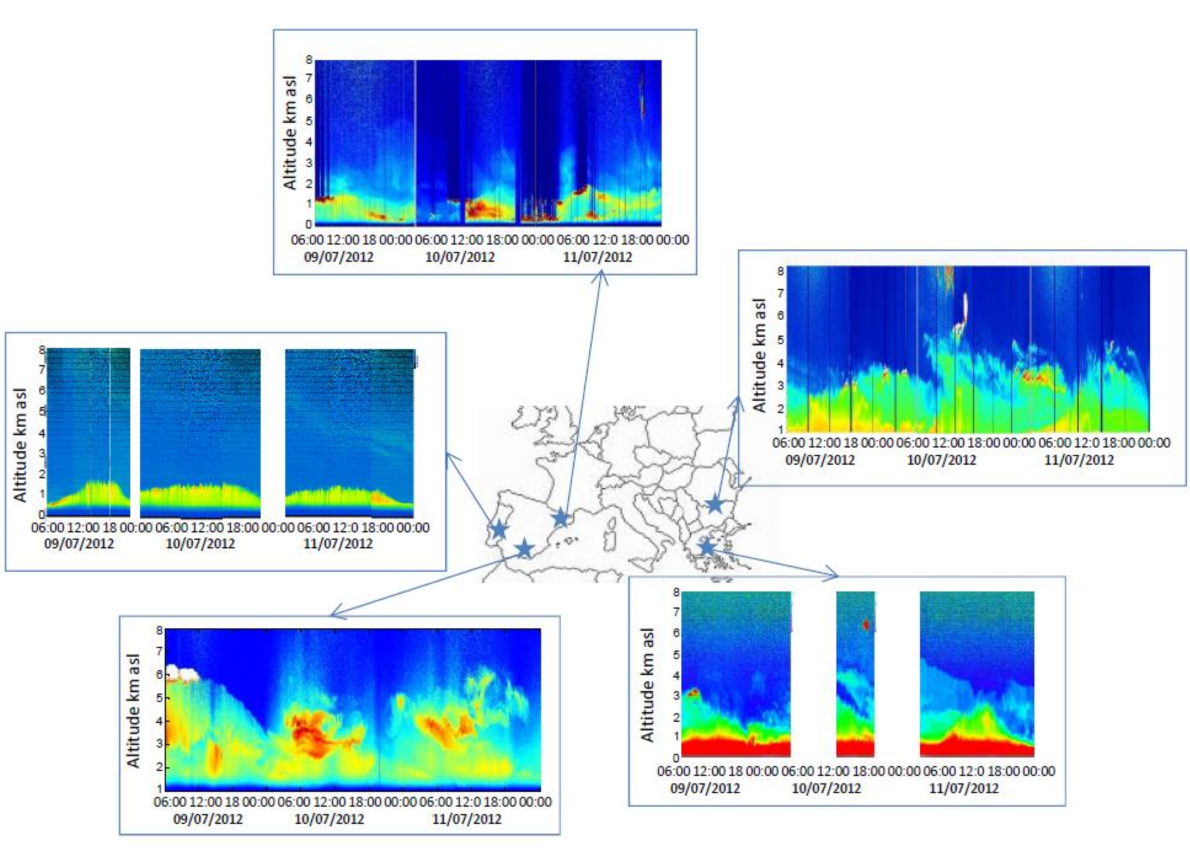
Data from Evora are mainly kept in the manuscript to evaluate the performance of the models in cases when no mineral dust is observed. Even though not much information on the microphysical properties can be extracted, we consider data are still valuable and reliable for Evora site. The influence of the lidar incomplete field of view below 1 km mentioned in Sicard et al. (2015) is considered when retrieving the microphysical properties with LIRIC. LIRIC software allows making an interpolation of the data from the lower point of the profile not affected by the incomplete field of view down to the surface. To make the interpolation, LIRIC takes into account the integrated volume concentration provided by the sun photometer for each mode, adjusting the volume concentration profiles to this value. More details can be found in Wagner et al. (2013), Granados-Muñoz et al. (2014) and Chaikovsky et al. (2008; 2016).
The sentence at line 255 refers only to the data used for the model-LIRIC intercomparison. Data presented in figure 6 (figure 4 in the new version of the manuscript) have 15-m vertical resolution. This information has been included in the manuscript.

Line149-150: "From the combination of all this data, volume concentration profiles $C_v(z_n)$ *are obtained for fine and coarse aerosol particles with a vertical resolution of 15 m in our case."*

Comment:
In addition, I believe that the altitude scale of the RCSs referring to Evora (fig. 5 of the manuscript) is wrong, since it should start at 0 and not at 1 km, as it is clearly shown in Fig. 5a of the paper by Sicard et al., (2015).

Response:

Scales in Figure 5 were mistaken. We thank the reviewer for pointing it out. Figure 5 (figure 3 in the new version) has been corrected.



Comment:

Lines 529-531: The sentence”.. the decrease in the fine mode in the coincidence with the increase in the coarse spherical mode could be associated to the aging of the mineral dust particles and aggregation processes” is to my opinion rather speculative.

Response:

The sentence has been modified:

Lines 497-502: *“During July 10 in the late afternoon and July 11, a decrease in the fine mode in coincidence with an increase in the coarse spherical mode was observed. The simultaneous decrease of the fine mode and increase of the coarse spherical particles together with the decrease in δ_532nm^p point out to processes such as mineral dust aging and/or aggregation processes. However, additional analysis would be necessary to confirm this hypothesis.”*

Comment:

I believe that Fig. 6 referring to Granada on 11 July , likely reveals the presence of a dust layer up to about 1.5 km and another dust layer from 3 to about 5.5 km agl. The presence of different dust layers along the aerosol column, as well as the high spatial and temporal variability of the aerosol vertical profile during dust events has been presented and discussed in several papers.

Response:

More detailed information about the dust event at Granada is shown in Figures 9 and 10 (figures 7 and 8 in the new version), whereas figure 6 shows the data at the different stations measured simultaneously in order to see the spatial (both in the vertical and horizontal coordinates) and temporal variability of the microphysical properties during the analyzed event. We would like to emphasize here again that our results are focused on the analysis of the microphysical properties, not the optical properties, which have indeed been analyzed in detail in many previous studies.

Taking into account the comments from both reviewers, part of the manuscript (mainly the results section) has been reorganized and discussion has been extended at some points and reduced where redundant. With this reorganization we intend to highlight the main findings and conclusions inferred from the present study.

Marked-up manuscript version:

PROFILING OF AEROSOL MICROPHYSICAL PROPERTIES AT SEVERAL EARLINET/AERONET SITES DURING JULY 2012 CHARMEX/EMEP CAMPAIGN

Abstract

The simultaneous analysis of aerosol microphysical properties profiles at different European stations is made in the framework of the ChArMEx/EMEP 2012 field campaign (July 9-11, 2012). During and in support to this campaign, five lidar ground-based stations (Athens, Barcelona, Bucharest, Évora and Granada) performed 72 hours of continuous lidar measurements and collocated and coincident sun-photometer measurements. Therefore it was possible to retrieve volume concentration profiles with the Lidar Radiometer Inversion Code (LIRIC). Results indicated the presence of a mineral dust plume affecting the Western Mediterranean region (mainly Granada station) whereas a different aerosol plume was observed over the Balkans area. LIRIC profiles showed a predominance of coarse spheroid particles above Granada, as expected for mineral dust, and an aerosol plume composed mainly of fine and coarse spherical particles above Athens and Bucharest. Due to the exceptional characteristics of the ChArMEx database, the analysis of the microphysical properties profiles temporal evolution was also possible. An in depth analysis was performed mainly at Granada station because of the availability of continuous lidar measurements and frequent AERONET inversion retrievals. The analysis at Granada was of special interest since the station was affected by mineral dust during the complete analyzed period. LIRIC was found to be a very useful tool for performing continuous monitoring of mineral dust, allowing for the analysis of the dynamics of the dust event in the vertical and temporal coordinates. Results obtained here illustrate the importance of having collocated and simultaneous advanced lidar and sun-photometer measurements in order to characterize the aerosol microphysical properties both in the vertical and temporal coordinates at a regional scale. In addition, this study revealed that the use of the depolarization information as input in LIRIC in the stations of Bucharest, Évora and Granada was crucial for the characterization of the aerosol types and their distribution in the vertical column, whereas in stations lacking of depolarization lidar channels ancillary information was needed. Results obtained were also used for the validation of different mineral dust models. In general, the models better forecast the vertical distribution of the mineral dust than the column integrated mass concentration, which was underestimated in most of the cases.

1. INTRODUCTION

The influence of the atmospheric aerosol particles in the Earth's radiative forcing is still affected by a large uncertainty, as indicated in the AR5 report from the Intergovernmental Panel for Climate Change [IPCC, 2013]. During past years, this uncertainty has been reduced from high to medium with respect to the data in the Fourth Assessment Report (AR4) of the IPCC, [2007]. However, atmospheric aerosol still contribute to the largest uncertainty to the total radiative forcing estimate, even though the level of confidence on the effects of atmospheric aerosols has increased from low and medium to medium and high (for indirect and direct effect, respectively) [IPCC, 2013].

The difficulty in accurately determining atmospheric aerosol properties and their influence on the Earth's radiative forcing lies in their large spatial and temporal variability. Ground based (active and passive) remote sensing techniques have proven to be quite robust and provide accurate results for atmospheric aerosol characterization [e. g. Nakajima et al., 1996; Dubovik and King, 2000; Mattis et al., 2004; Olmo et al., 2006]. Nonetheless, they provide information about atmospheric aerosol properties on a local scale. Since regional analyses are highly important when analyzing the aerosol variability, several observational networks have been developed. Namely, the lidar network GALION (Global Atmospheric Watch Aerosol Lidar Observation Network), which includes EARLINET (European Aerosol Research Lidar Network, www.earlinet.org) [Bösenberg et al., 2001; Pappalardo et al., 2014], MPLNET (Micro Pulse Lidar Network) [Welton et al., 2005], LALINET (Latin American Lidar Network, www.lalinet.org) [Guerrero-Rascado et al., 2014] and ADNET (Asian Dust Network) [Shimizu et al., 2004] among others; and the sun-photometer networks SKYNET (Skyradiometer network) [Takamura and Nakajima, 2004] and AERONET (Aerosol Robotic Network, http://aeronet.gsfc.nasa.gov/) [Holben et al., 1998].

