Abstract

In this study we present airborne observations of aerosol and trace gases obtained over the sea in the Western Mediterranean Basin during the TRAQa (TRansport and Air QuAlity) and SAFMED (Secondary Aerosol Formation in the MEDiterranean) campaigns in summers 2012 and 2013. A total of 23 vertical profiles were measured up to 5000 m a.s.l. over an extended area (40–45° N latitude and 2° W–12° E longitude) including the Gulf of Genoa, Southern France, the Gulf of Lion, and the Spanish coast. TRAQa and SAFMED successfully measured a wide range of meteorological conditions which favoured the pollution export from different sources located around the basin. Also, several events of dust outflows were measured during the campaigns. Observations from the present study indicate that continental pollution largely affects the Western Mediterranean both close to coastal regions and in the open sea as far as ~250 km from the coastline. Aerosol layers not specifically linked with Saharan dust outflows are distributed ubiquitously which indicates quite elevated levels of background pollution throughout the Western Basin. The measured aerosol scattering coefficient varies between ~20 and 120 M m\(^{-1}\), while carbon monoxide (CO) and ozone (O\(_3\)) mixing ratios are in the range of 60–170 and 30–85 ppbv, respectively. Pollution reaches 3000–4000 m in altitude and presents a very complex and highly stratified structure characterized by fresh and aged layers both in the boundary layer and in the free troposphere. Within pollution plumes the measured particle concentration in the Aitken (0.004–0.1 µm) and accumulation (0.1–1.0 µm) modes is between ~ 100 and 5000–6000 s cm\(^{-3}\) (standard cm\(^{-3}\)), which is comparable to the aerosol concentration measured in continental urban areas. Additionally, our measurements indicate the presence of highly concentrated Aitken layers (10 000–15 000 s cm\(^{-3}\)) observed both close to the surface and in the free troposphere, possibly linked to the influence of new particle formation (NPF) episodes over the basin.
1 Introduction

Atmospheric aerosols play an important role on climate through their participation to several chemical, dynamical, and radiative processes. At present, still large uncertainties persist in the estimation of the aerosol direct and indirect effects mainly due to the difficulty of fully characterizing their spatial and vertical distribution and properties (Boucher et al., 2013).

The Mediterranean region is a complex area where atmospheric aerosols of different origins and types may be found (Pace et al., 2006; Kallos et al., 2007; Gkikas et al., 2012). High levels of anthropogenic aerosol particles and pollutants are measured in the Mediterranean (Lelieveld et al., 2002), which is also indicated as one of the main hot spots for air quality issues (Monks et al., 2009).

The North-Western part of the Mediterranean Basin, due to its proximity to highly polluted industrialized areas (such as the Po Valley in northern Italy and the Fos/Berre in southern France) and large coastal cities (Barcelona, Genoa, Marseilles, Nice, or Valencia), is frequently affected by continental outflows and severe pollution episodes (Mallet et al., 2005; Pérez et al., 2008; Pey et al., 2010). The strength of these episodes is particularly intense during summer when stable meteorological conditions and the high level of insolation promote photochemical reactions and the build-up of ozone and other pollutants (e.g. Millán et al., 2000).

A number of studies have investigated the dynamics of pollution export over the Western Basin with the aim of characterizing the impact of anthropogenic emissions over this region. Most of these studies have been conducted in continental coastal areas and provide information on the vertical distribution of aerosols and their properties mainly close to local pollution sources. They include ground-based observations with lidars (Soriano et al., 2001; Pérez et al., 2004; Ancellet and Ravetta, 2005), and airborne campaigns, such as MECAPIP (MEso-meteorological Cycles of Air Pollution in the Iberian Peninsula) and RACAPMA (RegionAl Cycles of Air Pollution in the west central Mediterranean Area) in coastal Spain (Millán et al., 1996, 1997) and ESCOMPTE.
Continental pollution in the Western Mediterranean Basin

C. Di Biagio et al.

The capability of reproducing this complexity by air quality models represents a real challenge (Jimenez et al., 2006; Jiménez-Guerrero et al., 2008), and experimental observations gives a fundamental support to test the performances of the model outputs over the Western Mediterranean environment.

The large set of observations conducted in the last decades has permitted to acquire a detailed characterisation of pollution aerosols in the surroundings of the Western Basin. However, at the present time we miss an extensive representation of the mean aerosol load, distribution, and properties in the whole region, in particular over the remote sea. In addition, there is a significant lack of observations over some key areas, as for example the Gulf of Genoa, directly under the influence of the outflow from the highly polluted Po Valley (Velchev et al., 2011).

In this study we present measurements of aerosols and trace gas vertical profiles acquired during 24 scientific flights performed with the ATR-42 French research aircraft during the TRAQA (TRansport and Air QuAlity) and SAFMED (Secondary Aerosol Formation in the MEDiterranean) campaigns in summers 2012 and 2013 in the framework of the Chemistry-Aerosol Mediterranean Experiment (CHARMEX, https://charmex.lsce.ipsl.fr/). The TRAQA and SAFMED flights explored an extended region of the Western Mediterranean Basin between 40–45° N latitude and 2° W–12° E longitude including the Gulf of Genoa, Southern France, the Gulf of Lion, and the Span-
ish coasts. Measurements were performed over the sea at various distances from the coastline with lidar and in situ instruments. During TRAQA and SAFMED the Western Basin was interested by diverse synoptic conditions which led to the occurrence of different pollution export regimes (Mistral/Tramontane events, outflow from the Po Valley and the Iberian Peninsula) and allowed sampling atmospheric aerosols of different origin and types.

The main objective of the present work is to provide extensive observations of the vertical distribution of aerosols and trace gases related to the export of anthropogenic pollution at the regional scale of the Western Mediterranean Basin. The detailed knowledge of the vertical structure of the atmosphere is very important to understand the impact of continental pollution over the basin.

The paper is organized as follows: in Sects. 2, 3, and 4 we describe the flight trajectories and strategy during TRAQA and SAFMED, the in situ measurements carried out on board the ATR-42 aircraft, and the meteorological conditions observed during the campaigns. In Sect. 5 we present the results. The aerosols and trace gases vertical profiles are shown in Sects. 5.1 and 5.2. Section 5.3 is dedicated to analyse the variability of the pollution plume composition and atmospheric structure also in link with the different outflow conditions. Airborne measurements in presence of layers with high concentrations of fine particles are discussed in Sect. 5.4. The main conclusions are reported in Sect. 6.

2 Overview over flights

Figure 1 shows the trajectories of the flights performed during the TRAQA (20 June–13 July 2012) and the SAFMED (24 July–1 August 2013) campaigns. Research flights were performed with the SAFIRE (Service des Avions Français Instruments pour la Recherche en Environnement, http://www.safire.fr/) tropospheric aircraft ATR-42. The aircraft has a maximum endurance of 4 h. The flight altitude ranges between a minimum of $\sim 60$ m over the sea, to a maximum of $\sim 5000$ m above sea level (a.s.l.).
aircraft was based in Toulouse (43°36’ N, 1°26’ E, France) during TRAQA and in Genoa (44°24’ N, 8°55’ E, Italy) during SAFMED. Twenty-four flights for a total of ∼75 h of data have been collected. Seventeen of the twenty-four flights presented in the paper were performed during TRAQA (flight numbers V16 to V32) and 7 during SAFMED (V46 to V52). All flights were carried out during daytime, when light-induced chemistry favours the pollution levels. Frequently, two flights per day, with intermediate stops in different airports in Southern France, Corsica, and Sardinia, were performed. The majority of flights were over the sea, with some exceptions investigating inland areas in Southern France and central Italy. Main information concerning the TRAQA and SAFMED flights is summarized in Table 1.

