Response to reviewers, manuscript #ACPD2014-1024

Interactive comment on ñSurvival and ice nucleation activity of bacteria as aerosols in a cloud simulation chamberò by P. Amato et al.

Anonymous Referee #1

We thank Referee 1 for raising weaknesses in the discussion manuscript. Our responses to each comment are indicated below.

Specific comments:

Referee#1: Introduction, page 4059: It is well explained why certain bacteria stains were used in this study, but I miss here the motivation to investigate the influence of sulfates.

Response of the authors: a precision indicating that these were ñas surrogates for the presence of anthropogenic aerosolsò was inserted in the text after ñsulfatesò (line 98 of the revised manuscript).

Referee#1: Material and methods, page 4061, line 23: It is not clear to me what òthe frequency of INP per cell was > 2% etc.ò means. If it means that more than 2% of the cells in the suspension were IN active shouldnôt it be per total cells then? This would make more sense when reading the text. Why not use frequency of IN active cells as later used in the text (page 4069, line 27).

Response of the authors: We agree that the INP mentioned actually refers to cells, so ñINPò has been changed to ñIN active cellsò in this section.

Referee#1: Page 4063, line 6: It is written that in all cases clouds were generated. Can the authors explain why only in two out of 14 cases aerosol samples were collected after dissipation?

Response of the authors: The number of experimental time points was limited due to practical reasons, notably the time needed for conditioning the chamber. Collecting more samples after cloud dissipation would have been interesting of course, but we had to compromise between (i) taking more samples before expansion cooling for investigating closely bacteria as aerosols and their impact on clouds, and (ii) focusing on the impact of clouds on bacteria by taking some samples after dissipation. We chose to give priority to (i), and still briefly approached (ii). We thought that the results obtained in (ii) were quite original and worth mentioning here, despite the fact that only a few samples were investigated.

Referee#1: Figure S1: The symbols are partly hard to distinguish e.g. Exp 10 and Exp 7 have both red lines? I suggest to also including the information in the legend that the temperature was reduced in Exp.8.

Response of the authors: the color settings of the figure have been rearranged for better clarity. We did not find relevant to include the information that the temperature was reduced in Exp. 8 in particular, as we should then also indicate experimental details for the other Exp., and that these are already presented in Table 1. Rather, the information that experimental conditions are indicated in Table 1 has been included in Fig S1 legend as ñDetails about the experimental conditions used in each experiment are given in Table 1ò.

Referee#1: Throughout the manuscript: Why are IN active cells called sometimes INP and sometimes IN active cells? Can the authors clarify?

Response of the authors: INP is for referring to the particle carrying the site at the origin of ice formation, disregarding its nature, while the term IN active cells refers to the phenotype of the bacteria in question. This is based on the recent terminology proposed by Vali et al. (2014), where it is recommended to use the term INP in all cases for atmospheric applications.

Other comments/typos:
Referee#1: Abstract: page 4057, line20: space is missing in perm2
Material and methods, page 4061, line 7: it seems that a word is missing here: acted ñasò cloud condensation nuclei.
Page 4061, line 23: particleòsò or ñanò ice nucleating particle?
Results and Discussion page 4070, line 14: frequency of INòPò per cell?
Response of the authors: all these have been corrected

Referee#1: Figure 4 caption: ñper total airborne cellò sounds odd, just per cell or airborne cell is good.
Response of the authors: the word ñtotalò has been removed here.

Anonymous Referee #2

We thank Referee 2 for raising weaknesses in the discussion manuscript. Our responses to each comment are indicated below:

Referee#2: Comments: Page 4059; line 21 ï define AIDA right after ñAIDAò.
Response of the authors: This has been corrected in the revised manuscript.

Referee#2: Page 4060; Recommend authors to include an introduction to their experimental approach after introducing the AIDA chamber and to direct the reader to Table 1. It could be as simple as a very brief overview of their experiment types (c, d, and e markers listed in Table 1). Suggest authors rearrange section to include chamber experiment descriptions follow by sampling frequency and SMPS/APS descriptions.
Response of the authors: Section 2.1 was reorganized following Reviewer 2ôs recommendations.

Referee#2: Page 4060; line 8- ñFor the ageing experiments at constant atmospheric pressureò ï what does this mean? Is the aerosolization process not the same for all experiments? Where there experiments for which this spraying/evaporating was not true?
Response of the authors: the aerosolization process was similar for all the experiments, so the specification that this was ñfor the ageing experiments at constant atmospheric pressureò has been removed.

Also, could the authors provide a discussion on how the aerosolization process used in this study relates to any hypothesized natural aerosolization processes? Bacteria can be emitted from spray (ocean) but also is often dry generated. The comparison is later made to bacteria released from agricultural fields, yet agricultural emissions are not necessarily release from a spray.
Response of the authors: It is true that spraying cultivated bacteria in a simulation chamber is probably different from naturally grown bacteria aerosolized by wind or bubble bursting. A paragraph discussing the different ways of aerosolization was inserted in the text, Section 3.3 (lines 323-338 of the revised manuscript):
ñAerosolization, *i.e.* the transfer of cells from a solid surface or from a liquid to the air, is a critical step. In nature, the dragging forces created by wind on surfaces generate aerosols by saltation/blasting phenomena (Grini et al., 2002) and result in increased amounts of airborne microorganisms during high wind speed events (e.g., Lindemann and Upper, 1985). Splashing raindrops on surfaces colonized by microorganisms like plant leaves also lead to the aerosolization of living bacteria (Graham et al., 1977). From liquids, a well-know process of aerosolization is bubble-bursting (Blanchard and Syzdek, 1982). This is actually a phenomenon by which certain types of cells in a community are preferentially aerosolized, thus adding a new layer of complexity in the process of bacterial aerosolization as it results in dissimilarities between the microbial composition in the bulk liquid source and in the air above (Agogué et al., 2005; Fahlgren et al., 2015). The complexity of this phenomenon was probably not reflected in our experimental setup, with bacterial cells being sprayed from liquid suspensions. However, the results presented here only considered bacteria already aerosolized and avoided taking into account the aerosolization step. Hence, considering that the process of aerosolization did not affect subsequent survival rates as aerosol, we can place our results in natural atmospheric context.ò

Referee#2: Page 4060; line 10- This sentence is fairly confusing and reads as if evaporation is a mechanism for releasing bacterial cells a dry aerosol state. ñwereò should be written as ñwhereò. Suggest they rewrite as: ñThe relative humidity of the chamber was 90 to 95% with respect to ice, thus sprayed droplets evaporated upon entering the chamber. The dried bacterial cell aerosol was then aged for up to 18 hours at the given chamber pressure, temperature and relative humidity, as summarized in Table 1.ò
Response of the authors: We thank Reviewer 2 for this suggestion, which we integrated in the text (line 113 of the revised manuscript).