In addition to the regional coverage, these networks can provide useful information on the vertical and temporal coordinates, if adequate measurement protocols are stablished. Information on the vertical structure of the aerosol is of high importance, since the atmospheric aerosol effects can be very different near the surface, within the boundary layer, and in the free troposphere. Estimates of radiative forcing are sensitive to the vertical distribution of aerosols [Claquin et al., 1998; Huang et al., 2009; Sicard et al., 2014] and the vertical information is required for accounting the indirect effect [McCormick et al., 1993; Bréon, 2006]. In addition, atmospheric aerosol can change the vertical profile of temperature and atmospheric stability, which in turn influences the wind speed profile within the lower atmosphere [Pérez et al., 2006; Guerrero-Rascado et al., 2009; Choobari et al., 2014]. Furthermore, continuous and/or regular measurements provided by the networks, would allow us to analyse the temporal evolution and dynamics of the atmospheric aerosol particles, which will be very useful not only for accurately determining the radiative forcing, but also to improve the performance of numerical weather prediction (NWP) [e.g. Pérez et al., 2006a] and climatological models [Nabat et al., 2014, 2015].

Lidar systems are widely used to determine the vertical distribution of aerosols. There are already many regional studies on the vertical characterization of optical properties based on lidar systems [e. g. Papayannis et al., 2008]. However, the characterization of the microphysical properties profiles is still not so straightforward, due to the complexity of the retrievals. Algorithms designed to combine lidar and sun-photometer measurements have been developed in order to overcome this difficulty (e.g. LIdar Radiometer Inversion Code, LIRIC [Chaikovsky et al., 2008; 2012; 2016] and Generalized Aerosol Retrieval from Radiometer and Lidar Combined data, GARRLIC [Lopatin et al., 2013]. The combination of simultaneous information about the aerosol vertical structure provided by the lidar system and the columnar properties provided by the sun photometer has proven to be a promising synergetic tool for this purpose. LIRIC, which is used in this study, has already provided interesting results about vertically resolved aerosol microphysical properties for selected case studies [Tsekeri et al., 2013; Wagner et al., 2013; Granados-Muñoz et al., 2014; 2015; Papayannis et al., 2014; Binietoglou et al., 2015]. The increasing number of stations performing these simultaneous measurements foresees an optimistic future concerning the increasing spatial coverage.

Regional studies in the Mediterranean region are of huge scientific interest since multiple studies indicate that aerosol radiative forcing over the Mediterranean region is one of the largest in the world [Lelieveld et al., 2002; *IPCC*, 2013]. In this context, the ChArMEx (the Chemistry-Aerosol Mediterranean Experiment, http://charmex.lsce.ipsl.fr/) [Dulac et al., 2014] international project involving several Mediterranean countries aims at developing and coordinating regional research actions for a scientific assessment of the present and future state of the atmospheric environment in the Mediterranean Basin, and of its impacts on the regional climate, air quality, and marine biogeochemistry. The ChArMEx project organized a field campaign between 25 June and 12 July 2012, in order to address interactions such as long range transport and air quality, and aerosol vertical structure and sources. The period of the campaign falls within the ACTRIS (Aerosols, Clouds, and Trace Gases Research Infrastructure Network) summer 2012 campaign (8 June – 17 July, 2012) that aimed at giving support to both ChArMEx and EMEP (European Monitoring and Evaluation Programme) [Espen Yttri et al., 2012] field campaigns. Within the ACTRIS summer 2012 campaign, the European lidar network (EARLINET) [Pappalardo et al., 2014] performed a controlled exercise of feasibility to demonstrate its potential to perform operational, coordinated measurements [Sicard et al., 2015]. The exercise consisted of continuous lidar measurements during a 72-hour period in July 2012 at different European sites. Most of those lidar data have been successfully assimilated by a regional particulate air quality model to improve 36-h operational aerosol forecasts both in terms of surface PM and aerosol optical depth [Wang et al., 2014].

Our study takes advantage of those continuous lidar measurements combined with simultaneous sun-photometer data to perform a characterization of the vertical distribution of the aerosol microphysical properties at different European stations with LIRIC. Temporal evolution of the aerosol microphysical properties is also analysed when the continuity of the inverted data is available. Up to our knowledge, it is the first time that LIRIC algorithm is applied in a continuous and automated way to retrieve simultaneous and continuous data acquired at different stations, proving the algorithm capability to provide reliable microphysical properties information with high spatial and temporal resolution. In addition, this exceptional aerosol observational database is used for the spatio-temporal evaluation of different regional mineral dust models

2. MEASUREMENT STRATEGY

During the summer of 2012, an intensive measurement campaign was performed in the framework of ChArMEx and EMEP in the Mediterranean Basin at twelve ground-based lidar stations throughout Europe. The main aim of these measurements was to obtain an experimental vertically-resolved database for investigating aerosol radiative impacts over the Mediterranean basin using 3-D regional climate models. The extensive lidar database acquired during this campaign combined with AERONET regular measurements represents a unique opportunity to evaluate the performance of LIRIC microphysical inversion retrieval during the event in both temporal and spatial (horizontal and vertical) coordinates, proving the utility of combined measurements and the potential of LIRIC algorithm for routinary aerosol microphysical properties measurements.

The measurement campaign consisted in 72-hours of continuous and simultaneous lidar measurements performed at twelve European stations, with eleven out of them participating in ACTRIS/EARLINET [Sicard et al., 2015]. The measurement period started on July 9 at 06:00 UTC and lasted until July 12, 2012 at 06:00 UTC, in coincidence with a forecast mineral dust event over the Mediterranean basin according to dust transport models.

LIRIC algorithm requires lidar data at least in 3 different wavelengths and simultaneous AERONET retrievals in order to obtain the aerosol microphysical properties profiles. Therefore, to evaluate the performance of LIRIC algorithm and characterize the distribution and temporal evolution of the aerosol microphysical properties during the event, only those stations where multiwavelenght lidar data at 3 wavelengths and AERONET data were available for the period July 9-11 were selected. Namely, those stations were Athens (AT), Barcelona (BA), Bucharest (BU), Évora (EV) and Granada (GR) (Figure 1). The main characteristics of each station are included in Table 1.

[Figure 1]

All the five stations are part of both EARLINET and AERONET networks. Thus, these five stations are equipped with at least a multiwavelength lidar and a sun photometer. ~~Multiwavelength lidar systems are used in this study to measure vertical profiles of the atmospheric aerosol properties.~~ Lidar systems in all these five stations emit and receive at least at three different wavelengths (355, 532 and 1064 nm), with the systems in Granada, Bucharest and Évora including depolarization capabilities at 532 nm (Table 1). Depolarization information can be used in the retrieval of the aerosol microphysical properties profiles with LIRIC to distinguish between coarse spherical and coarse spheroid mode.

Stations are also equipped with collocated standard sun photometers CIMEL CE-318-4, used in the AERONET network. AERONET retrieval algorithm provides atmospheric aerosol properties integrated in the atmospheric vertical column [Dubovik and King, 2000; Dubovik et al., 2006]. The automatic tracking sun and sky scanning radiometer makes sun direct measurements with a 1.2° full field of view every 15 min at different nominal wavelengths, depending on the station (Table 1). These solar extinction measurements are used to compute aerosol optical depth (τ_λ) at each wavelength except for the 940 nm channel, which is used to retrieve total column water vapour (or precipitable water) [Estellés et al., 2006; Pérez-Ramírez et al., 2012]. The estimated uncertainty in computed τ_λ, due primarily to calibration uncertainty, is around 0.01–0.02 for field instruments (which is spectrally dependent, with the larger errors in the UV) [Eck et al., 1999; Estellés et al., 2006].

[Table 1]

3. METHODOLOGY

3.1. RETRIEVAL OF AEROSOL PROPERTIES FROM REMOTE SENSING MEASUREMENTS

The analysis of aerosol microphysical properties profiles is performed with LIRIC algorithm. Details about LIRIC retrieval algorithm and its physical basics can be found in previous studies [Chaikovsky et al., 2012; 2016; Kokkalis et al., 2013; Wagner et al., 2013; Granados-Muñoz et al., 2014; 2015; Perrone et al., 2014; Binietoglou et al., 2015], but a brief description is included here for completeness. LIRIC provides profiles of atmospheric aerosol microphysical properties from atmospheric aerosol columnar optical and microphysical properties retrieved from direct sun and sky radiance measurements from the sun-photometer using AERONET code (Version 2, Level 1.5) [Dubovik and King, 2000; Dubovik et al., 2006] and measured lidar elastic backscatter signals at three different wavelengths (355, 532 and 1064 nm). If available, also the 532-nm cross-polarized signal is used. Raw lidar data used for this analysis have been prepared accordingly to the EARLINET Single Calculus Chain (SCC), described in detail in D’Amico et al., [2015]. From the combination of all this data, volume concentration profiles $C_v(z_n)$ are obtained for fine and coarse aerosol particles, <u>with a vertical resolution of 15 m in our case</u>. The use of the 532-nm cross-polarized lidar channel allows for distinguishing between spherical and non-spherical particles within the coarse fraction of the aerosol. The uncertainty in LIRIC retrievals associated to the input data is not yet well described, but the algorithm has proven to be very stable and the variations in the output profiles associated to the user-defined input parameters are below 20% [Granados-Muñoz et al., 2014].

3.2. MODEL DESCRIPTION AND VALIDATION STRATEGY

Models of dust emission, transport and deposition are used as a tool to understand the various aspects that control distributions and impacts of dust. While global models of the dust cycle are used to investigate dust at large scales and long-term changes, regional dust models are the ideal tool to study in detail the processes that influence dust distribution as well as individual dust events. The analysis of the aerosol microphysical properties with LIRIC using ChArMEx comprehensive database was used here for the evaluation of a set of 4 regional mineral dust models. This model evaluation was performed for both the vertical and horizontal coordinates and the temporal evolution.

Firstly, the spatial distribution of the mineral dust was examined by using the experimental data from the five EARLINET/AERONET sites considered in the present study. Dust optical depth (at 550nm) provided by four different regional mineral dust models (BSC-DREAM8b, NMMB/BSC-Dust, DREAM8-NMME and the regional version of COSMO-MUSCAT) was used at this stage. Experimental data were used here just to corroborate the presence or non-presence of mineral dust at the different regions and periods indicated by the models.