The general flight strategy consisted in plane flights with lidar observations and vertical ascents/descents to sound the vertical atmospheric column (from ∼60–100 m to 3000–5000 m a.s.l.) and identify main meteorological and aerosol features, followed by straight levelled runs (SLRs) within the detected aerosol layers. In this study we focus on vertical profiles data. A total of 23 profiles were acquired in 20–30 min each by performing a spiral trajectory ∼10–20 km wide. Fig. 1 also identifies the geographical position of each sounding. As shown in Fig. 1 the profiles were performed at different distances from the coastline, from a minimum of ∼5–10 km for V31 and V32 to more than ∼250 km for V20 and V25, and covered almost all the different sectors of the Western Basin.

3 Measurements and methods

The basic equipment of the ATR-42 aircraft includes sensors for the measurements of meteorological parameters (pressure, temperature, relative humidity, wind components), radiative fluxes (down- and up-welling shortwave and longwave radiation), and carbon monoxide (CO) and ozone (O₃) mixing ratios.

Aerosol sampling was performed using the AVIRAD system (Formenti et al., 2011). AVIRAD is an iso-axial and iso-kinetic inlet which, at the normal cruise speed of the
ATR-42 (∼ 93 m s⁻¹), samples air at a volumetric flow of ∼ 350 L min⁻¹. The 50 % passing efficiency of the inlet was tested to be 12 µm diameter. Various sampling lines depart from AVIRAD to connect to different instruments mounted inside the aircraft cabin: (i) a 3-wavelength nephelometer (TSI Inc., model 3563) for the measurement of the dry particle volume total scattering (σₛ) and hemispherical backscattering (σₚₛ) coefficients at 450, 550, and 700 nm, (ii) a 7-wavelengths aethalometer (Magee Sci., model AE31) for the measurement of the particle absorption coefficient (σₐ) at 370, 470, 520, 590, 660, 880, and 950 nm, (iii) an optical particle counter (OPC) (GRIMM Inc., model 1.129) for the measurement of the particle number concentration over 32 size classes between 0.3 and 32 µm in diameter, (iv) a Condensation Particle Counter (CPC, TSI Inc., model 3775) for the measurement of the total particle number concentration in the diameter range 0.004–1.0 µm; and (v) 3 lines for aerosol sampling on filter membranes and a 4-stage cascade impactor (Dekati Inc.) to measure the bulk and size-segregated particle composition. In addition, the ATR-42 was equipped with a Passive Cavity Aerosol Spectrometer Probe (PCASP, model 100X) OPC for the measurement of the aerosol number concentration over 31 size classes between 0.1–3.0 µm. The PCASP was installed outside the cabin on the left side of the aircraft fuselage.

In this study we consider measurements of the (i) aerosol scattering coefficient from the nephelometer, (ii) particle concentration from the CPC and PCASP instruments (GRIMM data are not considered since they are available only below ∼ 350 m during TRAQA), (iii) CO and O₃ trace gases from the MOZART analyser, and (iv) meteorological parameters from the ATR-42 sensors. A more detailed description of the nephelometer, CPC, PCASP, and MOZART measurements and their data analysis is provided in the following sections.

The present analysis is based only on measurements obtained in cloud free conditions.
3.1 Aerosol scattering coefficient

A three-wavelength integrating nephelometer has been used to measure the dry particle volume total scattering ($\sigma_s$) coefficient at 450, 550, and 700 nm. The sampling flow rate was 30 L min$^{-1}$. Data were acquired at 6 s resolution during TRAQA and 1 s resolution during SAFMED. The instrument was calibrated prior the campaign with free-particle air and CO$_2$ as gases of low and high known scattering coefficient. Nephelometer measurements have been corrected for angular truncation and Lambertian non-idealities by applying the formulae by Anderson and Ogren (1998). The measurement uncertainty on $\sigma_s$ is calculated taking into account for the photon counting, gas calibration, and angular corrections uncertainties (Anderson et al., 1996; Anderson and Ogren, 1998). The total uncertainty on $\sigma_s$ is estimated to be lower than 10 % at the three wavelengths.

The nephelometer measured the scattering coefficient in dry air conditions. This is due to the heating of the airflow while entering the aircraft cabin and the temperature in the cavity of the instrument. The relative humidity measured during the flights inside the nephelometer was < 25 % in more than ninety percent of cases, with values up to ~ 40 % occasionally observed at very low altitudes (< 200 m) over the sea surface. A possible underestimation of the scattering coefficient may thus occur in case of hygroscopic aerosols, especially under high relative humidity conditions in the atmosphere.

The particle scattering Ångström exponent ($\alpha_s$) has been calculated from spectral nephelometer measurements with a power-law fit of the measured scattering coefficients vs. wavelength.

3.2 Aerosol particle number concentration

The vertical profiles of the total particle number concentration in the Aitken ($dN_{\text{Aitken}}$, 0.004 nm–0.1 µm), accumulation ($dN_{\text{Acc}}$, 0.1–1.0 µm) and coarse ($dN_{\text{Coarse}}$, > 1.0 µm) modes have been obtained by combining CPC and PCASP data. The CPC and the
PCASP measured at a sample flow of 1.5 and 0.06 L min\(^{-1}\), respectively, and with a time resolution of 1 s for the PCASP and 5 and 1 s for the CPC during TRAQA and SAFMED, respectively.

The PCASP was factory calibrated with monodisperse polystyrene sphere latex (PSL) whose complex refractive index at the instrument operating wavelengths (632.8 nm) is 1.59-0i. The measured sphere-equivalent optical diameter has been converted to a sphere-equivalent geometrical diameter (\(D_g\)) by taking into account the complex refractive index of the sampled aerosol (Liu and Daum, 2000). Given that in the very large majority of cases the aerosol sampling during TRAQA and SAFMED was associated to the export of pollution plumes, only pollution aerosols have been considered for OPC correction. Note that these data are not optimized for dust or marine aerosol observations. A large interval of values (\(n \sim 1.50–1.72, k \sim 0.001–0.1\) for UV-visible wavelengths) are reported in the literature for the real and the imaginary parts of the refractive index for anthropogenic aerosols over Europe (e.g., Ebert et al., 2002, 2004; Müller et al., 2002; Mallet et al., 2003, 2011; Chazette et al., 2005; Raut and Chazette, 2008). For our calculations at 632.8 nm we have fixed the imaginary part of the refractive index to 0.01, thus representing a mean absorbing aerosol, and then we have varied the real part between its minimum (1.50) and maximum (1.72) reported value. \(D_g\) is then set at the mean ± one SD of the values obtained for the different values of \(n\). We assume in these calculations that the refractive index does not vary with height. After refractive index correction the \(D_g\) range for the PCASP becomes 0.10–4.47 µm, with an uncertainty between 1 and 25 %. The smallest and the largest size bins of the OPC, for which the minimum and maximum edges respectively are not defined, have been excluded from the datasets, thus reducing the PCASP \(D_g\) range to 0.11–4.17 µm.