Page 4061; line 4 ï ñ: : :and then saturation with respect to the supercooled liquid droplet phase.ò should be ñ: : :and is saturated with respect to water.ò.
Response of the authors: This has been corrected.

Referee#2: Page 4061; line 7 ï replace ñ: : :bacterial cells acted cloud: : :ò with ñ: : :bacterial cells acted as cloud: : :ò
Response of the authors: This has been corrected.

Referee#2: Page 4061; line 12 ï Please clarify that the chamber was not particle free. Recommend changing ñfilled withò to ñre-pressurized to atmospheric pressure usingò.
Response of the authors: The chamber was particle free at all times, except for the bacteria that were sprayed into it. This information is now indicated in Section 2.1 as ñAfter each experiment, the chamber was cleaned by deep depressurization, and refilled with particle free air, so that the chamber was particle free at the beginning of the next experiment.ò. When it was repressurized after expansion cooling, particle free air was also used.

Referee#2: Page 4061; lines 22- 28 ï Recommend including a table to describe different IN activities for these bacterial strains for ease of read.
Response of the authors: As indicated, the information concerning the ice nucleation activity of the 3 bacterial strains used in this study was from previous work (Attard et al., 2012; Joly et al., 2013). Data is already presented in the form of such table for 13b-2 and 32b-74 in Joly et al. (2013). Since the main findings for the 3 strains are summarized here in a few lines (onset temperature of IN activity and frequency of active cells at characteristic temperatures), we think that including such a table is not really appropriate.

Referee#2: Page 4062; line 8 ï ñas describedò where? I think they mean ñas described in Section 2.4ò?
Response of the authors: This has been changed to ñas describe in Section 2.4ò as suggested.

Referee#2: Page 4062; lines 17-19 ï The wording here is confusing, suggest authors clarify that the control was impingement liquid placed in the impinger without aerosol sampling.
Response of the authors: This was modified into ñUnexposed aliquots of the water used as the impingement liquid served as negative controls for ice nucleation assays and cell countsò, line 183 of the revised manuscript.

Referee#2: Page 4063; line 1 ï Is this assumption correct? Please provide a reference. Is there a size-dependence to the collection efficiency of the impinger (eg. can the impinger collect a 100 nm particle as efficiently as a 5000 nm particle?)? Please address.
Response of the authors: The assumption that the collection efficiency of BioSampler impinger is 100% was used for relating the concentrations measured in the impingement

liquid to the air inside the chamber. Our main constraints in the choice of the sampler here was to use a method largely spread in bioaerosol studies, to avoid altering cell viability and integrity upon sampling, while having good collection efficiency. Impingers were found to be the most appropriate samples in our case. They are widely used for studying airborne bacteria and fungi (e.g. Angenent et al., 2005; Fierer et al., 2008). However, no information was found concerning their actual absolute collection efficiency. Jensen et al. (1992) already used these samplers as the upper reference in a comparative study about the collection efficiency of bioaerosol samplers. It was maximum for particles of 1 µm in diameter, and the collection efficiency was decreased by onlyless than 20% in the case of 0.3 µm particles. It was found that cells can be damaged upon long sampling periods (i.e. > 60min, Terzieva et al., 1996), but they systematically appear as the most appropriate methods for living bioaerosols collection, especially over short sampling times like in our study (10 min) (Griffin et al., 2010; Thorne et al., 1992). The reference Jensen et al., (1992) was included in the manuscript for justifying the assumption of 100% collection efficiency (line 194 of the revised manuscript), and the reference Terzieva et al. (1996) was included for indicating that cell aggregates may have disrupted upon sampling (line 261 of the revised manuscript).

Referee#2: Page 4064; header ï should this be INP (rather than IN) assays? Also, please provide a description of how you calculate the error bars presented on Figure 4. Why are some points in Figure 4 without error bars?
Response of the authors: ñIN assaysò refers here to ñIce nucleation assaysò, so it is correct here. The error bars were standard deviations from the mean of independent replicate experiments, so these were not possibly calculated in the cases where experiments were not replicated i.e. for example in the presence of ammonium sulfate). The information about error bars was already indicated in Figure 4ôs legend.

Referee#2: Page 4065; Section 3.1 ï Interesting results and the translation to an atmospheric perspective is great and useful. However, I think that if these results are presented this way, there should be a discussion on the caveats of the jump that is made from these lab experiments to the complex natural population of atmospheric bacteria. It is important to translate these results to an atmospheric context, but there is a significant amount of discussion that should be included to address how the translation could be invalid. Although the species evaluated in this study were identified in atmospheric samples, the impact of evaporation (during aerosolization process in these experiments), cloud activation, etc could potentially differ depending on the origin of the bacteria.
Response of the authors: We agree that the experimental set up is probably quite different from what happens in nature. Such discussion about the impacts of other atmospheric factors that could alter survival (i.e. UV light, osmotic shocks and free radicals) was already present in the original manuscript (now in Section 3.4 of the revised version).

I also recommend the authors to reorganize this section. Suggest having subsections for ñTime dependent survival ratesò and ñImpact of cloud processing on cell survival ratesò and ñatmospheric implicationsò.
Response of the authors: We agree on the fact that Section 3.1 is probably too long and that it mixed different results together. So it was cut into ñ3.1 Initial total and cultivable airborne cell concentrationsò (lines 244-270 of the revised manuscript), ñ3.2 Survival rate time dependenceò (lines 272-308), ñ3.3 Implications for airborne bacteria disseminationò (lines 310-350) and ñ3.4 Impact of cloud processing on survivalò (lines 352-373). The structure of the next section ñice nucleation activityò remained unchanged, but is now consequently numbered 3.5 (line 375).