BSC-DREAM8b and DREAM8-NMME models are based on the Dust Regional Atmospheric Model (DREAM), originally developed by Nickovic et al., [2001]. The main feature of the updated version of the model, BSC-DREAM8b (version 2), include an 8-bins size distribution within the 0.1–10 μm radius range according to Tegen and Lacis [1996], radiative feedbacks [Pérez et al., 2006a,b] and upgrades in its source mask [Basart et al., 2012]. BSC-DREAM8b model provides daily dust forecasts at Barcelona Supercomputing Center–Centro Nacional de Supercomputación (BSC-CNS, http://www.bsc.es/projects/earthscience/BSC-DREAM/). The model has been extensively evaluated against observations [see, e.g. Basart et al. 2012b]. Recently, the DREAM8-

NMME model [Vukovic et al, 2014], driven by the NCEP Nonhydrostatic Mesoscale Model on E-grid [Janjic et al., 2001], provides daily dust forecasts available at the South East European Virtual Climate Change Center (SEEVCCC; http://www.seevccc.rs/).

NMMB/BSC-Dust model [Pérez et al., 2011; Haustein et al., 2012] is a regional to global dust forecast operational system developed and maintained at BSC-CNS. It is an online multi-scale atmospheric dust model designed and developed at BSC-CNS in collaboration with NOAA-NCEP, NASA Goddard Institute for Space Studies and the International Research Institute for Climate and Society (IRI). NMMB/BSC-Dust model includes a physically based dust emission scheme, which explicitly takes into account saltation and sandblasting processes. It includes an 8-bin size distribution and radiative interactions. NMMB/BSC-Dust model has been evaluated at regional and global scales [Pérez et al. 2011; Haustein et al. 2012; Gama et al., 2015].

BSC-DREAM8b, NMMB/BSC-DDUST and DREAM8-NMME models are participating in the World Meteorological Organization Sand and Dust Storm Warning Advisory and Assessment System (WMO SDS-WAS) Northern Africa-Middle East-Europe (NAMEE) Regional Center (http://sds-was.aemet.es//). Additionally, NMMB/BSC-Dust is the model that provides operational dust forecast in the first Regional Specialized Meteorological Center with activity specialization on Atmospheric Sand and Dust Forecast, the Barcelona Dust Forecast Center (BDFC; http://dust.aemet.es/).

On the other hand, COSMO-MUSCAT is an online coupled model system based on a different philosophy: COSMO is a non-hydrostatic and compressible meteorological model which solves the governing equations on the basis of a terrain-following grid [Schättler et al., 2008; Baldauf et al., 2011], whereas MUSCAT is a chemistry transport model that treats the atmospheric transport as well as chemical transformations for several gas phase species and particle populations using COSMO output data [Knoth and Wolke, 1998; Wolke et al. 2012]. More details about COSMO-MUSCAT model can be found elsewhere [Schepanski et al., 2007, 2009; Heinold et al., 2009; Laurent et al., 2010; Tegen et al., 2013].

The spatial resolution, domain size, initial and boundary conditions, differ, in addition to the different physical parameterizations implemented in the models. Details on the individual mineral dust models and their respective model configurations evaluated here are summarized in Table 2.

[Table 2]

In a further step, modelled mineral dust mass concentration profiles were compared with LIRIC output profiles in order to evaluate the model performance on the vertical coordinate. The temporal evolution of the modelled vertical profiles was evaluated in more detail only at Granada, which was the station most affected by the dust outbreak during the analysed period and thus provided a more extensive database. Since LIRIC provides volume concentration profiles, a conversion factor was needed to obtain mass concentration. This conversion factor was the density of the aerosol particles, namely 2.65 $g \cdot cm^{-3}$ for the coarse mode (1-10 μm) and 2.5 $g \cdot cm^{-3}$ (0.1-1 μm) for the fine mode [Pérez et al., 2006a,b]. In addition, the initial vertical resolution of the different models and LIRIC was established to a common values of 100 m, in order to obtain a compromise between the loss of information from LIRIC and from the different models, following a similar procedure to that in Binietoglou et al., [2015].

After this processing, mineral dust mass concentration profiles provided by BSC-DREAM8b, NMMB/BSC-DUST, DREAM8-NMME and COSMO-MUSCAT models were evaluated against LIRIC results in those cases when mineral dust was detected. For the comparison, the fine mode was assumed to be fine mineral dust since it is not possible to distinguish which part of the fine mode corresponds to dust or non-dust particles with LIRIC. This assumption may cause an overestimation of the mineral dust concentration that becomes more important in those cases with high concentrations of the fine mode (which was not the case in our study). Alternative methods, such as POLIPHON (Polarization-lidar photometer networking) method, could be applied to overcome this difficulty [Mamouri and Ansmann, 2014], but this is out of the scope of our study.

In our study, model output profiles were retrieved every 3 hours and compared to LIRIC retrievals during the three analyzed days. Only daytime data are presented here (from 06:00 to18:00 UTC) because of the limitations of LIRIC retrieval during night-time. Due to the difficulties of the models to correctly represent the convective processes occurring within the planetary boundary layer and PBL-free troposphere interactions and the photochemical reactions producing secondary aerosols at the considered resolution, the lowermost part of LIRIC profiles (affected by these processes) was not considered in the comparison presented here. Only data between 2000 m asl, which is the mean value of the PBL height during summer at Granada [Granados-Muñoz et al., 2012], and the highest value (up to between 5 and 6 km) provided by LIRIC were included in the comparisons.

In order to quantify the model agreement with the total dust load observed in the profiles, the integrated dust mass concentration from the different profiles was obtained by integrating the profiles between 2 km asl and the highest altitude value provided by LIRIC profiles.

The altitude of the center of mass of the dust column (C_m) was also calculated according to Equation 1, where z_{min} and z_{max} are 2 and the highest altitude value provided by LIRIC respectively:

$$C_m = \frac{\int_{z_{min}}^{z_{max}} z_n C_{mass}(z_n).dz_n}{\int_{z_{min}}^{z_{max}} C_{mass}(z_n).dz_n} \quad (1)$$

Additional parameters used in the comparison between LIRIC and the model dust mass concentration profiles are the root mean square error (RMSE), the correlation coefficient (R), the normalized mean bias (NMB) and the normalized mean standard deviation (NMSD), defined in equations 2 to 6:

$$RMSE = \sqrt{\frac{1}{n}\sum_n \left(C_{mass}^{LIRIC}(z_n) - C_{mass}^{model}(z_n)\right)^2} \quad (2)$$

$$R = \frac{\sum_n \left(C_{mass}^{model}(z_n) - \overline{C_{mass}^{model}}\right)\left(C_{mass}^{\mathrm{LIRIC}}(z_n) - \overline{C_{mass}^{LIRIC}}\right)}{\sqrt{\sum_n \left(C_{mass}^{model}(z_n) - \overline{C_{mass}^{model}}\right)^2}\sqrt{\sum_n \left(C_{mass}^{LIRIC}(z_n) - \overline{C_{mass}^{\mathrm{LIRIC}}}\right)^2}} \quad (3)$$

$$NMB = \frac{\overline{C_{mass}^{model}} - \overline{C_{mass}^{LIRIC}}}{\overline{C_{mass}^{LIRIC}}} \quad (4)$$

$$NMSD = \frac{\sigma_{\mathrm{model}} - \sigma_{\mathrm{LIRIC}}}{\sigma_{\mathrm{LIRIC}}} \quad (5)$$

where n is the number of height levels; $C_{mass}(z_n)$ is the dust mass concentration at each height level z_n, either for LIRIC or the models; $\overline{C_{mass}}$ are mean values; and σ indicates the standard deviation.

A detailed comparison of BSC-DREAM8b, NMMB/BSC-DUST, DREAM8-NMME (three out of the four models presented here) dust mass concentration profiles with LIRIC results was performed in Binietoglou et al. [2015] using additional stations and selected case studies for the period 2011-2013. However, due to the characteristics of ChArMEx database this study goes a step further. Up to our knowledge, it is the first time that the different models are evaluated at different stations using simultaneous data, thus providing information about the horizontal coordinate, following the evolution of a regional event. Additionally, a validation of the mass concentration profiles temporal evolution of a specific mineral dust event is presented for the first time.

4. RESULTS

During the 72-hour intensive measurement period, information from different models, platforms and instrumentation was available. A detailed characterization of the situation above the Mediterranean Basin during the campaign focused on aerosol microphysical properties using the different resources available is presented in the subsection 4.1., followed by the models evaluation in subsection 4.2.

4.1. SPATIAL-TEMPORAL CHARACTERIZATION OF AEROSOL MICROPHYSICAL PROPERTIES DURING CHARMEX/EMEP 2012

4.1.1. Ground-based column-integrated measurements

Column-integrated properties retrieve from the AERONET sun-photometer are presented in Figure 2. Figure 2a and b shows the time series of the τ_{440nm} and AE(440-880nm) for the selected 5 stations during the analysed period and mean values for each day and station are indicated in Table 3.