Once corrected for the refractive index, PCASP data have been combined with those from the CPC to calculate \(dN_{Aitken}\), \(dN_{Acc}\), and \(dN_{Coarse}\). Values for \(dN_{Acc}\) and \(dN_{Coarse}\) are obtained by integrating the PCASP number concentrations in the 0.1–1.0 and 1.0–4.17 µm ranges, while \(dN_{Aitken}\) is estimated as the difference between CPC concentra-
tion and the integral of PCASP data between 0.1 and 3.0 µm. The comparison between the PCASP and the GRIMM below 350 m altitude indicates that the former underestimates by about 50 % the aerosol concentration in the range 0.4–1.0 µm (the accuracy of the GRIMM has been verified by optical closure study against simultaneous aircraft nephelometer measurements). This is estimated to induce a ~20 % underestimation of the dN_{Acc} calculated here. Conversely, the PCASP underestimation in the 0.4–1.0 µm range has almost a negligible impact on dN_{Aitken}.

CPC measurements, and so dN_{Aitken} data, were not available during SAFMED flights V49, V50, and part of V51.

### 3.3 Trace gases

Carbon monoxide (CO) and ozone (O₃) mixing ratios were measured by the MOZART instrument described in detail by Nedélec et al. (2003). CO is a long-lived tracer for air masses influenced by combustion processes, whereas O₃ in the troposphere is a photochemical product of the oxidation of CO and volatile organic compounds (VOCs) in the presence of nitrogen oxides (NOₓ). CO and O₃ are measured at a resolution of 30 and 4 s, respectively. The nominal uncertainty is ±5 % for CO and ±2 % for O₃ (Nedélec et al., 2003). However, a recent airborne intercomparison in May 2014 in the framework of the French ChemCalInt project and the TGOE European Joint Research Activity has suggested a greater uncertainty (up to 30 %) on CO measurement by MOZART on-board the ATR-42 (A. Borbon, personal communication, 2015). Trace gas analysis will focus mostly on the vertical distribution of the ∆O₃/∆CO ratio rather than absolute concentrations (see Sect. 5.3) and the uncertainty on CO should not affect data interpretation.

### 3.4 STP conversion

In order to compare measurements obtained at different altitudes the data presented here are reported at standard temperature and pressure (STP) using T = 293.15 K.
and \( p = 1013.25 \text{ hPa} \) (NIST, National Institute of Standards and Technology, values). Hence, the scattering coefficient is scaled to STP conditions and the particle concentrations are given as particles per standard cm\(^{-3}\) (s cm\(^{-3}\)). For a generic parameter \( x \) measured at the temperature \( T \) and pressure \( p \), the conversion at STP is done with the formula:

\[
x(\text{STP}) = x(T, p) \frac{T}{293.15} \frac{1013.25}{p}.
\]  

(1)

CO and O\(_3\) do not need to be corrected for STP since the mixing ratio does not depend on temperature and pressure.

### 3.5 Meteorological parameters

The vertical profiles of the pressure (\( p \)), the temperature (\( T \)), the relative humidity (RH) and the wind components towards the east and the north (\( U, V \)) have been used to analyse the atmospheric structure during flights. Starting from the measured parameters the potential temperature (\( \theta \)) has been also calculated as \( \theta = T \left( \frac{p_0}{p} \right)^{0.286} \) with \( p_0 = 1013.2 \text{ mbar} \). For each profile the height of the marine aerosol boundary layer (MABL) and planetary boundary layer (BL) has been estimated visually by looking at the vertical gradients of \( T, \theta, \) and RH. Meteorological parameters have been also used to calculate the vertical profiles of the gradient Richardson number (\( Ri \)):

\[
Ri = \frac{g}{\theta} \frac{\partial \theta}{\partial z} \sqrt{\left( \left( \frac{\partial U}{\partial z} \right)^2 + \left( \frac{\partial V}{\partial z} \right)^2 \right)}.
\]

(2)

In Eq. (1) \( g \) is the gravitational acceleration and \( z \) is the height. The \( Ri \) number is the ratio between the buoyancy force and the wind shear and it is used to indicate dynamic stability and the formation of clear air turbulence. Turbulence can develop when \( Ri \) is below the critical threshold \( Ri_{\text{crit}} = 0.25 \), while it is inhibited for \( Ri > 1 \) (e.g., Wallace and Hobbs, 2006). In this study the profiles of \( Ri \) are used to provide indications of
favorable/unfavorable conditions for the development of turbulent conditions within the atmosphere.

### 3.6 Tracking the air mass back-trajectories

The Lagrangian trajectory model FLEXTRA (FLEXible TRAjectories, Stohl et al., 1995) has been used in selected cases to track the origin of sampled air masses. Five days three-dimensional back-trajectories have been calculated using the ECMWF (European Centre for Medium-Range Weather Forecast) operational analysis with a 0.5° by 0.5° horizontal resolution and up to 30 vertical model levels below 4000 m. The model specific humidity and potential vorticity is also interpolated along the trajectory path.

### 4 Meteorological conditions, aerosol load, and pollution export regimes

In order to characterize the general aerosol conditions encountered over the Western Mediterranean Basin during the TRAQA and the SAFMED campaigns we have plotted the time-series of the aerosol optical depth ($\tau$) at 440 nm and the 440–870 nm Ångström exponent ($\alpha$) measured at the three AERONET stations of Barcelona, Frioul, and Ersa located around the basin. Data are shown in Fig. 2 and correspond to the period of the campaign of measurements plus 10 days before and after. Table 1 reports the date, location, and main meteorological and export conditions encountered during TRAQA and SAFMED flights.

The TRAQA campaign in 2012 was characterized by very variable meteorological conditions which prevented the accumulation of high levels of pollutants over the basin. The aerosol optical depth was below 0.2 before the beginning of the campaign over the whole basin and increased to $\sim$ 0.3–0.5 (with $1 < \alpha < 2$) in the periods 23–26 June and 3–13 July. Isolated peaks of $\tau$ were measured in correspondence of two Saharan dust intrusion events which occurred on the 17–23 June ($\tau \sim$ 0.6) and 29 June 2012 ($\tau \sim$ 1.4). Different wind regimes occurred during TRAQA and favoured the continental...
outflow from different regions located around the basin. Two examples of wind maps derived from WRF-Chem model (Grell et al., 2005) at 925 mbar are shown in Fig. 3 for 26 June and 3 July 2012. Main observed meteorological/export conditions can be summarized as follows: (i) on 26–27 June north/north-easterly winds blew across northern Italy determining an air mass outflow towards the Gulf of Genoa (measurements on flights V18-V19-V21), (ii) on the same days a strong Mistral-Tramontane episode favoured the dispersion of pollutants towards the central part of the Western Basin. Measurements during the event were performed during flight V20, (iii) on 3–4 July the wind regime was dominated by weasterly/south-weasterly winds mostly blowing at the surface across the Iberian Peninsula and southwestern France. This condition allowed measuring the export of pollution from the Spanish coasts, in particular close to the area of Barcelona (flights V24-V25-V26, see Fig. 3). Additionally, flight V31 sounded the atmospheric structure close to the Spanish coasts reaching the southern urban area of Valencia, (iv) moderate Mistral episodes occurred on the 6–7 and 11 July 2012. In those cases the Mistral wind combined with a persistent westerly flow thus yielding pollution export towards the central and central-eastern part of the Western Basin, as measured during flights V27-V28-V30-V32, (v) finally, Saharan dust aerosols were sampled during flights V16 and V20 (episode of the 17–23 June) and flights V22 and V23 (episode of the 29 June).

