Abstract

We present a new method for assimilating CH₄ measurements from satellites, which have been retrieved using the proxy-ratio approach, for inverse modeling of CH₄ fluxes. Unlike conventional approaches, in which retrieved CH₄ / CO₂ ratios are multiplied by model derived total column CO₂ and only the resulting CH₄ is assimilated, our method assimilates the ratio of CH₄ and CO₂ directly and is therefore called the ratio method. It is a dual tracer inversion, in which surface fluxes of CH₄ and CO₂ are optimized simultaneously. The optimization of CO₂ fluxes turns the hard constraint of prescribing model derived CO₂ fields into a weak constraint on CO₂, which allows us to account for uncertainties in CO₂. The method has been successfully tested in a synthetic inversion setup using the TM5-4DVAR inverse modeling system. We show that the ratio method is able to reproduce assumed true CH₄ and CO₂ fluxes starting from a prior, which is derived by perturbing the true fluxes randomly. We compare the performance of the ratio method with that of the traditional proxy approach and the use of only surface measurements for estimating CH₄ fluxes. Our results confirm that the optimized CH₄ fluxes are sensitive to the treatment of CO₂, and that hard constraints on CO₂ may significantly compromise results that are obtained for CH₄. We see that the relative performance of ratio and proxy methods have a regional dependence. The ratio method performs better than the proxy method in regions where the CO₂ fluxes are most uncertain. However, both ratio and proxy methods perform better than the surface measurement-only inversion confirming the potential of space borne measurements for accurately determining fluxes of CH₄ and other GHGs.

1 Introduction

In the past century, the concentrations of many potent greenhouse gases (GHGs) have increased in the atmosphere due to anthropogenic activities. The atmospheric dry air mole fraction of the greenhouse gas methane (CH₄), which has a global warming po-

tential of 28–34 on a 100 year time horizon (Myhre et al., 2013), has increased from 700 ppb during the pre-industrial era to ≈ 1800 ppb today (Ferretti et al., 2005). These atmospheric concentrations are unprecedented during at least the last 650 000 years (Spahni et al., 2005). The direct radiative forcing caused by the increase of methane since pre-industrial times is $+0.48 \pm 0.05 \text{ W m}^{-2}$ (Myhre et al., 2013), which amounts to 20 % of the present day cumulative radiative forcing due to all anthropogenic GHGs. Methane also influences atmospheric chemistry and it is an important control on the oxidising capacity of the atmosphere. Further details about methane budget can be found in Kirschke et al. (2013). The atmospheric growth rate of methane has varied considerably in the last two decades (Nisbet et al., 2014; Bousquet et al., 2006). Causes of these variations are still not fully understood, which calls for better monitoring of its sources and sinks using both top-down and bottom-up studies.

The top-down approach uses inverse modeling techniques to reduce the uncertainty in the bottom-up derived emission estimates on the basis of atmospheric measurements of CH₄. In the past, several studies applied the top-down method to surface-based measurements from global monitoring networks such as the National Oceanic and Atmospheric Administration–Earth System Research Laboratory (NOAA/ESRL), the Advanced Global Atmospheric Gases Experiment, and Commonwealth Scientific and Industrial Research Organisation (Houweling et al., 1999; Bousquet et al., 2011, 2006; Hein et al., 1997). However, due to poor spatial coverage of the surface measurement sites, such inversions are effective in constraining the fluxes at sub-continental scales at best (Houweling et al., 1999).

Total column measurements of CO₂ and CH₄ (X_{CH_4} and X_{CO_2}) from satellites have proven valuable for inversion studies of CH₄ and CO₂, especially in regions where surface measurement sites are sparse (Bergamaschi and Frankenberg, 2009; Basu et al., 2014, 2013; Houweling et al., 2014). For example, atmospheric retrievals from the Thermal and Near infrared Sensor for carbon Observations (TANSO) onboard Greenhouse gases Observing SATellite (GOSAT, Kuze et al., 2009) have provided valuable constraints on the fluxes of CH₄ and CO₂ (Basu et al., 2013; Fraser et al., 2013). The CH₄

Interactive Discussion

absorption band at 1.6 micron allows retrieval of its atmospheric concentration with high sensitivity to the planetary boundary layer, where the signals of the sources are strongest. Besides a good sensitivity to the sources, the quality of the inversion-derived CH₄ budget depends strongly on the precision and accuracy of the measurements. It has been shown that systematic errors on regional or seasonal scales of less than 1 % can jeopardize the usefulness of satellite measured CH₄ columns for estimating CH₄ budget (Bergamaschi et al., 2007).