According to these data, the lowest values of τ_{440nm} were measured at Évora station during the whole period, with values below 0.18. The AE(440-880nm) was close to one, except in the early morning and late evening, when it decreased down to ~0.5. These values, together with the columnar volume size distributions observed in Figure 2c indicates a very low aerosol load, mostly related to aerosol from local sources, and no impact of the North African aerosol plume forecast to arrive at the Iberian Peninsula. A decrease of τ_{440nm} value with time was observed at Granada station, with maximum values reaching up to 0.40 on July 9 around 16:00 UTC. During July 10 and 11, τ_{440nm} values were between 0.10 and 0.20, except for the late afternoon of July 10 from 17:00 UTC, when the aerosol load decreased and τ_{440nm} below 0.10 were observed. On the contrary, values of the AE(440-870 nm) were increasing from 0.3 on July 9 up to 0.7 on July 11, with maximum values on the late evening on July 10 (AE(440-870 nm) >1). It is worthy to note that the AE(440-870nm) was below 0.5 during the whole period except for the late afternoon on July 10, in coincidence with the decrease in $\tau_{440nm,}$ indicating a clear predominance of coarse particles [e. g. Pérez et al., 2006a; Basart et al., 2009; Valenzuela et al., 2014]. The columnar volume size distributions for the different days agreed with these data. Data from July 9 show a very large coarse mode and a small contribution of fine particles. The contribution of fine particles was almost constant during the three days, whereas the coarse mode was decreasing with time. There was a predominance of the coarse mode during the whole period, with maximum values of 0.13 $\mu m^3/\mu m^2$ during the first day. All these data are usually related to the presence of mineral dust in the station and the temporal evolution of the analyzed properties clearly suggest a decrease of the mineral dust event intensity throughout the analysed period and a possible mixing or aging of the mineral dust. At Barcelona station no AERONET data were available on July 9. During July 10 and 11, τ_{440nm} values were relatively high and quite constant (around 0.30) and the AE(440-870nm) values were larger than 1.5, indicating a strong contribution of fine aerosol particles. In the columnar volume size distributions, similar values for the fine and coarse mode were observed on the July 10, but larger values of the fine mode were obtained on July 11. Therefore, it can be inferred from these data that the impact of the North African aerosol plume was almost negligible at this station.

In Athens and Bucharest the aerosol plume presented very different characteristics to those observed on the Western region. **Error! Reference source not found.**In this region, large τ_{440nm} values (>0.35) and large values of the AE(440-870 nm) suggested a situation with high aerosol load mainly composed of fine particles. At Athens both τ_{440nm} and AE(440-870 nm) values were very constant during the three analysed days, except for a slight decrease of the AE(440-870nm) on July 11 (from ~1.70 to ~1.30). This is in agreement with the columnar volume size distributions (Figure 3c), where a slight increase of the coarse mode was observed on July 11 when compared to July 9 and 10. In the case of Bucharest, τ_{440nm} was almost constant on July 9 and 10 (around 0.37), but increased on July 11 (over 0.60). The AE(440-870nm) was almost constant around 1.10 during the three days, indicating a balanced presence of coarse and fine particles despite the increase in the aerosol load during July 11. The columnar volume size distributions were very similar to those of Athens on July 9 and 10, but larger presence of fine particles was observed here on July 11. According to these sun-photometer data, the aerosol plume over this region was not composed of mineral dust particles, even though low concentrations of mineral dust might have been advected over Athens on July 11.

[Table 3]

[Figure 2]

4.1.2. Aerosol vertical distribution

[Figure 3]

Figure 3 shows the time series of the lidar range-corrected signal (RCS) in arbitrary units at 532 nm (at 1064 nm in Athens) for the 72-hour period at the different stations. From these plots, it is clearly observed that at Barcelona and Évora the aerosol load was mainly confined within the planetary boundary layer and the time series reveal the evolution of the planetary boundary layer height, even though at Barcelona some aerosol layers are observed in the free troposphere. Therefore, it is expected that most of the aerosol particles are from local origin. However, at the rest of the stations a more complex vertical structure was observed and the presence of lofted aerosol layer reaching up to 6 km asl at some periods indicated the advection of different aerosol types.

[Figure 4]

The aerosol microphysical properties profiles retrieved with LIRIC for different periods at the different stations are shown in Figure 4. Namely, the volume concentration profiles of the total coarse mode and the fine mode were retrieved at Barcelona and Athens, whereas the volume concentration profiles of fine, coarse spherical and coarse spheroid mode were retrieved at Évora, Bucharest and Granada because of the availability of depolarization information.

At Évora it was clearly observed that the aerosol was located below 1000 m asl, within the planetary boundary layer, and concentrations were very low, ranging from 25 to 46 $\mu m^{3} \cdot cm^{-3}$. No advected aerosol layers were observed for the analysed period.

At Granada a clear predominance of coarse spheroid particles reaching altitudes around 6000 m asl was observed on July 9, related to the mineral dust event. A small contribution of fine particles was also observed during the three days. Values of the volume concentration (below 50 $\mu m^{3} \cdot cm^{-3}$ for the total concentration) indicate a medium intensity dust event, which was considerably decreasing with time. Concentration values around 30 $\mu m^{3} \cdot cm^{-3}$ on July 9 for the coarse spheroid mode went down to values below 20 $\mu m^{3} \cdot cm^{-3}$. The altitude of the mineral dust layers was also decreasing from 6000 to 4000 m asl for the highest layers.

At Barcelona site, an aerosol layer dominated by fine particles with a slight presence of coarse particles was observed between 2000 and 4000 m asl on July 11, being these coarse particles possibly related to a faint presence of mineral dust. The 5-day backward trajectories analysis performed with HYSPLIT model [Draxler and Rolph, 2003] (not shown) indicates that air masses arriving at this altitude came from the North of Africa through the Iberian Peninsula. This information together with previous studies [e.g Wang et al., 2014], suggest that the mineral dust plume was moving from the North of Africa towards the Northeast, being detected at Granada and later on at Barcelona. However, the possibility of these coarse particles being linked to the presence of biomass burning from the Eastern Iberian Peninsula (see Figure 5) cannot be dismissed. Depolarization information would be crucial here to discriminate the origin of the aerosol particles arriving at this height above Barcelona and would provide very valuable information for the aerosol typing at the station.

At Athens station the aerosol reached up to 5000 m asl and total concentration values of up to 55 $\mu m^{3} \cdot cm^{-3}$ in the free troposphere. The coarse mode was located below 2000 m asl, whereas a predominance of fine particles was observed at higher altitudes. The top of the aerosol layer was increasing with time from 3800 to almost 5000 m asl. This temporal evolution of the microphysical properties is coherent with the optical properties shown in Sicard et al., [2015] for the same period. It is worthy to point out that on July 11, coarse particles were detected between 3000 and 4800 m asl at this station, probably related to the arrival of mineral dust as indicated by the column-integrated values. Backward trajectories analysis with HYSPLIT (not shown) revealed a change in the trajectory of the air masses arriving at 3500 m asl, coming from Northern Africa, which would explain the presence of mineral dust on July 11. However, according to the trajectories and the different characteristics, the mineral dust observed at Athens corresponds to a different plume than the one observed above Granada and faintly above Barcelona.

At Bucharest, similar volume concentration of fine and coarse particles was observed on July 9 and 10, reaching total volume concentration values around 35 $\mu m^{3} \cdot cm^{-3}$. The observed coarse particles were spherical according to LIRIC; therefore the presence of mineral dust at this region can be totally neglected. On July 11 a strong increase of the fine mode volume concentration was observed between 2500 and 5000 m asl, with values reaching up to 55 $\mu m^{3} \cdot cm^{-3}$, suggesting the advection of an aerosol plume dominated by fine particles at this altitude. Again, this is in agreement with the optical properties presented in Sicard et al. [2015], where a larger spectral dependence (related to fine particles) is observed at Bucharest station in the height range between 3 and 4 km asl. As suggested in the study by Sicard et al. [2015] this large spectral dependence of the backscatter coefficient could be originated by the presence of fine particles related to the advection of smoke. The combined information provided by backward trajectories analysis and MODIS FIRMS comes to confirm the presence of active fires along the air masses paths arriving at Bucharest on July 11 (Figure 5).

[Figure 5]

The use of the depolarization information as input in LIRIC in the stations of Bucharest, Évora and Granada provided additional information which is very valuable for aerosol typing. In the cases of Bucharest and Granada, this information turned out to be very useful for the characterization of the aerosol types and their distribution in the vertical coordinates. The differences in the aerosol type were already evidenced in the columnar volume size distributions retrieved by AERONET code (Figure 2), and here LIRIC confirmed that these two stations presented really different situations. The volume concentration profiles retrieved with LIRIC indicated a predominance of the spheroid mode in Granada and a predominance of spherical particles in Bucharest, highlighting very different aerosol composition in the coarse mode. However, at stations such as Barcelona or Athens where lidar depolarization was not measured, ancillary information, e.g. backward trajectories or sun-photometer-derived optical properties, was needed to discriminate if the coarse mode was related to non-spherical particles, usually associated to mineral dust, or to spherical particles, mostly present in cases of anthropogenic pollution or aged smoke. Therefore, here we have a clear example of the importance and the potential of the depolarization measurements in the vertical characterization of the aerosol particles and for aerosol typing.

4.1.3. Temporal evolution of the aerosol microphysical properties profiles

The continuous analysis of the aerosol microphysical properties profiles during the three days provided very valuable information about the dynamics of the aerosol layers and revealed LIRIC potential to retrieve information with high temporal resolution. Because of the uninterrupted lidar measurements at Granada from 12:00 UTC on July 9 2012 to 00:00 UTC on July 12 and the frequent AERONET retrievals due to good weather conditions a more detailed analysis was performed at this station. A total of 60 different LIRIC retrievals were performed based on 60 lidar datasets and 21 AERONET inversion products.The retrieval of microphysical properties was performed using 30-min averaged lidar data (in order to reduce noise on the lidar profiles) and the closest in time AERONET retrieval, considering only those data with time differences lower than three hours.

Besides, Granada station was affected by a mineral dust event during the whole period as already shown in previous sections. This fact is of special interest since the retrieval of the mineral dust microphysical is not so straightforward and they are not so well characterized. Up to our knowledge not many comprehensive studies on dust microphysical properties vertical profiles have been performed [Tsekeri et al., 2013; Wagner et al., 2013; Granados-Muñoz et al., 2014; Noh, 2014] because of the difficulty of the retrievals due to different factors, e. g. the high temporal variation and non-uniform distribution of dust aerosol concentration around the globe [Sokolik and Toon, 1999; Formenti et al., 2011], mineral dust highly irregular shape and the chemical and physical transformations dust suffers during its transport [Sokolik and Toon, 1999; Chen and Penner, 2005; Formenti et al., 2011].

The dust outbreak analysed here started over Granada station on July 7 in 2012 as indicated by sun-photometer data and the model forecast from previous days (not shown). Thus, it was already well developed when the intensive measurement period started. The 5-day backward trajectories analysis performed with HYSPLIT model indicated that the air masses arriving at Granada on July 9 and 11 came from Africa passing by the North African coast above 2500 m asl and from the North Atlantic Ocean through South-western Iberian Peninsula below this altitude (Figure 6). On July 10 the air masses came from the central part of the Sahara desert through the North African coast for heights above 5000 m asl, from the Atlantic Ocean going along the coast of Africa between 2500 and 5000 m asl and from the North Atlantic Ocean overpassing the South-western Iberian Peninsula below 2500 m asl.