During SAFMED the meteorological conditions were more stable and two distinct phases were observed: (i) a stable anticyclone affected the whole Western Mediterranean area during the first half of July until the 26th, thus possibly favouring a more pronounced accumulation of pollution in this part of the basin. Relatively high values of both \( \tau \) (\( \sim 0.2–0.8 \)) and \( \alpha \) (\( \sim 1–2.5 \)) were measured at the three sites of Barcelona, Frioul, and Ersa in this period, (ii) a cyclonic system moving from the Atlantic region towards Europe then affected the Western Basin on 28–29 July 2013. Very clean conditions (\( \tau < 0.1–0.2 \)) were measured afterwards over the entire region until the end of the SAFMED campaign. Winds were mostly westerly/south-westerly in the first period of the campaign (24–29 July 2013, flights V46, V47, V48, V49, V50), which means that
the sampled air flow came mostly from the sea. Then, from 30 July to 1 August 2013 a north-easterly flow affected the SAFMED investigated area thus promoting the export of pollution from Northern Italy towards the Gulf of Genoa (flights V51, V52). A strong Mistral event (29 July–1 August) and two Saharan dust outbreaks (27–28 July and 1 August) affected the Western Basin, however not influencing vertical profile observations during SAFMED.

In order to identify the distribution of observations during TRAQA and SAFMED as a function of the aerosol type we have plotted in Figure 4 the distribution of the measured scattering coefficient \( \sigma_s \) at 450, 550, and 700 nm as a function of the calculated scattering Ångström exponent \( \alpha_s \) for all vertical profiles. The plot shows a similar scattering intensity between cases dominated by coarse particles (\( \alpha_s < 0.5–1.0 \)), such as desert dust, and those dominated by fine particles (\( \alpha_s > 1.0–1.5 \)), such as pollution aerosols. For both dust and pollution \( \sigma_s \) peaks at about 100–120 Mm\(^{-1}\). The frequency of occurrence of \( \alpha_s \) shows that pollution plumes represent the large majority of the cases observed, with more than 70% of measurements with \( \alpha_s > 1.0 \).

5 Results

Figure 5 shows the box and whisker plots of the aerosol scattering coefficient \( \sigma_s \) at 450, 550, and 700 nm, particle number concentration in the accumulation (\( dN_{Acc} \)) and coarse (\( dN_{Coarse} \)) diameter ranges, and CO and O\(_3\) measured in the boundary layer (BL) and in the free troposphere (FT) within pollution plumes for all the different vertical soundings analysed in this study. This plot summarizes the range of values observed during TRAQA and SAFMED. Even within the single BL and FT the different parameters show a large variability that will be explored in the following paragraphs.
5.1 Vertical profiles of aerosol concentration and scattering coefficient

Figure 6 shows the vertical profiles of $\sigma_s$, $dN_{Acc}$, and $dN_{Coarse}$ during TRAQA and SAFMED flights. The date, time and coordinates of each profile, as well as the heights of the top of the marine and planetary boundary layer (MABL and BL) estimated from meteorological data are also indicated in the plot.

For the different vertical soundings the particle concentrations $dN_{Acc}$ and $dN_{Coarse}$ vary in the range $\sim 100–3000$ scm$^{-3}$ and $\sim 5–4000$ scm$^{-3}$, respectively, for plumes with $\sigma_s$ between 10 and 120 Mm$^{-1}$. The profile of the aerosol scattering coefficient is mostly correlated to $dN_{Acc}$, and this also reflects the pronounced spectral variability of the scattering coefficient, typical of pollution/anthropogenic particles. $dN_{Coarse}$ also contributes to the scattering signal in some cases especially at high altitudes (see V16, V20, V21, V22, and V23 above $\sim 2000$ m). These observations are associated to the dust intrusion episodes which occurred in the Western Mediterranean Basin during TRAQA, which however will not be analysed in detail here. Aerosol layers affected by dust have been labelled with a “D” in Fig. 6.

Maxima of the scattering coefficient have been measured for TRAQA flights V21 and V23 ($\sim 120$ Mm$^{-1}$ for pollution in the BL and $\sim 100$ Mm$^{-1}$ in the dust layer), whereas flights V46-V48-V49, during the first and more polluted phase of SAFMED, are the richest in $dN_{Acc}$ (1500–3000 scm$^{-3}$ over the whole column). Minima of $\sigma_s$ and $dN_{Acc}$ are obtained for flight V51 at the beginning of the second SAFMED phase.

Pollution plumes observed in the different flights extend from the boundary layer to the free troposphere up to 3000–4000 m altitude. The vertical structure of the aerosol scattering coefficient/particle concentration is linked to the variability of the atmospheric thermodynamic structure and is generally characterized by a first layer confined in the MABL ($\leq 400$ m, profiles V16, V20, V22, V25, V48, V51), followed by one or more layers within the BL. In the FT pollution particles occur both as single isolated plumes each about 500–1000 m deep (V21, V24, V25, V30, V46, V49), or as a more uniform layer extending from the top of the BL up to 2500–4000 m altitude (V26, V27, V28, V32,
The highest values of both the scattering coefficient and d\(N_{\text{Acc}}\) for pollution are found within the MABL or BL in most cases, while a local minimum of \(\sigma_s\) and d\(N_{\text{Acc}}\) is generally identified at the top of the BL. The scattering coefficient and the particle concentration measured in the FT are comparable with the values observed in the BL, and in few cases even larger (V25, V26, V30). Only in one case (profile V31) \(\sigma_s\) and d\(N_{\text{Acc}}\) decrease monotonically with height. The aerosol vertical distribution, both in the BL and in the FT, often presents a strongly stratified structure characterized by the presence of several thin sub-layers within one main identified aerosol plume, as it can be seen in particular in the d\(N_{\text{Acc}}\) profiles (V20, V21, V22, V25, V46, V49).