High quality X_{CH_4} and X_{CO_2} retrievals require accurate knowledge of the light-path of the photons that are measured by the satellite. Scattering of light on atmospheric particles (aerosol particles and cloud droplets) may lead to significant light-path perturbations. The accuracy of X_{CH_4} retrievals depends to a large extent on how well the retrieval technique can account for such scattering induced perturbations. A commonly used technique is the so-called proxy method, which was originally developed for retrieving X_{CH_4} and X_{CO_2} using nearby spectral windows from SCIAMACHY (Frankenberg et al., 2005). Since atmospheric scattering affects both compounds in a similar way, light-path errors largely cancel out in the ratio. The retrieval-derived ratio ($\frac{X_{\text{CH}_4}^{\text{obs}}}{X_{\text{CO}_2}^{\text{obs}}}$) is multiplied with a priori knowledge of atmospheric CO₂ derived from a model ($X_{\text{CO}_2}^{\text{model}}$) to generate proxy column measurements of CH₄ ($X_{\text{CH}_4}^{\text{proxy}}$) (Eq. 1).

$$X_{\text{CH}_4}^{\text{proxy}} = \frac{X_{\text{CH}_4}^{\text{obs}}}{X_{\text{CO}_2}^{\text{obs}}} \times X_{\text{CO}_2}^{\text{model}}, \quad (1)$$

$X_{\text{CO}_2}^{\text{model}}$ is usually derived from the results of a CO₂ inversion using the surface measurements, such as CarbonTracker (Peters et al., 2007). It is assumed that: (1) CO₂ exhibits comparatively smaller unknown variations in the atmosphere than CH₄, and (2) residual differences in scattering between the spectral windows of CO₂ (1562 to 1585 nm) and CH₄ (1630 to 1670 nm) used in the retrieval are insignificant. Hence,

Interactive Discussion

CO₂ is used as proxy for changes in the light-path. Schepers et al. (2012) discuss the performance of the GOSAT RemoteC proxy retrieval in detail. This retrieval dataset has been used successfully in inversion studies for optimizing CH₄ fluxes (Monteil et al., 2013; Alexe et al., 2014). In these studies the error in $X_{\text{CO}_2}^{\text{model}}$ is assumed to be negli-

gible compared to retrieval error in $\frac{X_{\text{CH}_4}^{\text{obs}}}{X_{\text{CO}_2}^{\text{obs}}}$. However, with the gradually improving quality of the GOSAT retrievals, errors in model-derived CO₂ may become a bottleneck for improving inversion-derived CH₄ fluxes (Schepers et al., 2012).

In some regions, the sparse network of surface measurement sites does not provide sufficient constraints on CO₂ fluxes, leading to possible biases in $X_{\text{CO}_2}^{\text{model}}$ (Schepers et al., 2012). In this study we investigate a new method, called the ratio method, which circumvents the use of $X_{\text{CO}_2}^{\text{model}}$ by directly assimilating the retrieved ratio of total column CH₄ and CO₂ into an inversion that optimizes CH₄ and CO₂ fluxes simultaneously. Thus, in the ratio method Eq. (1) is replaced by

$$X_{\text{ratio}} = \frac{X_{\text{CH}_4}^{\text{obs}}}{X_{\text{CO}_2}^{\text{obs}}} \quad (2)$$

Our motivation for implementing the ratio method is to find a representation of CO₂ in the inversion system, that is more consistent with both X_{ratio} and CO₂ surface measurements. It is noteworthy that Fraser et al. (2014) have also assimilated $\frac{X_{\text{CH}_4}^{\text{obs}}}{X_{\text{CO}_2}^{\text{obs}}}$ for constraining the surface fluxes of CH₄ and CO₂. However, the transport model and inversion method used in their study are different from the ones used here.

We perform Observing System Simulation Experiments (OSSEs) to test the performance of the ratio method for reproducing the assumed true fluxes of CH₄ and CO₂. The results are compared with inversions using proxy retrievals and only surface measurements. In the following Sect. 2, we elaborate on our inverse modeling setup, and describe our OSSE experiments. In Sect. 3, we analyze and compare the

inversion-estimated posterior fluxes of CH₄ and CO₂. In Sect. 4, we further discuss the significance and limitations of our findings and evaluate the future potential of the ratio method for application in inversion studies, leading to our final conclusions.

