47 AMS Organic Aerosol Source Apportionment

48 Source apportionment analysis on the high resolution organic aerosol (OA) mass spectra
49 provided by the AMS was made using the Multilinear Engine algorithm (ME-2) developed by
50 *Paatero* [1999] and the interface Solution Finder (SoFi 4.9) [*Canonaco et al.*, 2013]. Prior to
51 analysis, the organic matrix was prepared according to the recommendations of *Ulbrich et al.*
52 [2009]. First, isotope ions were removed and a minimum counting error was applied. Fragments
53 with a signal-to-noise ratio (SNR) below 0.2 were down-weighted by a factor of 10 and
54 fragments with a SNR between 0.2 and 2 were down-weighted by a factor of 2. Finally, the
55 fragments related to ion CO_2^+ were also down-weighted since they are calculated as a constant
56 fraction of the ion CO_2^+ [*Allan et al.*, 2004]. Elemental analysis on the mass spectra of the
57 identified factors was performed using the Analytic Procedure for Elemental Separation (APES
58 vers. 1.06) based on *Aiken et al.* [2007, 2008] and including the improved estimation from
59 *Canagaratna et al.* [2015].

60 For the first attempt, a non-constrained approach was investigated using a factor number
61 ranging from 1 to 6 and applying 10 seeds (Figure S1). The best solution was obtained for the 4-
62 factors solution (Figure S2) including 3 different oxygenated OA (OOA-a, OOA-b and OOA-c)
63 and a mixed-sources factor (mix-OA). The mix-OA factor contributes to 16% of the total OA
64 and it has a mass spectrum with ions typically associated with hydrocarbon-like OA and shows
65 the lowest O/C (oxygen/carbon) ratio (0.28) compared to the other factors. Although, it indicates
66 that this factor can be related to primary OA, its elemental ratios are higher than reported
67 Hydrocarbon-like OA (HOA) factors [*Canagaratna et al.*, 2015]. This factor also has a large
68 contribution of oxygenated fragments at m/z 43 (CHO^+) and 44 (CO_2^+) compared to previously
69 reported HOA factors. Regarding its time variation, this factor correlates relatively well with
70 gas-phase primary emissions tracers (e.g., benzene ($r=0.35$), toluene ($r=0.48$)) and particulate
71 black carbon (BC, $r=0.49$) as well as with semi-volatile inorganic compounds (e.g., nitrate
72 ($r=0.57$)). Therefore, considering the mass spectrum and time series particularities, this factor
73 was identified to represent a mixture of Hydrocarbon-like OA (HOA) and semi-volatile OA (SV-
74 OOA). The three OOA factors have quite similar mass spectra, but they present clear distinct
75 time trends. Therefore, they are considered as separate factors and identified as follows:

76
77 - OOA-a (10% of total OA) appears to be specific to a certain time period of the campaign
78 characterized by high temperature, a high pressure system, and stagnant air masses. Therefore,
79 this OOA-a factor can be related to an accumulation of aged particles on the regional
80 background. The OOA-a mass spectrum is dominated by oxygenated ions and shows the highest
81 O/C ratio (1.02) in agreement with aged OA.

82
83 - OOA-b (30% of total OA) is the least oxygenated OOA factors (O/C = 0.55). It also correlates
84 well with sulfate ($r=0.58$), but also with methanesulfonic acid (MSA, $r=0.60$). Therefore, this
85 suggested that OOA-b might be related to marine OA rather than continental OA. This is in
86 agreement with previous measurements made at the same location by *Saarikoski et al.* [2012],
87 who reported a factor with a source originating from the Mediterranean Sea.

88
89 - OOA-c (44% of total OA) correlates with particulate sulfate ($r=0.55$) but not with MSA,
90 opposite to OOA-b, and therefore can be linked to more “continental” SOA formation.

91

92 Increasing the number of factors did not provide a significant change on the mix-OA
93 factor as illustrated in Figure S3 but rather a change in the split of the different OOA factors.
94 Therefore, as a second attempt, the source apportionment was performed in a semi-constrained
95 mode in order to dissociate primary OA from semi-volatile OA more clearly. The principal
96 primary OA source expected is the HOA factor. In contrary to *Saarikoski et al.* [2012] who
97 reported the contribution of a Biomass Burning OA (BBOA) factor in the spring season, here no
98 BBOA is expected since the contribution of the fragment m/z 60 (a tracer for BBOA) to total OA
99 was systematically below the background level of 0.3% defined by *Cubison et al.* [2011].
100 Consequently, a reference HOA mass spectrum corresponding to an average of 2 HOA factors
101 previously identified in this area (M. Rinaldi, personal communication) was used as a priori
102 information to partially constrain the model.

103 For this approach, the number of factors was varied from 5 to 7 since at least 5 factors are
104 expected based on previous AMS measurements in the Po Valley (HOA and 4 types of OOA). In
105 order to test the sensitivity of the results, the difference in the degree of variation for the various
106 fragments for the output HOA factor to the input reference mass spectra (the so-called a-value)
107 was investigated for a-values ranging from 0.05 (i.e., extremely constrained run where fragments
108 of the resulting HOA factor can only vary from 5% compared to the reference HOA) to 0.5 (50%
109 variation). The contribution of the HOA to the total OA was extremely stable over the
110 investigated a-value range indicating that identification of the HOA factor is quite robust (Figure
111 S4). The 5-factors solution (with an a-value of 0.1) was considered as the final solution (Figure
112 S5). This solution corresponds to better discrimination between HOA and the semi-volatile OA
113 (referred in the following as OOA-1), while the 3 others OOA factors correspond to the
114 previously identified ones in the non-constrained model and here are referred to as OOA-2 (12%
115 of OA), OOA-3 (28% of OA), and OOA-4 (45% of OA) in order to avoid confusion when
116 referring to the first (unconstrained) analysis (Figures S6 and S7). Increasing the number of
117 factors to 6 or 7 solely leads to a further splitting of the OOA factors without a clear
118 identification.

119 The HOA factor (4% of OA) now better follows the time trend of benzene ($r=0.58$),
120 while no real improvement of the correlation with BC ($r=0.50$) and toluene ($r=0.49$) can be
121 reported. However, the semi-volatile OOA-1 is now better correlated with nitrate ($r=0.74$) than
122 HOA ($r=0.36$) confirming the presence of these two factors in the previously identified mix-OA.

123 Although the OOA-1 factor (12% of total OA) is related to semi-volatile OA, its mass
124 spectrum appears to be more oxygenated (higher contribution of the CO_2^+ fragment compared to
125 the CHO^+) than classical SV-OOA ($\text{CHO}^+ > \text{CO}_2^+$). However, this is quite similar to the
126 previously reported semi-volatile OOA measured at SPC by *Saarikoski et al.* [2012].

127 Although contributions of the 3 others OOA factors (OOA-2, OOA-3, and OOA-4) to the
128 total OA are quite similar to the contribution of their corresponding factors in the non-
129 constrained mode (12%, 28% and 45%, respectively), some small differences can be reported
130 either in terms of their mass spectra (and consequently their elemental ratios) or their time trends.
131 These differences can be explained by a small contribution of the non-constrained OOA factors
132 (i.e., OOA-a, OOA-b, and OOA-c) to OOA-1. The most stable factor is OOA-2 which correlates
133 quite well with the previously identified OOA-a, even if the final factor has a lower oxidation
134 state. Although OOA-2 contributed to 12% over the entire time period, during its prevalent
135 period it accounted for up to more than half of the OA.