The particle concentration in the Aitken mode (0.004–0.1 \(\mu m\); d\(N_{\text{Aitken}}\), not shown in Fig. 6) is generally below 5000–6000 \(s \text{ cm}^{-3}\) at all altitudes up to 4000 m within pollution plumes. d\(N_{\text{Aitken}}\) is correlated with d\(N_{\text{Acc}}\) in most of the observed cases, which indicates the common source of particles in these two size ranges. Few layers exceeding \(\sim 10000–15000 \text{ s cm}^{-3}\) are observed occasionally both in the BL and in the FT. These will be discussed in more detail in Sect. 5.4.

The d\(N_{\text{Acc}}\) and d\(N_{\text{Aitken}}\) measurements within the BL and in the FT over the sea are comparable with the values measured close to the surface at urban continental sites under pollution conditions (Petzold et al., 2002; Mallet et al., 2005; Weigner et al., 2006; Junkermann, 2009; Hamburger et al., 2012). This suggests that the export towards the basin favours the redistribution of the pollution plumes along the vertical. Because of mixing in the BL, measured concentrations within the BL can be as high as those observed close to the surface at urban continental site under pollution conditions. Values of d\(N\) as high as in the BL are observed in the FT because of transport in specific conditions, as discussed below.

The observations of aerosol profiles obtained during TRAQA and SAFMED are representative of the complex transport regimes which characterizes the export towards the Western Basin and that is mostly determined by the interaction between regional meteorology and local dynamics (e.g., Gangoiti et al., 2001). A first example is associated to the measurements in the area of Barcelona. As discussed in Pérez et al. (2004)
the presence of mountains up to ~ 500–3000 m altitude a few kilometres inland favours, during summertime, the recirculation of pollutants along the coasts of Spain. In these cases, the aerosols emitted at the surface in coastal areas are transported inland and uplifted by sea breezes and mountain winds then the plumes are re-injected at different altitudes and distances from the coast. During the TRAQA flights V24, V25, and V26, under the influence of pollution outflow from the Barcelona area, we detected the presence of aerosol layers with elevated concentrations ($dN_{Acc} \sim 2000–3000 \text{ s cm}^{-3}$) up to 3500 m altitude at a distance of ~ 30 to 250 km from the coast of Spain. Another example of complex dynamics linked to coastal orography is that associated to the export from northern Italy and the Po Valley towards the Gulf of Genoa. The presence of the Apennine Mountains close to the Ligurian coasts (max elevation ~ 1500–2000 m) causes the uplift of continental air masses so determining the injection of aerosol plumes at different altitudes both inside and outside the BL. Examples are given by flights V19, V21 and V52 for which pollution aerosols from northern Italy are measured up to ~ 2000–3000 m altitude throughout the Gulf of Genoa. Finally, another meteorological condition which largely influences the aerosol export and distribution over the Western Mediterranean is the Mistral/Tramontane wind regime. Under the influence of the Mistral flow, atmospheric aerosols can be dispersed as far as hundreds of kilometres over the open sea, as discussed by Salameh et al. (2007). Examples are given in profiles V20 and V28, performed at more than 100 km from the French coasts, for which pollution layers associated to a Mistral flow are measured up to 2000–3000 m altitude.

5.2 Trace gases vertical profiles

Figure 7 shows $O_3$ vs. CO for all TRAQA and SAFMED flights, while examples of CO and $O_3$ profiles representatives of different conditions are reported in Figs. 8 and 10.

CO and $O_3$ vary in the range 60–170 and 30–85 ppbv, respectively. The 25th and 75th percentiles are 87 and 105 ppbv for CO and 49 and 62 ppbv for $O_3$, representative of moderate pollution conditions. CO and $O_3$ are generally correlated (correlation coef-
ficient $R^2 \sim 0.5–0.8$) within measured pollution plumes, and also correlated with $\sigma_s$ and $N_{Aitken}$ both in the BL and in the FT, which indicates photochemically active plumes. CO is generally higher in the BL, and shows absolute maxima in the lowest levels (V20, V21, V24, V28, V46), then it decreases in the FT. Ozone presents a more complicated vertical structure due to the different photochemical and dynamical processes which control its formation and distribution. At first, local peaks of O$_3$ correlated with CO are observed in correspondence of pollution plumes both in the BL and in the FT. An absolute maximum of O$_3$ is sometimes found near the top of the BL (V24, V25, V30) possibly due to aged air masses trapped in the boundary layer. Isolated peaks of O$_3$ ($\sim 75–80$ ppbv) not correlated with aerosols and CO are also measured in few cases above 3000–3500 m (V21, V25, V27, V28, V52). The analysis of back-trajectories indicates that these high-altitude ozone layers are associated to the descent of air masses travelling at about 7–8 km, which thus may suggest a downward transport from the upper troposphere or the tropopause region due to a stratosphere-troposphere exchange (Ancellet and Ravetta, 2005). Finally, absolute minima of O$_3$ ($\sim 15–30$ ppbv) are measured within the dust layers during flights V20 and V21, maybe related to the dust/ozone heterogeneous reactions which leads to O$_3$ destruction, as documented in several studies (Bonasoni et al., 2004; Haywood et al., 2011).

### 5.3 $\Delta$O$_3$/ΔCO and $dN_{Aitken}/dN_{Acc}$ ratios and variability of pollution plume composition

Using the O$_3$, CO, $dN_{Aitken}$ and $dN_{Acc}$ measurements we have estimated:

- The O$_3$-CO enhancement ratio ($\Delta$O$_3$/ΔCO), i.e. the ratio of the ozone to carbon monoxide variations compared to their baseline values. The $\Delta$O$_3$/ΔCO enhancement ratio is frequently used to estimate the efficiency of O$_3$ formation and its export (Parrish et al., 1993; Zhang et al., 2006). From our observations (Fig. 7) we have estimated a background value of $\sim 70$ ppbv in the BL and 60 ppbv in the FT for CO and $\sim 30$ ppbv for O$_3$ both in the BL and in the FT.
The Aitken to accumulation number ratio ($dN_{\text{Aitken}}/dN_{\text{Acc}}$), which defines the relative importance of particles in the Aitken and accumulation modes. $dN_{\text{Aitken}}$ is generally associated to gas-to-particle conversion and nucleation events and is higher in fresh plumes, while it decreases with the increasing of the plume lifetime due to coagulation or condensation of water-soluble chemical species on the particle surface (Kulmala et al., 2004).

The combination of $\Delta O_3/\Delta CO$ and $dN_{\text{Aitken}}/dN_{\text{Acc}}$ has been used to retrieve additional information on the atmospheric vertical structure, layering, and particle aging.

Within detected pollution plumes the $\Delta CO$ and $\Delta O_3$ reach up to 100–120 ppbv and 45–55 ppbv, respectively, with a corresponding $\Delta O_3/\Delta CO$ ratio which varies in the range $\sim 0.10–2.0$ for all cases. These values are comparable with the range of observations available in the literature for fresh and moderately aged pollution plumes in the BL and in the lower FT (Chin et al., 1994; Parrish et al., 1998; Zhang et al., 2006; Cristofanelli et al., 2013). $dN_{\text{Aitken}}/dN_{\text{Acc}}$ is between about 1 and 20 in most of pollution cases, which indicates the presence of both fresh layers rich in Aitken particles and aged plumes poor in Aitken particles. Extremely high values of $dN_{\text{Aitken}}/dN_{\text{Acc}}$ ($\sim 50–100$) are measured in few cases in layers with very low $dN_{\text{Acc}}$ concentrations.