Abstract

The residence time of bacterial cells in the atmosphere is predictable by numerical models. However, estimations of their aerial dispersion as living entities are limited by lacks of information concerning survival rates and behavior in relation to atmospheric water. Here we investigate the viability and ice nucleation (IN) activity of typical atmospheric ice nucleation active bacteria (*Pseudomonas syringae* and *P. fluorescens*) when airborne in a cloud simulation chamber (AIDA, Karlsruhe, Germany). Cell suspensions were sprayed into the chamber and aerosol samples were collected by impingement at designated times over a total duration of up to 18 hours, and at some occasions after dissipation of a cloud formed by depressurization. Aerosol concentration was monitored simultaneously by online instruments. The cultivability of airborne cells decreased exponentially over time with a half-life time of 250 ± 30 min (about 3.5 to 4.5 hours). In contrast, IN activity remained unchanged for several hours after aerosolization, demonstrating that IN activity was maintained after cell death. Interestingly, the relative abundance of IN active cells still airborne in the chamber was strongly decreased after cloud formation and dissipation. This illustrates the preferential precipitation of IN active cells by wet processes. Our results indicate that from 10^6 cells aerosolized from a surface, one would survive the average duration of its atmospheric journey estimated at 3.4 days. Statistically, this corresponds to the emission of 1 cell that achieves dissemination every ~33 minutes per m² of cultivated crops fields, a strong source of airborne bacteria. Based on the observed survival rates, depending on wind speed, the trajectory endpoint could be situated several hundreds to thousands of kilometers from the emission source. These results should improve the representation of the aerial dissemination of bacteria in numeric models.

1. Introduction

Microorganisms are known to be dispersed into the atmosphere and disseminated over long distances (e.g., Bovallius et al., 1978; Brodie et al., 2007; Griffin et al., 2001; Smith et al., 2013, and review by Morris et al., 2014b). This has obvious implications for Human, animal and plant epidemiology as well as microbial ecology (Monteil et al., 2014; Morris et al., 2007, 2008; Ġantl-Temkiv et al., 2013). Moreover, some particular bacteria notably found in the atmosphere and clouds can induce heterogeneous ice formation (Cochet and Widehem, 2000; Joly et al., 2013; Lindemann et al., 1982), which probably affects cloud physics and potentially triggers precipitation (Möhler et al., 2007). All these aspects motivated the development of numerical models intended to describe and predict the aerial dispersion of microorganisms. For instance, Burrows et al. (2009a, 2009b) constrained a general atmospheric circulation model using data from the literature and estimates of concentrations and vertical fluxes of airborne microorganisms. They estimated that ~10^{24} bacteria are emitted into the atmosphere each year at the global scale, with a residence time aloft between 2 and 10 days (~3 days on average) depending on emission sources and on meteorological conditions. Such a time span should allow microbial cells (*i.e.* particles of ~1 µm) to travel over hundreds or thousands of kilometers. However, it is not clear what fraction of the aerosolized microorganisms ~~aerosolized~~ survive over this time scale, and if they maintain properties ~~pertinent with~~allowing ~~-~~interactions with atmospheric water.

Most studies aiming at predicting the death rate of airborne bacteria were carried out in the late 1960ôs and early 70ôs, with particular emphasis on the influence of temperature and relative humidity (Cox and Goldberg, 1972; Ehrlich et al., 1970; Lighthart, 1973; Wright et al., 1969). The ability of bacteria to survive as aerosols and the influence of abiotic parameters on survival were shown to strongly depend on the microorganism (Marthi et al., 1990). In experiments at constant temperature ranging from -18°C to 49°C, the survival rate

Mis en forme : Anglais (États-Unis)

of *Mycoplasma pneumoniae*, *Serratia marcescens* and *Escherichia coli* decreased with increasing temperature, while this had no or little effect on the survival of *Bacillus subtilis* (Ehrlich et al., 1970; Wright et al., 1969). The highest survival rates were invariably observed at extreme low and high levels of humidity (Cox and Goldberg, 1972; Wright et al., 1969). Finally, carbon monoxide concentration was shown to have variable impacts on the viability of airborne bacteria, with protective or deleterious effects depending on humidity and on the species (Lighthart, 1973). Lighthart (1989) compiled these data and others to build statistical models describing the death rate of airborne bacteria based on aerosol age, temperature, Gram reaction and humidity. Survival rate was resolved by aerosol age, i.e. time after aerosolization, at more than 90%.

In a scientific context motivated by interrogations about cloud-microbes interactions, we studied bacteria originating from atmospheric samples and selected for their relevance to atmospheric questions, *Pseudomonas syringae* and *P. fluorescens*. Indeed, these bacteria are among the most frequent species recovered from natural clouds (Vaïtilingom et al., 2012), some strains are known plant pathogens (Berge et al., 2014) and some, including those investigated here, are ice nucleation (IN) active and have potential impacts on cloud microphysics and precipitation (e.g., Attard et al., 2012; Cochet and Widehem, 2000; Joly et al., 2013; Möhler et al., 2007; Sands et al., 1982). IN active bacteria were shown earlier to induce the formation of ice crystals within simulated clouds (Maki and Willoughby, 1978; Möhler et al., 2008). Here we aimed at examining the survival and IN activity of such typical bacterial aerosols in the atmosphere, using the AIDA (Aerosol Interactions and Dynamics in the Atmosphere) cloud chamber ~~(Aerosol Interactions and Dynamics in the Atmosphere)~~. Cell suspensions were sprayed in the chamber and the concentrations of airborne micron-sized particles, total and cultivable cells and ~~IN~~ ice nucleating particles (INP) were measured over time for up to several hours after aerosolization. The influence of cloud formation, and the

Mis en forme : Anglais (États-Unis)

presence of sulfates as surrogates for the presence of anthropogenic aerosols were briefly approached and seemed to deeply alter cell survival and IN activity. The data presented could be used for improving the parameterization of numerical models describing the atmospheric dispersion of bacteria.

2. Material and Methods

2.1 Experimental setup and particle concentration measurements

The AIDA ~~(Aerosol Interaction and Dynamics in the Atmosphere)~~ 84-m^3 chamber at the Karlsruhe Institute of Technology was used in this study both as a static aerosol chamber in order to store and age the bacterial cell aerosols ~~for up to 18 hours~~, and as an expansion cloud chamber in order to simulate cloud activation events and investigate the impact of fresh and aged IN active bacterial aerosols on cloud microphysics ~~and its effect on the viability of bacterial cells~~. The experiments were conducted during the BIO06 campaign in May 2011. ~~For the ageing experiments at constant atmospheric pressure, the c~~Cell suspensions (see **section 2.2**) were sprayed into the ~~aerosol and cloud~~ chamber at the beginning of the experiments. ~~-~~ The initial relative humidity i~~I~~nside the chamber was around 90% to 95% with respect to ice, ~~, the~~thus the sprayed droplets ~~water~~ quickly evaporated upon entering the chamber. ~~and the~~The dried bacterial cell aerosols~~s~~ were then ~~thus released into a dry aerosol state were they just floated~~aged for up ~~around for up~~ to 18 hours at the given chamber pressure, temperature and relative humidity~~, which was around 90% to 95% with respect to ice in all ageing experiments~~, as summarized in ~~. Three ageing experiments were performed at constant temperature, in one experiment the temperature was slightly reduced with time (see~~ **Table 1**~~)~~. Aerosol samples were collected (see **section 2.3**) during this step of aerosol ageing in order to measure the airborne concentrations of total cells, the cultivable cell number fraction (**section 2.4**), and the IN activity of the material collected (**section 2.5**). Samples

were systematically taken 30 min after spraying, and also after 120 min (2 h), 300 min (5 h), 420 min (7 h), 1020 min (17 h), and 1080 min (18 h).