[Figure 6]

Figure 7 shows the time series of the volume concentration profiles retrieved with LIRIC. It is clearly observed that the dust event was decreasing its intensity along the whole study period with the largest aerosol concentrations for the coarse spheroid mode retrieved on July 9 (~35 $\mu m^3/cm^3$) and the lowest concentrations on July 11 (~15 $\mu m^3/cm^3$), in agreement with AERONET data. Maximum values of total volume concentration were around 60 $\mu m^3 \cdot cm^{-3}$ on July 9. There was a strong predominance of the coarse spheroid mode during the whole period with maximum values on July 9 in the afternoon, reaching values up to 55 $\mu m^3 \cdot cm^{-3}$. Some fine particles were also observed, with larger volume concentrations during the first day (~10 $\mu m^3 \cdot cm^{-3}$). For this first day of measurements, fine particles reached altitudes around 6000 m asl, whereas on July 10 and 11 larger volume concentration values were confined to the lowermost region from surface up to 3 km asl. The presence of this fine mode in the upper layers might be related to the advection of anthropogenic pollutants coming from Moroccan industrial activity in the North of Africa mixed with the mineral dust as reported in previous studies [Basart et al., 2009: Rodríguez et al., 2011; Valenzuela et al., 2012; Lyamani et al., 2014; Valenzuela et al., 2014]. Figure 6b reveals that air masses overpassed North African industrial areas before reaching Granada. However, it is also well known that mineral dust emissions produce a submicronic size mode [e.g. Gomes et al., 1990; Alfaro and Gomes, 2001]. Depolarization lidar observations over the Mediterranean have illustrated that irregularly shaped fine dust particles significantly contribute to aerosol extinction over the boundary layer during dust transport events [Mamouri and Ansmann, 2014]. A more detailed analysis with additional data (e.g. chemical components measurements, single scattering albedo profiles) would be needed in order to come to a quantitative attribution of soil dust and anthropogenic particles to the fine mode.

The contribution of the fine mode in the lowermost part may be due mainly to anthropogenic sources of local origin. From July 11 around 12:00 UTC up to the end of the study period, an increase in the coarse spherical mode concentration was observed. This increase of the coarse spherical mode was associated with a decrease of the particle linear depolarization profiles δ^{p}_{532nm} obtained from the lidar data according to *[Bravo-Aranda et al., 2013]* as shown in Figure 8. On July 9 the values of δ^{p}_{532nm} were around 0.30 in the layer between 3 and 5 km asl. These values are representative of pure Saharan dust [Freudenthaler et al., 2009]. However, they decreased down to 0.25 during the following days, indicating either a possible mixing of dust particles with anthropogenic aerosols or aging processes affecting the mineral dust. During July 10 in the late afternoon and July 11, a decrease in the fine mode in coincidence with an increase in the coarse spherical mode was observed. The simultaneous decrease of the fine mode and increase of the coarse spherical particles together with the decrease in δ^{p}_{532nm} point out to processes such as mineral dust aging and/or aggregation processes. However, additional analysis would be necessary to confirm this hypothesis.

According to δ^{p}_{532nm} profiles, a mineral dust layer was clearly located above 2500 m asl or even at higher altitudes depending on the analysed period (see Figure 10). Below this altitude, values were lower indicating a mixing of the mineral dust with anthropogenic particles from local origin. In the case of LIRIC, these vertical structures were not so clearly defined and a more homogeneous structure was detected. Values of the fine and coarse mode volume concentration presented very low variations with height when compared to δ^{p}_{532nm} profiles. This vertical homogeneity is related to the assumption of height independency of properties such as the refractive index, size distribution of the modes or the sphericity, which according to the results presented in previous studies [Wagner et al., 2013; Granados-Muñoz et al., 2014], is an issue that needs to be carefully considered in the analysis of the results retrieved with LIRIC algorithm.

[Figure 7]

[Figure 8]

Despite the limitations in the use of LIRIC, the analysis presented here shows that LIRIC can reliably provide microphysical properties profiles with high vertical and temporal resolution even in cases of mineral dust. LIRIC algorithm can be a useful tool to detect changes in the aerosol composition possibly associated to processes affecting the mineral dust particles such as aging or nucleation, even though additional information is needed for more in-depth analysis.

4.2. EVALUATION OF THE MINERAL DUST MODELS

In order to obtain a general overview of the dust horizontal extension, Figure 9 shows the standard aerosol optical depth product retrieved using the dark-target approach from MODIS/Terra [Remer et al., 2005 and references therein] and the AERUS-GEO from MSG/SEVIRI [Carrer et al., 2014] for the three analysed days (9-11 July 2012).

[Figure 9]

Satellite data evidence the presence of an aerosol plume extending from the North African coast towards the East with higher aerosol load, as τ_λ values from MODIS sensor indicate, mainly affecting the South-East of the Iberian Peninsula and the South of Italy (Figure 9). As indicated by the data presented in the previous section, this plume corresponds to the mineral dust event, whereas a different plume is observed above the Balkans area. The pathways of the aerosol plumes suggested by satellite data are in agreement with both the meteorological analyses of ECMWF and HYSPLIT air mass trajectories based on GDAS analysed meteorological fields at 2 km a.g.l. presented in the study by Wang et al., [2014]. The air masses were moving from Spain and Portugal to the East whereas in the Balkans region they were moving southwards.

[Figure 10]

τ_{550nm} data simulated by BSC-DREAM8b, DREAM8-NMME NMMB/BSC-Dust and COSMO-MUSCAT are shown in Figure 10. In general, when comparing to the satellite data in Figure 9, the aerosol plume located above the Balkans region is not captured by the models. This is not surprising, since it is not composed of mineral dust particles, as indicated by our aerosol volume concentration profiles, shown in the previous section and suggested in previous studies [e.g. Sicard et al., 2015]. The different models correctly forecast the dust plume leaving the North of Africa and moving towards the East and the dust plume reaching Athens, as also indicated by satellite data. However, the decrease in τ_{550nm} values with time observed with satellite data and in LIRIC profiles is not well captured by any of the different models. Regarding the extension of the dust event, in general it is better captured by BSC-DREAM8b and NMMB/BSC-Dust, whereas COSMO-MUSCAT and DREAM8-NMME tend to overestimate the mineral dust horizontal extension when compared to the satellite data.

Focusing on the five satiations analyzed in this study, the models showed that Granada station was affected by the mineral dust outbreak during the whole analyzed period, in agreement with the analyzed data. No presence of mineral dust was forecast above Évora as expected from the measurements, except for COSMO-MUSCAT, which predicted fair low values of dust τ_{550nm} above the station. BSC-DREAM8b, DREAM8-NMME and NMMB/BSC-Dust indicated no presence of dust above Barcelona, even though it was located close to the edge according to BSC-DREAM8b. As in the case of Évora, almost negligible values were forecast above the station by COSMO-MUSCAT. This would be in agreement with the previous data except for the possible dust layer observed on July 11.

In the Eastern region, the station of Athens was affected by mineral dust during the three days according to DREAM8-NMME model and COSMO-MUSCAT, only on July 10 according to NMMB/BSC-Dust and on July 10 and 11 according to BSC-DREAM8b. As indicated by the analysis in the previous section, mineral dust was observed only on July 11 and the models seem to not completely capture the event at Athens. However, in this case the situation is quite more complex than in the western stations. Athens is located at the edge of the mineral dust plume during the three analyzed days. Slight changes in the horizontal distribution of the dust related to the models uncertainty and the relatively coarse horizontal resolution may highly influence the results. In the case of Bucharest, BSC-DREAM8b, DREAM8-NMME and NNMB/BSC-DUST foresaw no influence of the mineral dust. Conversely, COSMO-MUSCAT forecast mineral dust during the three days, with larger loads on July 10 and 11, overestimating the extension of the mineral dust plumes as previously stated.

Due to the relatively coarse horizontal resolution of the model data presented in Figure 10 compared to the single-site measurements at the five analyzed stations, it is worthy to evaluate in more detail the mineral dust mass concentration profiles provided by the models at the specific locations of our interest. To perform this evaluation, mineral dust mass concentration profiles provided by the BSC-DREAM8b, NMMB/BSC-Dust, DREAM8-NMME and COSMO-MUSCAT models are evaluated against LIRIC results. The main focus is at Granada station since this site presents a larger number of mineral dust profiles due to the characteristics of the mineral dust event and allows evaluating the temporal evolution of the dust microphysical properties.

Figure 11 shows the dust mass concentration profiles provided by the four models and LIRIC every 3 hours from July 9 at 15:00 to July 11 at 18:00. From the profiles presented in Figure 12, C_m, the integrated mass concentration for each profile and the correlation coefficient, R, between LIRIC and the different models are calculated and presented in Figure 12. Figure 13 shows the profiles of statistical parameters such as R obtained for LIRIC and the models time series, RMSE, NMB and NMSD, calculated as described in Section 3 for every altitude level. This three figures needs to be analyzed and discussed as a whole in order to cover all aspects of the model performance regarding the temporal and vertical coordinates. An independent interpretation of each of the presented statistical parameters might be misleading at some points and lead to erroneous conclusions.

According to Figures 11, 12 and 13, BSC-DREAM8b shows a good temporal correlation with LIRIC, providing larger values on July 9 than on July 10 and 11, as observed in the experimental data. The correlation coefficient R between BSC-DREAM8b and LIRIC time series is larger than 0.5 for most of the altitudes (Figure 13a). However, the model strongly underestimates the aerosol load during the three studied days, as indicated by the NMB in Figure 13c. Positive and larger than 0.5 values of R and the small difference between LIRIC and BSC-DREAM8b values of C_m during most of the analyzed period in Figure 12 indicate that BSC-DREAM8b provides a good estimation of the mineral dust vertical distribution.