2 Method

2.1 Inverse modeling

We use the TM5-4DVAR inversion system in this study. It comprises of the Tracer Transport Model version 5 (TM5, Krol et al., 2005) coupled to a variational data assimilation system (4DVAR, Meirink et al., 2008). TM5 simulates the spatio-temporal distribution of a tracer in the atmosphere for a given set of fluxes and initial concentrations that are prescribed as boundary conditions to the model. We have setup a dual tracer version of TM5-4DVAR for simultaneous simulation of CH₄ and CO₂. By combining the output of the two tracers, this model allows us to simulate X_{ratio} (see Eq. 2). The 4DVAR technique uses model calculated and observational dataset of X_{ratio} to optimize a state vector \mathbf{x} , consisting of surface fluxes of CH₄ and CO₂. The optimum is found by minimizing a Bayesian cost function, defined as

$$J(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}_b) + \frac{1}{2}(\mathbf{y} - \mathbf{H}\mathbf{x})^T \mathbf{R}^{-1}(\mathbf{y} - \mathbf{H}\mathbf{x}) \quad (3)$$

where \mathbf{x}_b is the a priori knowledge of \mathbf{x} , and \mathbf{H} is the observation operator, which converts the output of the model, forced by \mathbf{x} , to corresponding mixing ratios at the measurement sites of \mathbf{y} . Hence, $\mathbf{H}\mathbf{x}$ represents the model simulated counterpart of the observation vector \mathbf{y} . \mathbf{R} and \mathbf{B} are error covariance matrices for $\mathbf{y} - \mathbf{H}\mathbf{x}$ and \mathbf{x}_b , respectively. Each iteration of TM5-4DVAR is composed of a forward and an adjoint TM5 run (Errico, 1997). The forward run is used to calculate the value of the cost function for a trial state vector \mathbf{x}_j (using Eq. 3). The adjoint run provides the corresponding cost function gradient ($\nabla J(\mathbf{x}_j)$). At the end of each inversion iteration j , $\nabla J(\mathbf{x}_j)$ and

the state vector x_j are fed into an optimizer module to calculate the state vector for the next iteration (x_{j+1}). For linear inverse problems we use the conjugate gradient optimizer (CONGRAD, Lanczos, 1950), that has been used extensively for linear inversion problems (Monteil et al., 2011, 2013; Houweling et al., 2014; Basu et al., 2013).

Mathematically, it has the fastest convergence rate for linear inversions problems, but it performs poorly for non-linear inversion problems, because it assumes that the shape of the cost function is a multi-dimensional parabola.

For non-linear problems we use M1QN3, a quasi-Newton algorithm based optimizer (Gilbert and Lemaréchal, 1989), which is also commonly used in inverse modeling (Cressot et al., 2014; Krol et al., 2013; Muller and Stavrakou, 2005). Our inversion setup for the proxy approach is linear. However, for the new ratio method operator H includes Eq. (2), and hence, the inversion becomes non-linear making M1QN3 a more suitable optimizer than CONGRAD. M1QN3 has a slower convergence rate in comparison to CONGRAD, and therefore the number of iterations needed to find the inversion solution is generally higher. Another drawback of the M1QN3 algorithm that is available to us is that, unlike CONGRAD, it provides no information about the posterior flux uncertainties in a straight forward way.

2.2 Truth and prior

The assumed true CH₄ and CO₂ fluxes for our inversion setup are taken from Houweling et al. (2014) and Basu et al. (2013), respectively. The generation of pseudo observations y is explained in the next section. Concerning the state vector x , CH₄ fluxes are optimized for a single category representing the net flux from all the contributing processes at the surface, discretized per model grid box and per month. For CO₂, we optimize for fluxes from the biosphere and the ocean, discretized in time and space like methane. We do not optimize emissions from other categories like biomass burning and fossil fuel usage, as they are assumed to have relatively small uncertainties. Table 1 shows the parameters used to calculate the error covariance matrix B for the prior fluxes. For details about the implementation of B in our inversion see Basu et al. (2013).

Interactive Discussion

We use one set of prior fluxes x_b for all inversions, which was created by adding Gaussian noise to the true CH₄ and CO₂ fluxes. The noise is generated using the a priori flux uncertainties accounting for spatial and temporal error correlations, as described in Chevallier et al. (2007). Figure 2 shows time series of the true and prior fluxes for four Transcom regions (explained in Fig. 1). As can be seen, the assumptions regarding the a priori flux uncertainties lead to realistic deviations from the truth in terms of seasonality and net monthly flux.