~~Aerosol concentration and size in the chamber were monitored using the combination of a Scanning Mobility Particle Spectrometer (SMPS) and an Aerodynamic Particle Sizer (APS), both from TSI Incorporated, USA. The concentration of particles in the size mode around 0.6 µm to about 5 µm is referred to here as **Cells**$_{APS}$; it corresponds to single intact bacterial cells and small agglomerates of cells.~~

~~Several aerosol samples were taken during these experiments in order to measure the number concentrations of total cells, and the cultivable cell number fraction. During most experiments, only one sample was taken 30 min after spray generation of the aerosol.~~

During three experiments, ~~a second sample~~aerosol samples for microbiological analyses ~~was~~ were also taken after a cloud activation and evaporation cycle in the AIDA chamber. ~~Such a~~Such a cloud ~~-~~cycle in AIDA is initiated by reducing the chamber pressure within a few minutes from about 1000 hPa to 800 hPa by strong pumping. This pressure change simulates the conditions of an air parcel rising in the atmosphere at a vertical updraft velocity of up to a few m s^{-1}, which induces a respective cooling of the air and an increase of the relative humidity. The expansion run starts at a relative humidity of about 90 to 95% with respect to ice, so that at start temperatures below 0°C the air in the cloud chamber first exceeds saturation with respect to ~~the~~ ice, ~~phase~~ and then saturation with respect to ~~the supercooled~~ liquid ~~droplet phase~~water. Depending on the temperature and the ice nucleation activity of the bacterial cells, some ice particles may already be formed in the regime between ice and water saturation. In all the experiments discussed here, water saturation was exceeded, so ~~that~~ all bacterial cells acted as cloud condensation nuclei and ~~by that~~ were first immersed in supercooled cloud droplets before ~~for a few minutes~~eventually targetting ice formation. After the pumping stopped at a pressure of about 800 hPa, the temperature started to increase due to

heat flow from the warmer chamber walls, and the cloud droplets started to evaporate. After full evaporation of the cloud droplets, the chamber was ~~filled~~ re-pressurized ~~with~~ using particle free synthetic air to atmospheric pressure ~~and the second cell sample was taken from the chamber~~. Aerosol samples were collected once the pressure inside the chamber was returned to ambient pressure. In one of the three experiments during which aerosol samples were collected for microbiological analyses after cloud evaporation, bacteria were sprayed as a suspension in $(NH_4)_2SO_4$ (50 g L^{-1}, or 0.38 M) (Exp. 12, **Table 1**), rather than deionized water, in order to generate sulfate aerosols and examine competition effects between sulfates and bacteria on cloud formation and ice nucleation. This also produced preliminary results about the potential impact of anthropogenic aerosols on the survival of airborne bacteria.

After each experiment, the chamber was cleaned by deep depressurization, and refilled with particle free air, so that the chamber was particle free at the beginning of the next experiment.

Aerosol concentration and size in the chamber were monitored during the experiments using a combination of a Scanning Mobility Particle Spectrometer (SMPS) and an Aerodynamic Particle Sizer (APS), both from TSI Incorporated, USA. The concentration of particles in the size mode around 0.6 µm to about 5 µm is referred to here as **$Cells_{APS}$**; it corresponds to single intact bacterial cells and small agglomerates of cells.

2.2 Bacterial strains and preparation of cell suspensions

The following bacterial strains were used: *Pseudomonas syringae* 13b-2 and *P. syringae* 32b-74, both isolated from cloud water samples collected from the puy de Dôme Mountain in France [GenBank accession numbers of the 16S rRNA gene sequences: DQ512785 and HQ256872, respectively (Amato et al., 2007; Vaïtilingom et al., 2012)], and *P. fluorescens* CGina-01 isolated from Cotton Glacier in Antarctica [GenBank accession number FJ152549;

(Foreman et al., 2013)]. These were all previously demonstrated to be IN active by droplet-freezing assays (Attard et al., 2012; Joly et al., 2013). *P. syringae* 32b-74 in suspension in deionized water at the concentration of ~10^9 cells mL^{-1} nucleated ice at -3°C ; the frequency of ~~ice nucleating particle (INP) per~~IN active cells was > 2% at -4°C and > 4% at -6°C, which ranks this strain among the most efficient IN active bacteria described so far. The onset freezing temperature of *P. fluorescens* CGina-01 at similar cell concentration was -4°C, with ~~an INP per cell frequency~~a frequency of IN active cells 3 to 4 orders of magnitude lower than that of 32b-74. *P. syringae* 13b-2 nucleated ice at -4°C to -5°C, with a much lower activity (~10^{-7} IN active cells~~P~~ per cell at -6°C).

Bacteria from stock suspensions were grown on Kingôs medium B agar (King et al., 1954) for two days at ambient room temperature (*i.e.* 22°C-25°C). Cells were then scrapped off agar using sterile plastic loops, suspended in sterile deionized water at a concentration of approximatively ~10^9 mL^{-1}, and incubated overnight at 4°C. In one experiment, cells were suspended in a solution of $(NH_4)_2SO_4$ (50 g L^{-1}, or 0.38 M) in order to examine the influence of sulfate coating. In each experiment, a volume of ~50 mL of the cell suspension was sprayed into the cloud simulation chamber (for details see Möhler et al., 2008). The actual cell concentration in the initial suspensions was later determined ~~later~~ by flow cytometry (total cells) and standard dilution platting (colony forming units; CFU), as described in **Section 2.4**. These were used for inferring the initial concentrations of total and cultivable cells airborne in the AIDA chamber, considering a volume of 84 m^3; these are referred to as $\mathbf{Cells_{SUSP}}$ and $\mathbf{CFU_{SUSP}}$, respectively.