The large variability in $\Delta O_3/\Delta CO$ and $dN_{\text{Aitken}}/dN_{\text{Acc}}$ indicates a strong heterogeneity in terms of composition and lifetime for the different observed plumes. This heterogeneity reflects the complexity in terms of sources, production processes, and transport mechanisms which characterizes the Western Basin. In order to illustrate this point, we have selected three examples representative of different conditions observed in different areas of the basin: (i) V19, performed in the Gulf of Genoa in correspondence of continental outflow events from Northern Italy/Po Valley, (ii) V20, performed in Southern France during a Mistral event, (iii) V24, which measured the export of pollution from the area of Barcelona. The vertical profiles of the spectral scattering coefficient $\sigma_s$, temperature $T$, relative humidity RH, $dN_{\text{Acc}}$, $dN_{\text{Aitken}}$, CO, $O_3$, $\Delta O_3/\Delta CO$, $dN_{\text{Aitken}}/dN_{\text{Acc}}$ and wind are reported in Fig. 8 for these cases.
5.3.1 V19: export from northern Italy/Po Valley

The profile shown for flight V19 (Fig. 8a) is characterized by the presence of two different aerosol structures: the first one below 800 m, characterized by low \(dN_{\text{Aitken}}\) and relatively high \(O_3\) concentrations (\(dN_{\text{Aitken}}/dN_{\text{Acc}} \sim 1–5\), \(\Delta O_3/\Delta CO \sim 0.4–1.5\)), possibly associated to moderately aged pollution, and the second one between 800 and 2600 m, very rich in fine particles (\(dN_{\text{Aitken}}/dN_{\text{Acc}} \sim 5–15\)) so possibly associated to fresh emissions. The export of fresh pollution at high altitudes from northern Italy as observed in V19 may be associated to the peculiar orography of this region and the uplift of continental air masses. This is confirmed by the analysis of the back-trajectories (Fig. 9) which indicates that the air masses arriving at 1000 and 2000 m passed over the western Po Valley at an altitude of about 400–1200 m and were then uplifted near the Ligurian coast to enter the basin above the BL. Junkermann (2009) measured high levels of fine particles up to about 2000 m in the western Po Valley, which means that the altitudes of 400–1200 m reached by our investigated air masses could have been sufficient for them to collect fresh emitted particles along their path. Conversely, below 800 m the air mass trajectory shows a longer subsidence over the sea surface in the troposphere which has possibly favoured the advection of more aged plumes, or the mixing with sea salts thus inducing the decrease of the \(dN_{\text{Aitken}}/dN_{\text{Acc}}\) ratio. It should be noted that the aerosol layer in the FT also shows relatively higher values of the \(\Delta O_3/\Delta CO\) ratio (\(\sim 0.6–1.0\)) compared to the more aged plume in the BL. The enhanced amount of \(O_3\) in this air mass can be linked to a high concentration of volatile precursors which may have favoured the build-up of ozone during the plume evolution. In a recent work, Kaiser et al. (2014) suggest that in the Po Valley the high content of formaldehyde, also observed by Junkermann et al. (2009), may be responsible for the excess of \(O_3\) production. Fresh layers in the FT up to \(\sim 2000–3000\) m possibly associated to pollution export from northern Italy have been also observed during flights V21 and V52 (not shown).
5.3.2 V20: export during a Mistral/Tramontane event

V20 provides an example of export during a Mistral/Tramontane event. As shown in Fig. 8b, winds from the northwest direction are measured at all altitudes during flight V20. The aerosol profile in the BL is characterized in the first 400 m by the presence of a layer richer in CO (100 ppbv close to the surface) and $dN_{\text{Aitken}} (dN_{\text{Aitken}}/dN_{\text{Acc}} > 20)$ possibly linked to fresh pollution, followed by the alternation of several layers characterized by a variable $dN_{\text{Aitken}} (1000–6000 \text{ s cm}^{-3})$ and lower CO ($\sim 70 \text{ ppbv}$). For all these layers the O$_3$ is very low ($\sim 30–40 \text{ ppbv}$) and the $\Delta$O$_3$/$\Delta$CO ratio is $< 0.6–0.8$.

At higher altitudes, between 1400 and 2000 m, we observe a layer enriched in O$_3$ ($\Delta$O$_3$/$\Delta$CO $\sim 1–2$) in correspondence of an almost aerosol-free region. This enriched ozone layer might be possibly associated to a downward transport from higher tropospheric layers, as also suggested by the back-trajectories (Fig. 9), as well as to the mixing with ozone rich layers along the air mass trajectory. Larger particles, from long-range transport of Saharan dust at latitudes below $30^\circ$ N, are measured between 2000 and 3000 m, with a minimum of O$_3$ ($\sim 15–20 \text{ ppbv}$) registered within the layer. Several other flights were performed during Mistral/Tramontane episodes (V27, V28, V30, V32) and show, similarly to V20, the presence of several layers both in the BL and the FT.

5.3.3 V24: export from the Barcelona area

Measurements during V24 may be taken as representative of local recirculation (Pérez et al., 2004). In the V24 profile in Fig. 8c we may recognize up to 5 different aerosol layers. A first layer at $< 200 \text{ m}$ within the MABL, coming from the southwest and directly exported from the area of Barcelona. The layer is characterized by high CO (90–120 ppbv), and relatively low values of $dN_{\text{Aitken}} (~ 4000 \text{ s cm}^{-3})$ and O$_3$ ($\sim 50 \text{ ppbv}$), which possibly suggest the mixing of pollution with marine particles close to the sea surface. A second layer of fresher particles, always coming from the southwest direction, is observed above the MABL between 200 and 600 m ($dN_{\text{Aitken}} \sim 6000–8000 \text{ s cm}^{-3}$, O$_3$ $\sim 70 \text{ ppb}$, with $dN_{\text{Aitken}}/dN_{\text{Acc}} \sim 5–15$, and $\Delta$O$_3$/$\Delta$CO $\sim 0.8–0.9$).
A third, more aged, sublayer \( (dN_{\text{Aitken}}/dN_{\text{Acc}} \sim 2–5, \Delta O_3/\Delta CO \sim 0.8–1.0) \) is observed within the BL between 600 and 1000 m. The FT is characterized by the presence of moderately aged plumes from \( \sim 1000 \) to 2800 m \( (dN_{\text{Aitken}}/dN_{\text{Acc}} \sim 2–10, \Delta O_3/\Delta CO \sim 0.2–0.8) \), and a very aged plume at 2800–3800 m almost deprived in Aitken particles and richer in \( O_3 \) \( (dN_{\text{Aitken}}/dN_{\text{Acc}} < 1, \Delta O_3/\Delta CO \sim 0.6–1.5) \). A marked local minimum is observed at the top of the BL for \( \sigma_s, dN_{\text{Acc}}, dN_{\text{Aitken}}, \text{CO, and } O_3 \), suggesting the presence of air masses with different origin between the BL and the FT. This is also confirmed by the analysis of the back-trajectories (Fig. 9) which indicates a low level air masses coming from the Spanish coasts in the BL, and air masses travelling at higher altitudes in the FT. In particular, the layer at 2800–3800 m is possibly associated to an intercontinental transport from Northern America, as shown in the trajectory ending at 3500 m. A similar structure characterized by the alternation of fresher and more aged plumes in the BL and FT is also observed in V25 for which aerosol layers are detected up to 4000 m altitude.