A relatively good performance of DREAM8-NMME is observed up to July 10 at 06:00 UTC, when τ_{440nm} was larger than 0.2. During this period the model captured quite well the maximum values and the aerosol load as observed in Figure 11 and indicated by the integrated mass concentration values in Figure 12, close to those obtained with LIRIC. Despite this good performance during the first part of the analyzed period, NMB values in figure 13c suggest an overall underestimation of the aerosol load below 5000 m asl, where it is higher, and overestimation above 5000 m asl, where concentration values are lower according to LIRIC. From 3500 m asl, good temporal correlation is observed between LIRIC and DREAM8-NMME, but R goes close to 0 below this altitude (Figure 13a). Regarding the vertical distribution of the load, C_m values in Figure 12 present very small differences with LIRIC before July 10 at 06:00, but this difference increased afterwards. Absolute values of R in figure 12 are usually larger than 0.5 and larger than those retrieved for the other models, indicating good correlation. However, they oscillate from negative to positive values, indicating a vertical shift in the location of the dust layers during some of the analyzed periods.

NMMB/BSC-Dust shows better performance on July 9, with τ_{440nm} values around 0.3, especially in the layer between 2500-6000 m asl. The difference between LIRIC and the model integrated mass concentration is also lower during July 9. However, in general the model tend to underestimate the aerosol load below 4.5 km asl (Figure 13c). Overestimation of the mass concentration is observed above this altitude though. NMMB/BSC-Dust correctly follows the aerosol load decrease with time as indicated by positive correlation values in Figure 13a, but it presents lower temporal correlation compared to the other models (except for COSMO-MUSCAT). Values of C_m in Figure 12 are close to those of LIRIC indicating that it correctly forecast the location of the aerosol load. Nonetheless, low values of R indicate that the vertical distribution of the aerosol layers needs to be improved. For this model it is worthy to point out the un-realistic increasing maximum at 5000 m asl at 15:00 and 18:00 on July 10 (Figure 11). However, this maximum is very similar to the one provided by LIRIC between 06:00 and 12:00 UTC. Therefore, it could be due to a time shift of the model when compared to the LIRIC values. To check this hypothesis, correlation between LIRIC and the models considering a 3 hours delay is calculated (Supplementary Figure S5). Correlation between LIRIC and NMMB/BSC-Dust for simultaneous data is on average below 0.5 (Figure 13a), indicating that the model does not reproduce very well the temporal evolution of the dust profiles. This correlation slightly increases between 3500 and 4500 m asl when considering a 3 hours delay between LIRIC and the model, but decreases at the other altitudes. Therefore, it does not appear to be a systematic delay between the model and LIRIC profiles. However, in the future it will be beneficial for the modeling community to gather a more extended database of continuous lidar measurements with similar characteristics to the one presented here in order to further explore and improve the possible existence of delays between the models forecast and experimental data.

COSMO-MUSCAT shows an increase in the mineral dust load during the analyzed period with an increasing maximum approximately located between 4 and 5 km. This behavior is totally opposite to the one observed in LIRIC profiles that show a decrease of the volume concentration with time, as indicated by the negative values of R in Figure 13a. According to the integrated mass concentration values in Figure 12, COSMO-MUSCAT underestimates the dust load during the first half of the analyzed period, whereas an overestimation of the dust load occurs in the second half. These two opposite behaviors seem to cancel and, as a result, NMB values in Figure 13c are closer to zero below 4 km than for the other models, leading to erroneous conclusions. The location of C_m and R values in Figure 12 indicate a good performance of the model regarding vertical distribution on July 9, 11 and the afternoon of July 10. Again, negative R values indicate a vertical shift in the location of the maximum concentration values during some periods, as observed also in Figure 11.

The four models have shown to have advantages and disadvantages, but a clear superior performance of any of the four has not been observed. As a general result, the four models tend to underestimate LIRIC values during the whole period, except for COSMO-

MUSCAT that clearly overestimate the dust mass concentration from the afternoon of July 10 onwards. DREAM8-NMME and NMMB/BSC-Dust show a better performance, both regarding the dust load and the temporal evolution of the event when the aerosol load observed with the ground-based instrumentation is higher. The temporal evolution of the event is mostly followed by the BSC models (namely BSC-DREAM8b, DREAM8-NMME and NMMB/BSC-Dust models) as indicated by the positive correlation with LIRIC time series, whereas COSMO-MUSCAT shows and opposite behavior (Figure 13a). BSC-DREAM8b shows the minimum values of the RMSE below 4 km, where most of the aerosol load is located, and maximum values are obtained for DREAM8-NMME. However, no statistically significant difference between the models is clearly observed. BSC-DREAM8b, DREAM8-NMME and COSMO-MUSCAT are not able to capture the high temporal variability observed with LIRIC, as indicated by the large absolute values of NMSD in Figure 13d. They range between -0.5 and -1 below 6 km asl for COSMO-MUSCAT and BSC-DREAM8b and between -1 in the lower altitudes to 2 at the upper levels for DREAM8-NMME. NMMB/BSC-Dust shows a good performance in this case with values close to 0 from 3 km upwards.

The location of C_m, which is an indicator of the vertical distribution of the dust mass concentration, is similar in the case of LIRIC and the models (Figure 12). Despite the models were capable to reproduce the temporal evolution of C_m, in general they tended to locate the dust load at higher altitudes, as indicated by the larger values of C_m obtained. Discrepancies are especially relevant in the case of DREAM8-NMME after July 10 in the afternoon. During this event, BSC-DREAM8b model presented the lowest differences with LIRIC regarding C_m height. COSMO-MUSCAT and NMMB/BSC-Dust presented the lower discrepancies on July 11. These results are comparable to those in the study by Binietoglou et al., [2015].

Even though they forecast the C_m fairly well, the analyzed models provided much smoother profiles than the ones retrieved with LIRIC, with usually a single-broad maximum located at different altitudes depending on the model. This result is not surprising due to the coarser vertical resolution of the models compared to lidar profiles, which can provide more detailed information about the vertical structures of mineral dust. The vertical correlation between the models, shown in Figure 12b, oscillates between positive and negative values, indicating a shift in the location of the maximum peaks in those cases when it is negative. R values range between 0.01 and 0.85 in absolute value. The correlation obtained in the present analysis is lower than the ones presented in Binietoglou et al., [2015], where most of the data presented determination coefficient (R^2) values above 0.5. This is related to the fact that in the study by Binietoglou et al., [2015] selected mineral dust events with higher aerosol load (τ_{440}>0.15) were presented whereas in this study the continuous evolution of the dust event was analyzed with τ_{440} ranging between 0.07 and 0.40. Therefore, according to the present study models seem to show a better performance in cases of higher aerosol load.

[Figure 11]

[Figure 12]

[Figure 13]

Model profiles were also obtained at the stations of Athens, Barcelona, Bucharest and Évora in order to evaluate their performance at stations where there is a slight or no presence of mineral dust. At Athens (Figure S1 from Supplementary material) almost negligible mass concentration values were forecast by the different models, with the exception of DREAM8-NMME. This model indicated the presence of mineral dust in mass concentrations up to 100 $\mu g \cdot m^{-3}$ reaching 4000 m asl on July,10 and up to 65 $\mu g \cdot m^{-3}$ on the July 11 which is not in agreement with LIRIC results. In spite of the disagreement, it is worthy to point out that the dust layer observed at Athens between 3000 and 5000 m asl on July 11 according to LIRIC data was correctly forecast by the different models. At Barcelona station (Figure S2), DREAM8-NMME were not in agreement with the experimental results since it forecasted dust mass concentrations of up to 100 $\mu g \cdot m^{-3}$ and located below 2000 m asl. At Bucharest (Figure S3), large dust concentrations were forecasted between 3000 and 7000 m asl by BSC-DREAM8b, DREAM8-NMME and NMMB/BSC-Dust on July 9. On July 10 and 11 the dust load forecasted by the models was much lower, even though it reached up to 50 $\mu g \cdot m^{-3}$. This is not in agreement with our experimental results since only coarse spherical and fine particles and no mineral dust should be forecasted here. Finally, at Évora station (Figures S4), DREAM8-NMME forecasted dust mass concentration lower than 10 μg·m^{-3} below 2000 m asl COSMO-MUSCAT forecasted similar concentrations above 2000 m asl These mass concentration values are almost negligible and therefore good agreement can be considered. In general, good results were provided by the different models at the five stations. However, DREAM8-NMME seems to be overestimating the dust mass concentrations at those stations affected by aerosol types different to mineral dust.

An in-depth analysis of the causes for the discrepancies between the models and LIRIC is out of the scope of this study, especially taking into account that they showed a similar performance here, with none of them proving to be more accurate than the others. In general we observed that the BSC models showed a similar behavior when compared with COSMO-MUSCAT, based on a different philosophy. However, none of them showed a statistically significant better performance. Differences between the obtained results lie on the different approaches used in the different models, the different meteorological fields used, dust sources, horizontal and vertical transport schemes, different resolutions, etc., as already pointed out in Binietoglou et al., [2015]. Robust conclusions at this respect cannot be withdrawn from this study and would require wider databases with higher temporal and spatial coverage in order to cover the different aspects of the model calculations and more dedicated studies. Nonetheless, the comparison presented here provided valuable results since it addresses the points of discrepancy and proves LIRIC potential as a tool for future model evaluations. Information inferred from the results obtained here could be used for the planning of future validation strategies and campaigns management.

5. SUMMARY AND CONCLUSIONS

In this study, the characterization of aerosol microphysical properties at different stations throughout Europe was performed in the framework of the ChArMEx/EMEP 2012 field campaign, in support to which EARLINET lidar stations performed continuous measurements during the 72 hours. LIRIC profiles were obtained at five different stations in Europe (i.e. Athens, Barcelona, Bucharest, Évora and Granada) in order to characterize atmospheric aerosol particles both in the vertical and horizontal coordinates and also their temporal evolution during this period. From the analysis of the aerosol microphysical properties at the different stations, two different aerosol plumes were clearly observed: one affecting the Western Mediterranean region, loaded with mineral dust, and another one over the Balkans area, mainly composed of fine particles and coarse spherical particles. Granada station was clearly affected by the mineral dust outbreak during these 72 hours, whereas mainly aerosol from local origin was affecting Évora and Barcelona. The dust plume was also observed above Barcelona on July 11. A mixture of fine and coarse spherical particles was observed over Bucharest, likely related to the presence of smoke from European fires, whereas at Athens mainly fine particles were observed, except on July 11, when mineral dust of different origin from the one in Granada and Barcelona was observed at 3.5 km asl as indicated by the backward trajectories analysis.