~~In one of the experiments, cell suspension was prepared in a solution of $(NH_4)_2SO_4$ (50 g L^{-1}, or 0.38 M) in order to examine the influence of sulfate coating.~~

2.3 Sampling from the cloud simulation chamber for microbiological analyses

Sampling for microbiological analyses was performed using an ethanol-washed impinger (SKC Biosampler; Lin et al., 1999) rinsed several times with sterile deionized water and filled with ~20 mL of sterile deionized water just prior to use. ~~The w~~Unexposed aliquots of the water used as the impingement liquid served as ~~a~~ negative controls for ice nucleation assays and cell counts. In those controls, no ice nucleation event was detected within the temperature range investigated, and cell count was < 0.005% of the cell counts in samples. Sampling operations were performed at a constant air flow of 12.5 L min^{-1} for 10 min periods using a membrane vacuum pump (KFC), with the inlet of the impinger connected to the inside of the chamber via a stainless steel sampling tube of 4 mm inner diameter. The exact volume of water contained in the sampler (~20 mL) before and after sampling was determined by weighting. It was used to relate the total and cultivable cell concentrations in the impingement liquid to their respective concentrations in the air in the AIDA chamber when equilibrated with atmospheric pressure, considering the volume of the impingement liquid and the sampling rate and time, and assuming 100% collection efficiency (Jensen et al., 1992). These are referred to as **$Cells_{IMP}$** and **CFU_{IMP}** throughout the manuscript.

~~Aerosols from the chamber were systematically collected 30 min after spraying bacterial suspensions. In the course of aerosol ageing experiments, samples were also taken 120 min (2 h), 300 min (5 h), 420 min (7 h), 1020 min (17 h), and 1080 min (18 h) after spraying. In all cases, from both fresh and aged bacterial aerosols, a cloud was generated afterwards by expansion cooling (*i.e.* depressurization) for microphysical characterization; at some occasions, aerosol samples were also collected once the cloud had dissipated and the pressure inside the chamber was returned to ambient pressure.~~

2.4 Total cells and colony counts

The concentrations of cultivable and total cells in the impingement liquid were determined by ~~2~~two complementary methods. Cultivable cells were counted as colony forming units (CFU). Twenty µL of 10-fold serial dilutions of the impingement liquid were spread on R2A medium (Reasoner and Geldreich, 1985) and incubated at 22-25°C for 2 to 3 days before counting the colonies formed. Total cells were counted by flow cytometry, on triplicate samples of 450 µL of the impingement liquid mixed with 50 µL of 5% glutaraldehyde (Sigma) (0.5% final concentration) and stored at -20°C. These were then mixed with one volume (500 µL) of Tris-EDTA buffer at pH 8.0 (10 mM Tris; 1 mM EDTA, final concentrations) and diluted in deionized water to a range of cell concentrations compatible with the analysis. Finally, 10 µL of the DNA specific fluorochrome SYBR-Green (100X concentration; Invitrogen) were added to the samples before incubation in the dark for at least 20 min then injection into the flow cytometer (Becton-Dickinson FACScalibur). Particles fluorescing at 530 nm when excited at 488 nm, *i.e.* labeled with SYBR-Green, were detected and counted by the cytometer. Counts were performed for 2 min or 100,000 events at a flow rate of about 90 µL min^{-1}. The exact flow rate was then measured for each series of measurements by weighting a water sample before and after a 20 to 30 minute run in the instrument. All solutions used for flow cytometry analyses were freshly filtered through polycarbonate syringe filters (0.22 µm porosity, Whatman) before use in order to prevent the presence of contaminating particles. In each sample, a population of particles unambiguously attributed to bacterial cells based on their intensity of fluorescence and side-scattering was detected. Finally, cultivability was calculated as the ratio between CFU and total cells counts.

2.5 IN assays

The concentration of ice nucleating particles (C_{INP}) in the collection liquid was assayed by the drop-freezing method described previously (Vali, 1971). Series of sixteen 0.2 mL

248 microtubes containing 20 µL of the impingement liquid, undiluted or diluted 10-fold in
249 distilled water, were placed in a cooling bath (Ecoline Staredition Lauda E200) and exposed
250 to decreasing temperatures from -2°C to -10°C with 1°C steps. The number of tubes
251 containing aliquots still in the liquid phase was counted after exposition for 8 min at each
252 temperature step, and C_{INP} was calculated as:

253 $$C_{INP} = [\ln (N_{total}) - \ln (N_{liquid})]_T / V \times (1 / D_f)$$

254 with N_{total} is the total number of tubes tested in a given dilution series (16), N_{liquid} the
255 corresponding number of tubes still liquid after 8 min at temperature T, V the volume of
256 liquid in each tube (0.02 mL) and D_f the dilution factor (1 or 10). C_{INP} were finally
257 normalized to the corresponding total cell concentrations measured by flow cytometry.
258
259 *2.6 Data analyses*

260 Exponential regression curves of the type $y = a*e^{(-bt)}$ were fitted to the data. As all the data
261 were normalized to the first time point measured in the corresponding experiment (i.e. 30
262 minutes after spraying, time set as the ñtime zeroò for data analysis), *a* was equal to 1 and the
263 concentration had its maximum value at t = 30 (time t being expressed in minutes). The time
264 constant of this first-order decay equation is Ű= 1/b, b being the decay rate constant, and the
265 half-life time $t_{1/2}$, at which the concentration has decreased to half the start value, can be
266 calculated as $t_{1/2} = \ln(2)/b$.

267 All statistical analyses were performed using PAST version 2.04 (Hammer et al., 2001).

Mis en forme : Hiérarchisation + Niveau : 2 + Style de numérotation : 1, 2, 3, … + Commencer à : 1 + Alignement : Gauche + Alignement : 0,63 cm + Retrait : 1,27 cm

A total of 9, 3 and 2 experiments were carried out in the cloud simulation chamber with the strains *Pseudomonas syringae* 32b-74, *P. fluorescens* CGina-01 and *P. syringae* 13b-2, respectively. The initial airborne total and cultivable cell concentrations inferred from in the initial cell suspensions (SUSP subscript), and the concentrations measured with the APS (APS subscript) and from impinger samples (IMP subscript) 30 min and up to 1080 min (18 h) after aerosolization are presented in **Table 1**. Fifty mL of cell suspensions at concentrations ranging from 3.65×10^{8} to 1.15×10^{9} cells mL^{-1} were sprayed in the chamber, corresponding to theoretical initial total airborne cell concentrations ($Cells_{SUSP}$) of 217 to 684 cells cm^{-3} in the 84 m^3-chamber. The concentrations actually measured 30 minutes later by the APS ($Cells_{APS}$) and from impinger samples ($Cells_{IMP}$) were both significantly lower (t-test; $p < 10^{-6}$ and $p = 0.02$, respectively; $n = 13$) and ranged in average between 138 and 289 cells cm^{-3} and between 258 and 451 cells cm^{-3}, respectively. At this time point, $Cells_{IMP}$ was significantly higher than $Cells_{APS}$ by a factor of 1.82 ± 0.40 in average (t-test; $p < 0.01$; $n = 13$), indicating the presence of cell aggregates in the ~1 µm aerosol population (it extended to about 5 µm at the beginning of the experiments). These were disrupted in the impinger during sampling and counted later as individual cells by flow cytometry (Terzieva et al., 1996). The presence of aggregates was also evidenced in the suspensions sprayed by the fact that the concentration of cultivable cell (CFU_{SUSP}) exceeded that of total cells ($Cells_{SUSP}$) (t-test; $p < 0.01$; $n = 13$), with particularly large deviations on CFU counts between technical replicates, and resulting in cultivability > 100%, and at some occasions > 1000% (see **Table 1**). Cell suspensions were prepared by scratching colonies from the surface of agar plates. Even though care was taken for homogenizing them, some heterogeneity probably persisted and resulted in the presence of cell clusters. However, it unintentionally mimicked bacterial aerosols in natural context, as most cultivable bacteria in the atmosphere were found associated with particles (Shaffer and Lighthart, 1997).