The detailed analysis of these three events evidences the complexity of the atmospheric structure over the Western Mediterranean Basin in link with the different dynamical processes involved.

### 5.4 Layers with enhanced Aitken mode particle numbers

Isolated layers with \( dN_{\text{Aitken}} \sim 10 \ 000–15 \ 000 \ \text{s cm}^{-3} \) have been observed in few cases both in the BL and in the FT. The vertical profiles of \( dN_{\text{Aitken}} \) only for some selected cases are shown in Fig. 10.

For about half of the observed events (V16 at \( \sim 200–400 \) m, V21 at \( \sim 400–800 \) m, V28 at \( \sim 250 \) m, and V31 at \( \sim 1000–3000 \) m; only V28 and V31 shown in Fig. 10) the \( dN_{\text{Aitken}} \) layer presents a good correlation with \( dN_{\text{Acc}}, \text{CO, and } O_3 \) which suggests that the layer has been transported from a region directly emitting in this size range. The most remarkable example is V31 (Fig. 10a), performed close to the coasts of Spain near Valencia, for which the high \( dN_{\text{Aitken}} \) layer extends from the top of the BL to \( \sim 3000 \) m altitude. The wind vector and the back-trajectories (not shown) indicates...
that the air mass comes from the western-southwestern direction above 1000 m, so the $dN_{\text{Aitken}}$ layer can be directly related to pollution export from the urban region of Valencia.

In all the other cases the high $dN_{\text{Aitken}}$ layer appears generally not related to simultaneous $dN_{\text{Acc}}$ and $O_3$ increase. Two of these cases (V16 at $\sim 800–1000$ m and V28 at $\sim 100$ m) occur in the BL.

For the V28 layer (Fig. 10b) the $dN_{\text{Aitken}}$ is correlated with CO which might indicate the influence of local emissions close to the surface level. CO values are relatively high (140–160 ppbv) within the layer. It has been often assumed that new particle formation events (NPF) only occur in almost clean environments (e.g., O’Dowd et al., 2010; Sellegrin et al., 2010), and that they are suppressed under polluted conditions. In a recent study, Brines et al. (2014) show the occurrence of NPF events also in urban areas with high level of pollution in the Mediterranean region. So, we explore the possibility of NPF in our observations. Given the size ranges of the CPC and PCASP, however, we cannot discriminate within $dN_{\text{Aitken}}$ the particle concentration in the sole 4–20 nm range, i.e. the size range involved in nucleation. So it is not possible to directly associate the V28 observations to NPF. In order to obtain a qualitative indication of the possible occurrence of NPF, we have looked at the air mass dynamics within the layer. Several studies suggest, in fact, that NPF might be favoured by turbulence and air mass mixing (e.g., Nilsson et al., 2001; Wehner et al., 2010). We have thus looked at the gradient Richardson number ($Ri$) which gives information on the atmospheric dynamical stability. Vertical profiles of $Ri$ are also shown in Fig. 10. For V28 the vertical profile of $Ri$ indicates that below 200 m the $Ri$ number is consistently below zero, which suggests well established turbulent conditions possibly favouring NPF in this layer.

In other two cases (V19, Fig. 10c, and V26, Fig. 10d), under lower pollution conditions (CO < 100), we measured high $dN_{\text{Aitken}}$ concentration in correspondence of low $dN_{\text{Acc}}$ layers in the FT at $\sim 2800–3000$ m for V19 and 3500–4500 m for V26. For V19 and V26 layers, $dN_{\text{Aitken}}$ seems anticorrelated to CO. Also in this case the Richardson number is below $Ri_{\text{crit}}$ in correspondence of the Aitken peak meaning that conditions
are favorable for turbulence within the layer, and this may indicate also in this case the possible role of NPF.

Finally, a case of high $dN_{\text{Aitken}}$ concentration has been also observed in correspondence of dust particles between $\sim 3000$ and $4000$ m (V23b, Fig. 10e). This layer can be possibly linked to the photochemically-induced nucleation which may occur in presence of dust and $\text{SO}_2$ as hypothesised in a recent study by Dupart et al. (2012) and observed by Nie et al. (2014).

6 Conclusions

The data presented in this paper gives an overview of the distribution of aerosols and trace gases within the tropospheric column up to 5000 m above the Western Mediterranean Basin.

These data add to the very few available measurements of aerosol and trace gases vertical profiles over the sea surface in the Central (e.g., Junkermann, 2001; Meloni et al., 2003; Di Iorio et al., 2003; Pace et al., 2014) and Eastern (e.g., Formenti et al., 2002; Dulac and Chazette, 2003) parts of the basin thus contributing to improve the description of the atmospheric composition and structure over the whole Mediterranean area.

Observations from the present study indicate that continental pollution strongly affects the composition and structure of the Western Mediterranean Basin both close to coastal regions and in the open sea. Pollution layers extend up to 250 km far from the coasts and reach up to 3000–4000 m altitude, presenting a complex and highly stratified structure. The measured particle concentration is comparable with the values reported for continental Europe (Petzold et al., 2002; Junkermann, 2009; Hamburger et al., 2012). In addition, the geographical distribution of aerosols and trace gases observed in this study appears quite homogeneous within the investigated area, suggesting a relatively similar contribution from the various sources located around the north-western basin.
Pollution plumes with different compositions, origins, and lifetimes are observed in link with the different observed dynamical export conditions and meteorological regimes. The aerosol and trace gas observations during TRAQA and SAFMED are consistent with the results of former campaigns and with the interpretation of observed or well known air-masses dynamics and meteorological phenomena that can occur in the Western Basin (Flamant and Pelon, 1996; Millan et al., 1997; Gangoiti et al., 2001; Pérez et al., 2004; Mallet et al., 2005).

The large heterogeneity in aerosol compositions, origins, and lifetimes as documented in this study can reflect in a large heterogeneity of aerosol optical properties, with consequences for their direct radiative effect in this part of the basin. This aspect will be investigated in a companion paper analysing the TRAQA and SAFMED in situ measurements of the aerosol absorption and scattering properties and their variability.

From the present observations, it is also interesting to note the relatively high values of \( dN_{\text{Aitken}} \) measured both in the BL and the FT, which evidences the important contribution of ultrafine particles at all altitudes over the basin. These can be linked to the different export mechanisms previously discussed, as well as the possible occurrence of NPF events. Aitken particle profiles are very rare over the sea surface in the Mediterranean (e.g., Junkermann et al., 2001; Pace et al., 2014) and data comparison is quite difficult. Few studies have observed NPF in the FT in continental areas (Boulon et al., 2010; Rose et al., 2014) and suggest that the export of pollution into the upper troposphere, as it is common in the Western Basin, might promote the occurrence of these events. The observations of the present study may thus also have very large implications due to the crucial role of NPF in controlling the atmospheric cloud condensation nuclei concentration (Spracklen et al., 2008) and the associated aerosol indirect effect on climate.