A thorough evaluation of the temporal evolution and the aerosol layers dynamics was possible at Granada station, where a total of 60 lidar profiles every 30-min and 21 AERONET inversion retrievals were available. The analysis of the microphysical properties profiles retrieved with LIRIC indicated that the dust event was decreasing in intensity, with larger concentrations on July 9 (~35 $\mu m^3 \cdot cm^{-3}$) decreasing towards July 11 (~15 $\mu m^3 \cdot cm^{-3}$), in agreement with AERONET and satellite data. On July 9 there was a strong predominance of the coarse spheroid mode with maximum values in the afternoon while an increase in the concentration of the coarse spheroid mode up to 15 $\mu m^3 \cdot cm^{-3}$ was observed during the afternoon of July 11. This temporal evolution of the microphysical properties reveals possible aging processes of the mineral dust above the station or even mixing processes with different aerosol types.

These results provide a good overview of the aerosol microphysical properties in the Mediterranean region during ChArMEx campaign. They also highlight the importance of having combined regular AERONET/EARLINET measurements for the characterization of aerosol microphysical properties in the vertical, horizontal and spatial coordinates with high resolution by means of algorithms such as LIRIC and suggest the importance of extending this kind of measurements. Our study remarks the capability of LIRIC to be implemented in a simple, automated and robust way within a network such as EARLINET and during special measurement campaigns obtaining reliable results. In addition, the advantages on the use of depolarization measurements with lidar systems are also emphasized here, since the stations with depolarization capabilities (namely Bucharest, Évora and Granada) provided much more complete information about the microphysical properties profiles.

The availability of LIRIC output profiles at the five different stations provided regional coverage and made possible a comparison with the modelled dust fields provided by BSC-DREAM8b, NMMB/BSC-Dust, DREAM8-NMME and COSMO-MUSCAT. The regional comparison revealed quite good agreement with the horizontal distribution of the dust plume forecast by models (based on a similar philosophy), but lower agreement for COSMO-MUSCAT over the Balkans region.

A more detailed comparison using dust mass concentration profiles derived every 3 hours from 06:00 to 18:00 UTC over the 3 days of interest was also performed. The four models tended to underestimate the dust mass concentration when compared to LIRIC results, except for COSMO-MUSCAT on the afternoon of July 10 and on July 11 that overestimated it. The overall underestimation of the dust mass concentration was between 80 and 100% for altitudes below 4 km depending on the model. Above this altitude, DREAM8-NMME and NMMB/BSC-Dust tended to overestimate the dust mass concentration values reaching up to 150% overestimation. The agreement between LIRIC and the models was better when determining the vertical location of the mineral dust load, even though the models tended to locate the mineral dust at higher altitudes than seen by lidar, as indicated by the determination coefficient values and the center of mass location. The correlation coefficient between LIRIC and the models reached absolute values of up to 0.85, even though in most of the cases the maximum peaks where shifted when compared to LIRIC showing anticorrelation. The difference in the center of mass location was below 1 km in 65% of the cases.

A comparison between LIRIC and the models was also performed at the stations of Évora, Barcelona, Athens and Bucharest. In general, good agreement was obtained for BSC-DREAM8b, NMMB/BSC-Dust and COSMO-MUSCAT when no dust is observed. DREAM8-NMME indicated the presence of mineral dust in large concentrations in Athens, Barcelona and Évora, opposite to LIRIC results, which indicated and almost negligible or no presence of mineral dust. BSC-DREAM8b, NMMB/BSC-Dust and DREAM8-NMME forecast the presence of mineral dust in the vertical coordinate in Bucharest station, where LIRIC indicated the presence of a different aerosol type (mostly fine and spherical particles), suggesting that COSMO-MUSCAT philosophy is more adequate for this specific case and location.

The four analyzed models present advantages and disadvantages but none of them showed a statistically significant better performance when evaluated against LIRIC results. In general, the three BSC models showed more similar results compared against COSMO-MUSCAT, based on a different philosophy. But further conclusions regarding the differences between the models cannot be withdrawn from our study. A more detailed analysis based on a wider and more specific database designed to cover the different aspects of the model calculations would be required. Results presented here are valuable since they prove LIRIC potential as a tool for model evaluation and provide valuable information for the planning of future validation strategies and campaign management.

Figure captions:

Figure 1. Stations where LIRIC algorithm was been applied during ChArMEx/EMEP 2012 intensive measurement period on 9th-11th of July. Source: Google Earth.

Figure 2. a) AERONET Level 1.5 retrieved τ_{440nm} and b) AE(440-870nm) during CHARMEX 2012 campaign at the five stations(see Table 1 for station descriptions). c) AERONET Version 2 Level 1.5 size distributions retrieved for 9th, 10th and 11th July. n/d indicates no data availability.

Figure 3. RCS at 532 nm (1064nm at Athens) in arbitrary units for the five stations during ChArMEx 2012 measurements campaign.

Figure 4. Volume concentration profiles of the total coarse mode and the fine mode at Barcelona and Athens, and volume concentration profiles of fine, coarse spherical and coarse spheroid mode at Évora , Bucharest and Granada (from left to right) for different periods of the 9th, 10th and 11th of July 2012 (from top to bottom).

Figure 5. MODIS FIRMS image indicating the active fires during the five previous days to the 11th July 2012. The red line correspond to the air-mass 5-day back-trajectory arriving over Bucharest at 3000 m asl on 11th of July 2012.

Figure 6. a) 5-day backward trajectories arriving over Granada on 9th, 10th and 11th July 2012 at 12:00 UTC (from left to right) computed by HYSPLIT model. b) Locations of the main industrial activity in the North of Africa (brown stars)taken from Rodriguez et al., [2011] together with the 5-day backwards trajectories arriving at Granada experimental site on 9th July 2012 at 12:00 UTC.

Figure 7. Time series of the volume concentration profiles (in $\mu m^3/cm^3$) for the fine mode (upper part), coarse spherical mode (middle part) and coarse spheroid mode (lower part) for days 9th, 10th and 11th July 2012 (from left to right).

Figure8. Time series of the δ^{p}_{532nm} profiles retrieved from Granada lidar system at different time intervals during during ChArMEx July 2012 intensive measurement period. Dark blue color represents regions and time periods where no data were retrieved.

Figure 9. τ550nm from MODIS/Terra (top) and τ675nm daytime mean from MSG-SEVIRI (bottom) on 9th, 10th and 11th of July.

Figure 10. τ550nm forecast by a) BSC-DREAM8b, b) DREAM8-NMME c) NMMB/BSC-Dust and d) COSMO-MUSCAT models for 9th, 10th and 11th July 2012 at 12:00 UTC over Europe and North Africa. The yellow stars represent the location of the stations where microphysical properties profiles are retrieved with LIRIC.

Figure 11. Dust mass concentration profiles obtained with LIRIC (dotted line) and BSC-DREAM8b-v2, DREAM8-NMME, DREAMABOL, NMMB/BSC-Dust for Granada station every three hours on 9th, 10th and 11th of July 2012.

Figure 12. (from top to bottom)Time series of the integrated mass concentration values (above 2 km in altitude) retrieved from LIRIC and the four evaluated models vertical profiles for the period between 15:00 UTC on 9th of July 2012 and 18:00 UTC on 11th of July 2012. Time series of the correlation coefficient R, between LIRIC-derived mass concentration profiles and each one of the four evaluated models for the same period. Time series of the dust center of mass, C_m, obtained from LIRIC and the models profiles.

Figure 13. Vertical profiles of the correlation coefficient between LIRIC and the models time series for every altitude level, the root mean square error RMSE, the normalized mean bias NMB and the normalized mean standard deviation NMSD.

Supplementary material:

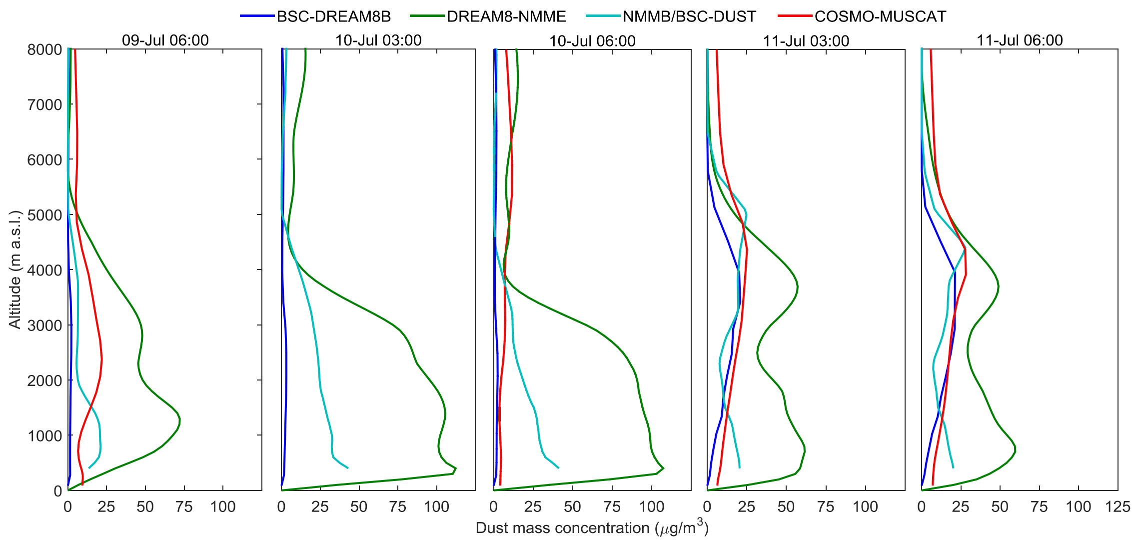

Figure S1. Dust mass concentration profiles forecast by BSC-DREAM8b-v2, DREAM8-NMME, NMMB/BSC-Dust and COSMO-MUSCAT at Athens in the period 9 July 2012-11 July 2012. Only those data coincident with AERONET inversion retrievals (± 3 hours) has been presented here.