3.2 Survival rate time dependence

Mis en forme : Police :Italique

Mis en forme : Retrait : Première ligne : 0 cm

With the intention to take only into account cells already airborne and avoid any ~~eventual~~ possible impact of the spraying process on cultivability, data analysis was restricted to t Ó 30 minutes after aerosolization and data were normalized to the values measured at this experimental time point. This normalization also allowed ~~cleaning~~ the data to be cleaned by avoiding the large deviations on cultivable cell concentration and on cultivability rate in the initial suspensions (CFU_{SUSP}). Each individual absolute value of cultivability (*i.e.* not normalized ~~to~~ by the cultivability measured at this time point) is plotted in **Figure S1**. The normalized temporal decay of airborne micron-sized particles ($Cells_{APS}$), total cells ($Cells_{IMP}$) and cultivable cells (CFU_{IMP}) concentrations was determined from experiments #7, #8, #10 and #11 (**Figure 1**). The concentration of particles in the 1 µm-mode ($Cells_{APS}$) decreased exponentially over time with a time constant Ű= 1260 ± 170 min (Pearsonôs r = 0.992; n = 7). The concentration of airborne cells ($Cells_{IMP}$) decreased faster with a time constant Ű= 500 ± 120 min (Pearsonôs r = 0.937; n = 9). The upper bound diameter of the $Cells_{APS}$ size mode, extending to approximately 5 µm at the beginning of the experiments, decreased to around 3 µm after 7 hours, and the cell-to-particle ratio ($Cells_{IMP}$/ $Cells_{APS}$) decreased from 1.82 ± 0.40 (n = 13) to 1.06 ± 0.06 (n = 2). These indicated that the cell clusters were progressively removed from the aerosol population by sedimentation. Cultivable cell concentration (CFU_{IMP}) decreased with a time constant Ű= 230 ± 10 min (Pearsonôs r = 0.990; n = 9). This concentration therefore decreased about twice as fast as that of the concentration of total cells $Cells_{IMP}$ due to additional temporal loss of cultivability. The decay rate constant b for cultivability was ~0.28% min^{-1}, corresponding to a time constant Ű= 360 ± 40 min and a half-life $t_{1/2}$ = 250 ± 30 min (3.5 to 4.5 h) (Pearsonôs r = 0.911; n = 9) **(Fig. 2)**. This has to be

regarded as the most conservative estimate (lower bound) for viability, as viable but non cultivable (VBNC) state is common in aerosolized cells (Heidelberg et al., 1997).

Despite the fact that the bacteria investigated here are non-spore-formers, they lost cultivability only 1.5 to 3 times faster than spores of *Bacillus subtilis* within the same temperature range, which decayed at rates of 0.19% and 0.10 % min^{-1} at -29°C and 4 °C, respectively (Ehrlich et al., 1970). Lighthart (1989) proposed a general time-dependent model of biological decay (decrease of survival rate) for airborne bacteria by mixing experimental data from several bacterial strains, including *Pseudomonas* species (**Figure 2**). This fits our data with a Pearsonôs *r* of only 0.517 (n = 9), and we observed a much higher cultivability than what would have been expected from this model, at least for the first 10 hours following aerosolization. This implies that the *Pseudomonas* strains investigated here, which were originally isolated from atmospheric samples, are more resistant as airborne than the ñaverageò bacterium considered in this model; it could indicate that these strains are to some extent adapted to atmospheric transport (e.g., Ġantl-Temkiv et al., 2012).

3.3 Implications for airborne bacteria dissemination

Assuming that bacteria have an aerodynamic diameter of about 1 µm, they have a low sedimentation velocity on the order of 10^{-4} m s^{-1} (Malcolm and Raupach, 1991). In addition, such particles fall into the so-called ñscavenging gapò, and they have a particularly long residence time in the atmosphere (Hobbs, 1993). Indeed, residence time was estimated to be 2.3 to 9.6 days in the case of single bacterial cells depending on the source ecosystem, with a global mean of 3.4 days (Burrows et al., 2009a). Under our conditions, after 1 day airborne, 1.7% of the cells would still be cultivable. ~~, and b~~Based on these extreme and mean residence times, between 0.009% and 1.22 × 10^{-15} % of aerosolized cells (0.0001% in average, *i.e.* 1/ 10^{6}) would survive the duration of their atmospheric journey until deposition. Statistically,

Mis en forme : Police :Italique
Mis en forme : Retrait : Première ligne : 0 cm
Mis en forme : Police :Italique
Mis en forme : Police :Italique

this implies that the emission of at least 11,000 cells is necessary, 10^6 in average, to assure that one survives the residence time and arrives at its endpoint by atmospheric dissemination.

Aerosolization, *i.e.* the transfer of cells from a solid surface or from a liquid to the air, is a critical step. In nature, the drag forces created by wind on surfaces generate aerosols by saltation/blasting phenomena (Grini et al., 2002) and result in increased amounts of airborne microorganisms during high wind speed events (e.g., Lindemann and Upper., 1985). Splashing raindrops on surfaces colonized by microorganisms like plant leaves also lead to the aerosolization of living bacteria (Graham et al., 1977). From liquids, a well-know process of aerosolization is bubble-bursting (Blanchard and Syzdek, 1982). This is actually a phenomenon by which certain types of cells in a community are preferentially aerosolized, thus adding a new layer of complexity in the process of bacterial aerosolization as it results in dissimilarities between the microbial composition in the bulk liquid source and in the air above (Agogué et al., 2005; Fahlgren et al., 2015). The complexity of this phenomenon was probably not reflected in our experimental setup, with bacterial cells being sprayed from liquid suspensions. However, the results presented here only considered bacteria already aerosolized and avoided taking into account the aerosolization step. Hence, considering that the process of aerosolization did not affect subsequent survival rates as aerosol, we can place our results in natural atmospheric context. Plants are among the strongest natural sources of airborne bacteria identified, with emission fluxes around 500 CFU m^{-2} s^{-1} measured above bean and alfalfa fields (Lindemann et al., 1982). At such a rate, each m^2 of crop field would emit 1 cell capable of surviving its atmospheric transport every 33 minutes. In other words, 1 cell capable of disseminating alive would be emitted every second by a field of ~2000 m^2.