**Author contributions.** J.-L. Attié, F. Ravetta, G. Ancellet, M. Beekmann, A. Borbon, P. Formenti and K. Sartelet designed the TRAQA and SAFMED experiments and coordinated the campaigns. C. Gaimoz, N. Grand, and C. Di Biagio operated the instruments on board the ATR-42 during the flights. C. Di Biagio performed the data analysis with contributions from L. Doppler,
P. Formenti, F. Ravetta, A. Borbon, G. Ancellet, J.-C. Raut, and M. Beekmann. G. Ancellet performed the FLEXTRA simulations. J.-C. Raut performed the WRF-Chem simulations. C. Di Biagio wrote the manuscript.

Acknowledgements. All measurement presented here are from the Chemistry-Aerosol Mediterranean Experiment project (ChArMEx, http://charmex.lsce.ipsl.fr), which is the atmospheric component of the French multidisciplinary program MISTRALS (Mediterranean Integrated Studies aT Regional And Local Scales). ChArMEx-France was principally funded by INSU, ADEME, ANR, CNES, CTC (Corsica region), EU/FEDER, Météo-France, and CEA. TRAQA was funded by ADEME/PRIMEQUAL and MISTRALS/ChArMEx programmes and Observatoire Midi-Pyrénées. SAFMED was funded by the ANR project SAF-MED (Secondary Aerosol Formation in the MEDiterranean). C. Di Biagio thanks the Centre National des Etudes Spatiales (CNES) for financial support.

The authors wish to thank the technicians, pilots and ground crew of SAFIRE (Service des Avions Francais Instruments pour la Recherche en Environnement) for facilitating the instrument integration and conducting flying operations. We thank S. Chevaillier, L. Girault, R. Loisil, J. Pelon, S. Triquet, and P. Zapf for their contribution during the campaigns. We thank S. Basart, J. M. Baldasano, M. Mallet, P. Goloub, J. Piazzola and their staff for establishing and maintaining the Barcelona, Ersa, and Frioul AERONET sites. Helpful discussions with G. Pace are gratefully acknowledged.

Figure 1. (Upper panel) Flight trajectories of the TRAQA (20 June–13 July 2012) and the SAFMED (24 July–1 August 2013) campaigns. The aircraft was based in Toulouse (43°36′ N, 1°26′ E, France) during TRAQA and in Genoa (44°24′ N, 8°55′ E, Italy) during SAFMED. (Lower panel) Zoom on the investigated area and geographical position of the different vertical soundings analysed in this paper.
Figure 2. Aerosol optical depth at 440 nm (τ) and Ångström exponent (α) measured at different stations in the Western Mediterranean Basin during the TRAQA 2012 (left panels) and the SAFMED 2013 (right panels) campaigns. Data are taken from the stations of Barcelona, Frioul, and Ersa located all around the basin. The time period for the different plots is ±10 days around the beginning/end of the two campaigns. The label D indicates the days affected by Saharan dust.
Figure 3. Example of wind maps at 925 mbar for 26 June and 3 July 2012. The maps are obtained from the WRF-Chem model (Weather Research and Forecasting – Chemistry) at 10 km horizontal resolution.
Figure 4. (Left) Scattering coefficient $\sigma_s$ at 450, 550, and 700 nm vs. the scattering Ångstrom exponent $\alpha_s$. Cases with extremely negative ($<-2$) and positive ($>4$) values of $\alpha_s$ are always related with very low scattering coefficients, and are likely due to instrumental noise under low scattering conditions. (Right) Frequency of occurrence of $\alpha_s$ obtained considering vertical profiles data from all TRAQA and SAFMED flights.
Figure 5. Box and whisker plot of the aerosol scattering coefficient ($\sigma_s$) at 450, 550, and 700 nm, particle concentration in the Aitken ($dN_{Aitken}$) and accumulation ($dN_{Acc}$) modes, and CO and O$_3$ measured within pollution plumes in the boundary layer (BL) and in the free troposphere (FT).
Figure 6. Vertical profiles of the spectral scattering coefficient $\sigma_a$ at 450, 550, and 700 nm and particle number concentration in the 0.1–1.0 µm ($dN_{Acc}$) and 1.–4.0 µm ($dN_{Coarse}$) diameter ranges observed during TRAQA and SAFMED. Data are reported at STP (standard temperature and pressure, $T = 293.15$ K and $P = 1013.25$ hPa). The heights of the top of the marine aerosol boundary layer (MABL) and planetary boundary layer (BL) estimated from the meteorological profiles are also indicated in the plots. The label D is used to identify the aerosol layers affected by Saharan dust. For certain flights (V22, V23, V27, and V28) two vertical soundings were performed; the letters “a” and “b” after the flight number in this plot specify if the considered data are taken from the first or the second sounding, respectively.
Figure 7. O$_3$ vs. CO in the boundary layer (BL) and the free troposphere (FT) for all TRAQA and SAFMED vertical profiles (dust observations excluded).
Figure 8. Aerosol and trace gases vertical profiles for flights V19 (export from northern Italy/Po Valley), V20 (Mistral event), and V24 (export from the Barcelona area). The plots show the: (a) spectral scattering coefficient $\sigma_s$ at 450, 550, and 700 nm (blue, green, and red lines, respectively), temperature ($T$, black line), and relative humidity (RH, light blue line); (b) particle number concentration in the 0.004–0.1 µm ($dN_{\text{Aitken}}$, purple line) and 0.1–1.0 µm ($dN_{\text{Acc}}$, black line) diameter ranges, (c) CO (black dots) and O$_3$ (grey dots) mixing ratios, (d) ozone enhancement factor $\Delta$O$_3$/$\Delta$CO (grey dots) and Aitken to accumulation ratio $dN_{\text{Aitken}}$/d$N_{\text{Acc}}$ (pink dots) and (e) horizontal wind vector. The heights of the top of the MABL (dotted line) and BL (solid line) are also indicated.
Figure 9. Five-days backward air mass trajectories for the V19, V20, and V24 flights calculated with the FLEXTRA model. The upper panel shows the trajectories over an extended latitude-longitude region, while the central panel zooms on the Western Mediterranean area. The altitude of the air masses and its temporal evolution along the five days trajectories is reported in the lower panel of each plot.
Figure 10. Vertical profiles of the accumulation and Aitken particle concentrations ($dN_{\text{Acc}}$, black line, and $dN_{\text{Aitken}}$, purple line), CO (black dots), $O_3$ (grey dots), and gradient Richardson number ($Ri$, green line) for flights (a) V31, (b) V28, (c) V19, (d) V26 and (e) V23b. The horizontal lines indicate the height of the marine boundary layer MABL (dotted line) and the planetary boundary layer BL (continuous line), while the vertical lines indicate $Ri_{\text{crit}} = 0.25$ and $Ri = 1$ (continuous and dashed lines, respectively).