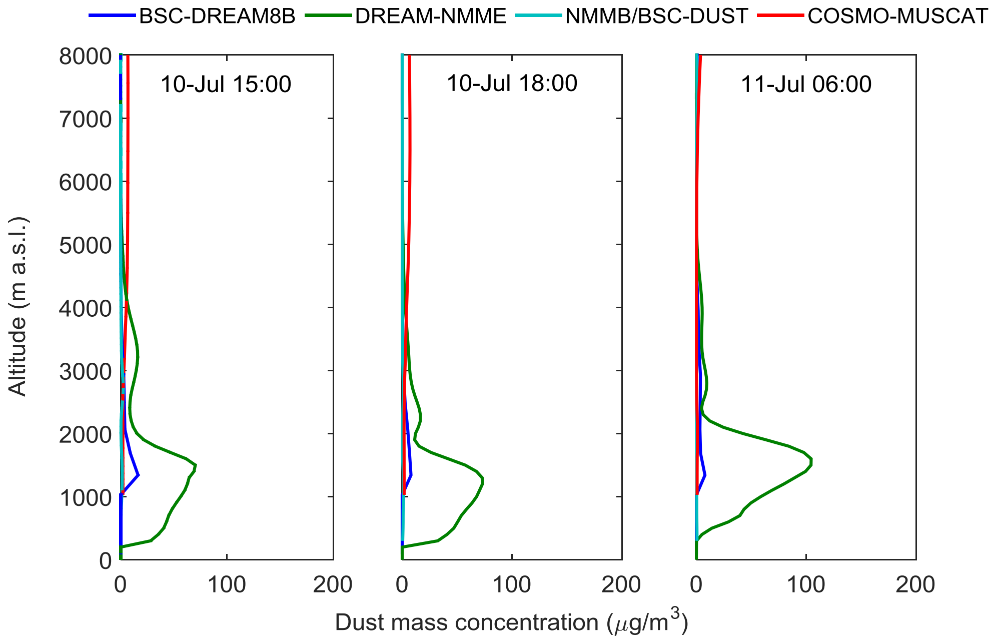

Figure S2. Dust mass concentration profiles forecast by BSC-DREAM8b-v2, DREAM8-NMME, DREAMABOL and NMMB/BSC-Dust at Barcelona in the period 9 July 2012-11 July 2012. Only those data coincident with AERONET inversion retrievals (± 3 hours) has been presented here.

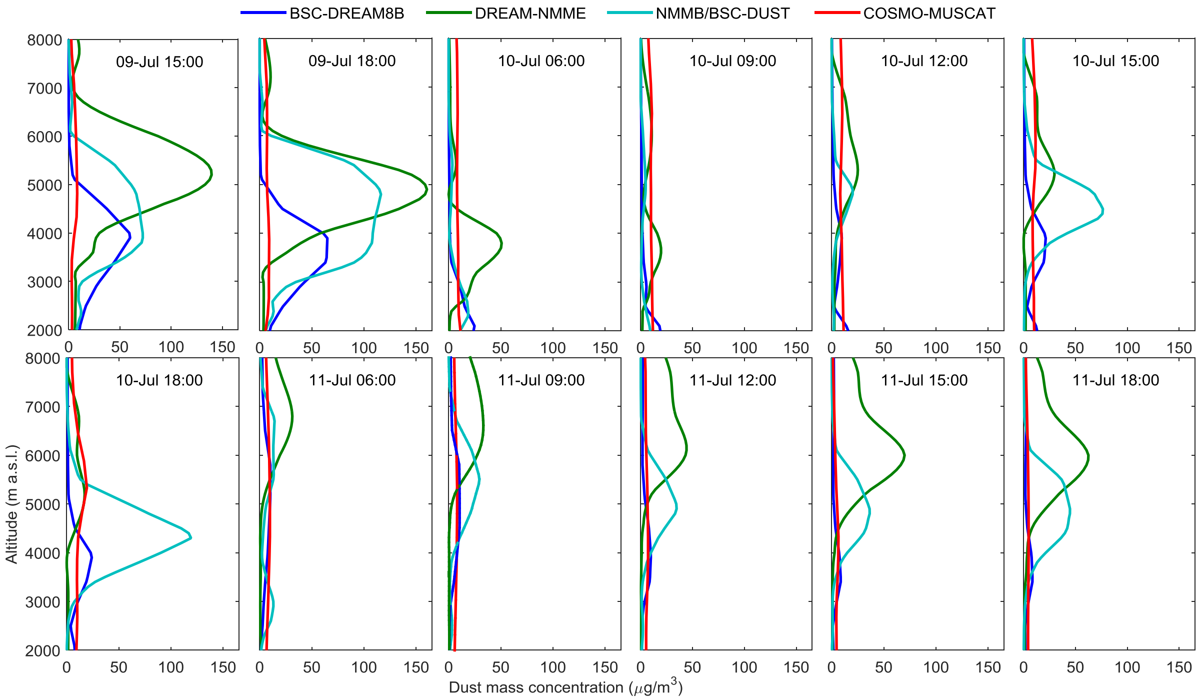

Figure S3. Dust mass concentration profiles forecast by BSC-DREAM8b-v2, DREAM8-NMME, NMMB/BSC-Dust and COSMO-MUSCAT at Bucharest in the period 9 July 2012-11 July 2012. Only those data coincident with AERONET inversion retrievals (± 3 hours) has been presented here.

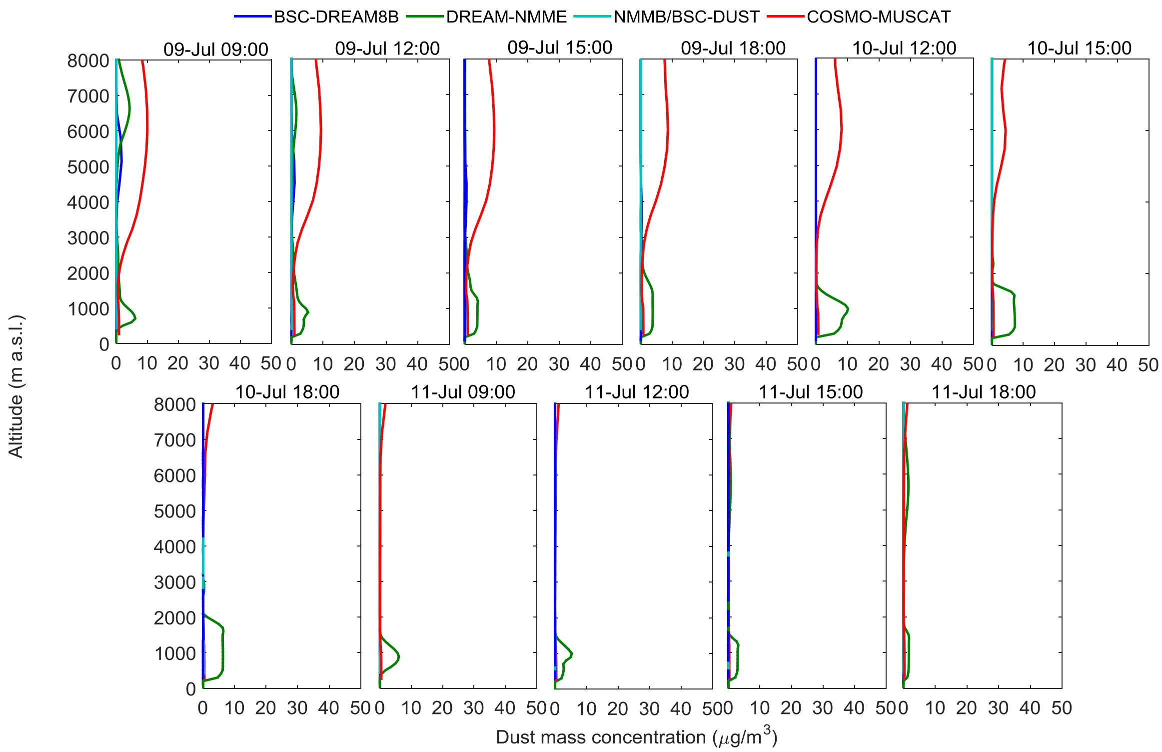

Figure S4. Dust mass concentration profiles forecast by BSC-DREAM8b-v2, DREAM8-NMME, NMMB/BSC-Dust and COSMO-MUSCAT at Évora in the period 9 July 2012-11 July 2012. Only those data coincident with AERONET inversion retrievals (± 3 hours) has been presented here.

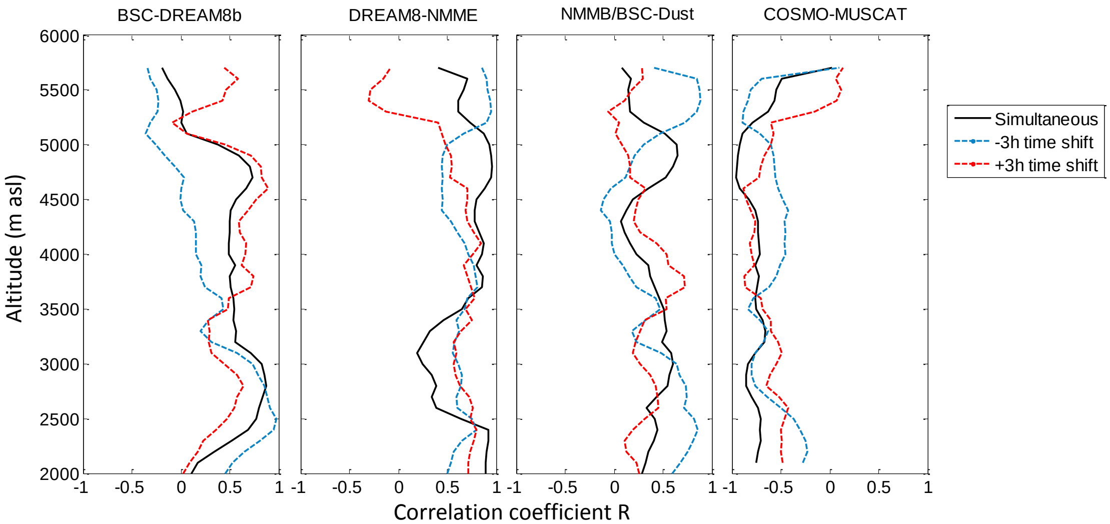

Figure S5. Correlation coefficient R between simultaneous LIRIC and modelled time series (solid black lines) for every altitude level. Dashed lines represent R values obtained for the modelled time series and LIRIC time series with a time shift of plus (red line) and minus (blue line) 3 hours.