Once airborne, as a first approximation bacteria are passively transported horizontally at the speed of horizontal wind. So, for typical horizontal winds in the troposphere, *i.e.* ~2 to ~30 m s^{-1} (not considering extreme events such as storms or cyclones), at the survival rate

measured here, 50% of the cells emitted alive from a source would be transported about 30 to 600 km away, and 1% would reach the ground up to 4000 km away (**Figure 3**). There are indeed many observations of such long distance transport of living bacteria between distant ecosystems in nature (Bovallius et al., 1978; Hervàs et al., 2009; Hervàs and Casamayor, 2009; Comte et al., 2014).

3.4 Impact of cloud processing

The conditions investigated here (temperature between -20°C and 0°C and absence of light) can be considered relatively close to the conditions encountered in the high atmosphere during the night. It is probable that in nature, during the day, UV light has~~ve~~ deleterious effect and increases mortality rates (Tong and Lighthart, 1997). In addition, cloud formation can alter viability, as shown in samples collected after expansion cooling (*i.e.* depressurization) experiments (experiments #6 and #9). Even though it is not statistically testable here, we noticed a strong decrease in the cultivability of *P. s.* 32b-74 and CGina-01 cells exposed to a cloud (see **Table 1, Figure 2 and Figure S1**). Fractions of only about ~12% and ~40% of the cells cultivable before expansion cooling remained cultivable after cloud dissipation for 32b-74 and CGina-01, respectively, compared to ~70% when the pressure was maintained constant. For cloud formation in the AIDA chamber, pressure was typically decreased at rates of 30 to 50 hPa min^{-1} during expansion, and the associated cooling rates were typically 2 K min^{-1} at the beginning of an expansion and below 0.5 K min^{-1} towards the end of the expansion. Considering pressure and temperature changes with altitude of 10 hPa and 1 K every 100 m, these roughly correspond to uplifts of air masses of around 100 to 500 m min^{-1} (1.7 to 8.3 m s^{-1}), which falls within the range of observations for convective precipitating clouds (Balsley et al., 1988). Our results suggest that the shifts in environmental conditions encountered by living cells transported upward, along with the osmotic shock and free

radicals generated by water condensation and freezing (e.g., Stead and Park, 2000; Tanghe et al., 2003) ~~in clouds~~ probably alter airborne cell survival in clouds to a larger extent compared with non convective situations.

3.~~2~~ 5 Ice nucleation activity

Figure 4 shows freezing profiles of air samples collected by impingement from the cloud chamber at different times after injection of *P. syringae* 32b-74 suspensions. Thirty minutes after aerosolization, there were ~2×10^{-5} INP $cell^{-1}$ at -3°C (1 INP every ~50,000 cells) and ~3×10^{-3} INP $cell^{-1}$ at -5°C (1 INP every ~333 cells) on a per-total-cells ($Cells_{IMP}$) basis. This is about one ~~thenth~~tenth the IN activity of cells in suspension for this strain (Joly et al., 2013). Decreased IN activity in airborne bacteria compared with suspension was expected from previous observations in cloud simulation chamber involving *P. syringae* (Maki and Willoughby, 1978). No further significant loss of activity over time was observed at temperatures Ò-4°C in aerosolized cells (ANOVA, 5% confidence level), *i.e.* the frequency of INP $cell^{-1}$ did not vary with time after aerosolization. This confirmed that non-viable cells retained IN activity, as previously reported (Kozloff et al., 1991).

In the natural atmosphere, phenomena such as coating may affect bacterial IN activity. For example coating with sulfate was reported to decrease the IN activity of soot or Arizona Test Dust particles, a material widely used in laboratory ice nucleation studies as a surrogate for natural mineral aerosols (Cziczo et al., 2009; Möhler et al., 2005~~; Niedermeier et al., 2011; Pinti et al., 2012~~). However, sulfate coating had no detectable impact on the IN activity of the commercial powder of lyophilized IN active *P. syringae* cells Snomax (Chernoff and Bertram, 2010). In order to further investigate the influence of sulfate coating, cells were suspended in a solution of ammonium sulfate instead of water before being sprayed into the chamber (experiment #12, **Table 1**). Thirty minutes after spraying, we found that the

frequency of INP per cell had decreased markedly compared to cells sprayed from water suspensions, especially at the warmest temperatures of activity: the frequency of INP per cell ~~active cells~~ was decreased by about 98.5%, 91% and 34% at -4°C, -5°C, and -7°C, respectively (**Fig. 4**). In this particular bacterial strain, pH at values typical for cloud water influenced by anthropogenic emissions (pH ~4) were also shown to be responsible for a significant decrease of INA (Attard et al., 2012). Such observations show that the IN activity of bacteria is clearly modulated by abiotic factors, and this must be kept in mind when replacing experimentations into environmental context.

The capacity of cells of nucleating ice in the atmosphere is particularly relevant where condensed water is present, i.e. in clouds. Using the AIDA chamber, it was shown previously that some strains of *P. viridiflava* and *P. syringae* can act as INP in clouds at temperatures around -10°C in the immersion-freezing mode (Möhler et al., 2008). Here, clouds were formed in the chamber by expansion cooling in two experiments (experiments #6 and #9), and aerosol samples were collected by impingement after cloud dissipation, when the pressure inside the chamber was back to ambient pressure (**Table 1**). The onset ice formation temperature of the impingement liquid was -6°C, compared to -3°C in samples not exposed to cloud, and the frequency of INP per cell was decreased by three orders of magnitude (**Fig. 4**). A possible ñdeactivation effectò of the IN activity of bacteria was already suggested from equivalent experiments (Möhler et al., 2008). However, our results expressed on a per-cell basis suggest that, more likely, IN active cells among a population of airborne bacteria were more efficiently precipitated than others. This could explain the observed distribution of IN active bacteria in natural air, clouds and precipitation: Stephanie and Waturangi (Stephanie and Waturangi, 2011) observed that the proportion of IN active bacterial strains was higher in falling rain water than in the air at the same location. In addition, whereas only 50% of the *P. syringae* strains isolated from non-precipitating cloud water were IN active (8 strains) (Joly et

al., 2013), those isolated from freshly fallen snow by Morris et al. (Morris et al., 2008) all had this capacity (47 strains).

4. Conclusions

In this work, we observed that the concentration and cultivability of cells aerosolized in the AIDA cloud chamber decreased exponentially over time at constant rates. Aggregation seemed to favor cell survival, but this was of course at the cost of the time span as airborne and so, in nature, of the potential distance of dispersion. Hence, ~~in~~ for bacteria, aerial dissemination is clearly a compromise between the distance travelled (which decrease~~ing~~s for large aggregates) and the chances of successful dissemination (which ~~increasing~~ increases for large aggregates).

The survival rate determined here should provide basis to the existing numerical models describing the aerial dispersion of bacteria (Burrows et al., 2009a; Sesartic et al., 2012), in order to better predict their atmospheric transport as living entities. By focusing on time as the only explicative variable, we were able to explain quite well (Pearsonôs r = 0.911) the decrease of cultivability observed for *Pseudomonas syringae* and *P. fluorescens* in the AIDA chamber, although adjustments of the predictions in an environmental context could be made by integrating viability parameters as needed, like temperature, humidity, UV, or phenotypic traits. Some work in this direction has already been carried out (Attard et al., 2012; Lighthart, 1973; Lighthart et al., 1971; Smith et al., 2011; Tong and Lighthart, 1997), but more experiments would help building a more mechanistic viability model. In addition, these models are still weakened by the large uncertainties that remain concerning the input to be used, as there are still very few data available about the sources of airborne bacteria and the associated emission fluxes (e.g. Lindemann et al., 1982). These need to be documented for different surface types and meteorological situations.

Numerical simulations demonstrated that the impact of IN active bacteria on precipitation is probably negligible at the scale of the planet (Hoose et al., 2010; Sesartic et al., 2012). However precipitation patterns at regional scales have important socio-economic impacts and the underlying processes still need to be elucidated. We observed that the IN activity of airborne bacteria did not change over time for at least several hours after aerosolization. In nature, this is enough time for an IN active cell to be transported to high altitudes and get incorporated into a cloud. Then, as suggested by others (Constantinidou et al., 1990; Möhler et al., 2008; Morris et al., 2008, 2014a), they can induce freezing of supercooled droplets, trigger precipitation and thus selectively prime their own redeposition. For a complete and accurate description of the transport of bacteria in the atmosphere, the partitioning of cells and~~,~~ in particular of IN active cells, between air, clouds and precipitation should be determined.

5. Acknowledgements

This research was funded by the joint DFG-CNRS project ñBIOCLOUDSò (DFG contract MO 668/2-1) and by the international program EUROCHAMP (Integration of European Simulation Chambers for Investigating Atmospheric Processes). We particularly thank Martine Sancelme, Catherine Glaux, and Jonathan Colombet for technical assistance with microbiology and flow cytometry. E. Attard acknowledges Blaise Pascal University and CNRS for postdoctoral fellowships. M. Joly is grateful to the Auvergne Region for PhD scholarship. Continuous support by the AIDA technical team is gratefully acknowledged. We also thank Dr. Thomas Schwartz from the KIT Institute for Functional Surfaces for kind material support to microbiological manipulations. The AIDA part is also funded by the Helmholtz Association through its program ñAtmosphere and Climate (ATMO)ò.

[a] As inferred from the cell suspensions sprayed;

[b] As measured by aerosol particle sizer and from impinger samples.

ö Experiments intended to investigate the impact of fresh IN active bacterial aerosols on the microphysics of clouds generated in the AIDA chamber by expansion cooling; no sample for microbiological analyses was collected after cloud dissipation.

p Experiments intended to investigate the impact of ageing on the survival and IN activity of bacteria as aerosols; clouds were generated afterward for investigating their impacts on microphysics; no sample for microbiological analyses was collected after cloud dissipation.

‡ Experiments intended to investigate the impact of clouds or sulfate coating on the survival and IN activity of bacterial aerosols.

Figure legends:

Figure 1: Temporal evolution of total airborne cell concentration measured with the APS ($Cells_{APS}$, open symbols) and total and cultivable cells concentrations measured from impinger samples ($Cells_{IMP}$, black symbols, and CFU_{IMP}, grey symbols, respectively) of *P. syringae* 32b-74 and *P. fluorescens* CGina-01 in the chamber, relative to the concentrations measured 30 minutes after spraying cell suspensions. Error bars are standard deviations from the mean of triplicate samples. The curves show fitted exponential temporal decays. For total particles: Pearsonôs r = 0.992. n = 7; for total cells: Pearsonôs r = 0.937. n = 9; for cultivable cells: Pearsonôs r = 0.990. n = 9. Corresponding calculated time constants (Ű) and half-life times ($t_{1/2}$) are indicated on the right of the figure (mean ± standard deviation).

Figure 2: Temporal evolution after aerosolization of the proportion of cultivable cells (cultivability) in impinger samples in *P. syringae* 32b-74 and *P. fluorescens* CGina-01, relative to the cultivability measured 30 minutes after spraying cell suspensions, in the absence of cloud (black symbols) or after cloud formation and dissipation (open symbols). Error bars are standard deviations from the mean of triplicate samples. The black dashed curve shows fitted exponential temporal decay of cultivability in the absence of a cloud (Pearsonôs r = 0.911. n = 9). The corresponding calculated time constant (Ű) and half-life time ($t_{1/2}$) are indicated on the right of the figure (mean ± standard deviation). Data using the equation (5) from (Lighthart, 1989) are also plotted for comparison (dashed grey line); this model valid for an ñaverageò bacterial strain fits our data with a Pearsonôs r of 0.517 (n = 9).

Figure 3: Proportion of cultivable airborne cells associated with the distance reached from their emission source for typical horizontal wind velocities (2. 5. 10 and 30 m s^{-1}, *i.e.* 7.2, 18, 36 and 108 km h^{-1}, respectively), relative to the respective initial cultivability, as inferred

726 from the data presented in **Figure 2**. The proportion of 0.0001% is reached in 3.4 days, the
727 mean residence time of bacteria in the atmosphere estimated by Burrows et al. (2009a).
728
729 **Figure 4**: Cumulative frequencies of INP per ~~total~~ airborne cell in *P. syringae* 32b-74
730 within the AIDA chamber 30 min, 7 h and 17 h after aerosolization in the absence of cloud
731 (black symbols), 30 min after aerosolization in the presence of ammonium sulfate (grey
732 symbols), and when the pressure inside the chamber was returned to ambient after cloud
733 formation by expansion cooling (open triangles). Error bars are standard deviations from the
734 mean of independent experiments, when available.