2.3 Measurements

Pseudo surface observations are generated from a forward run of TM5 using the “true” fluxes as boundary conditions, and they are sampled at coordinates and times of samples collected by the NOAA/ESRL cooperative flask-sampling network (Dlugokencky et al., 2009) in the period 1 June 2009 to 30 May 2010 at the sites shown in Fig. 1. In total, we use 3934 surface measurements of CH₄ (from 93 sites) and 1184 measurements of CO₂ (from 85 sites). Similarly, synthetic total column measurements are generated at the times and locations of the GOSAT RemoTeC v1.9 proxy satellite retrievals for the same time period (Schepers et al., 2012). The forward run of TM5 calculates 25 layer vertical model profiles at the retrieval coordinates. These profiles are converted into the corresponding total columns using the retrieval derived averaging kernels (see e.g. Monteil et al., 2013). In total, we use 443 523 GOSAT total column retrievals of both CH₄ and CO₂ (see Fig. 3).

The observational part of cost function is calculated by weighing the mismatch between the model simulations and measurements ($y - Hx$) with the data error covariance matrix R . The diagonal terms of R are the squared sum of measurement uncertainty and model representation error. The model representation error is the error made by our finite resolution model in simulating a sample at a specific location. Its size scales with the sub grid concentration variability, and is calculated using the local concentration gradient simulated by the model. Further details about the calculation of the model representation error in our setup can be found in Basu et al. (2013). For the mea-

surement uncertainties we follow the recommendations of the data providers. For the GOSAT retrieved total column ratios, the uncertainty was calculated by error propagation of the instrument's measurement noise of the CH₄ and CO₂ total columns given in retrieval data set. The uncertainties of proxy CH₄ total columns are also calculated in similar ways. In principle, they should be the ratio uncertainties plus the $X_{\text{CO}_2}^{\text{model}}$ uncertainty (see Eqs. 1 and 2). However, the uncertainties from $X_{\text{CO}_2}^{\text{model}}$ are neglected in real world applications, and we follow the same procedure. Hence, in our experiment, the ratio and proxy columns have the same relative uncertainties. For computational efficiency, we assume no correlation between the measurements (i.e. all the non-diagonal term of \mathbf{R} are set to zero).

Formally, we should perturb the pseudo measurements with noise according to the data covariance matrix \mathbf{R} , following the same procedure as for the a priori fluxes. However, to catch the mean behavior one would have to do several inversions with different noise realizations. This multi-inversion mean would correspond to the results of a single inversion without noise. For this reason we do not perturb the data. It should also be noted that satellite measurements are simulated using the same prior profiles as used for the real RemoTeC GOSAT retrievals. Since the same prior profile is used in the inversion and in the generation of pseudo data, its contribution cancels out in the model data mismatch and therefore does not influence the results.

In the ratio inversion, the GOSAT measurements are in terms of X_{ratio} , whereas the output of the Transport model is in terms of $X_{\text{CH}_4}^{\text{obs}}$ and $X_{\text{CO}_2}^{\text{obs}}$. The observation operator \mathbf{H} transforms the absolute columns to column ratios using Eq. (2). For calculating the gradient of $J(\mathbf{x})$, the adjoint of \mathbf{H} is needed for propagating the sensitivities of the cost function from X_{ratio} to the corresponding sensitivities of $X_{\text{CH}_4}^{\text{obs}}$ and $X_{\text{CO}_2}^{\text{obs}}$. This adjoint is derived by applying the adjoint coding rules described in Errico (1997). It should be noted that the problem is only weakly non-linear since the values of $X_{\text{CO}_2}^{\text{obs}}$ vary in the narrow range of ≈ 350 – 400 ppm in our calculations, and the inversion-derived adjustments to $X_{\text{CO}_2}^{\text{obs}}$ are only a small fraction of that range.

2.4 Experiment

In this study, we perform OSSEs comparing different global inversion setups using the same truth and a priori fluxes. The inversions system is run at a $6^\circ \times 4^\circ$ horizontal resolution and 25 vertical hybrid sigma-pressure levels from the surface to the top of the atmosphere. Simulations are performed for the period 1 June 2009 to 30 May 2010. The transport in TM5 is driven by meteorological fields from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-interim reanalysis project (Dee et al., 2011). Table 2 provides an overview of the inversions that have been performed, specifying the fluxes that were optimized, the optimizer that was used with number of iterations, and the type of measurements assimilated. The PROXY inversion requires $X_{\text{CO}_2}^{\text{model}}$ (see Eq. 1), which is calculated by sampling the output of a forward run of TM5 using posterior CO_2 fluxes from the SURFCO2 inversion and applying the GOSAT averaging kernel.

The TRU-DAT represents an inversion which assumes that we have perfect knowledge of $X_{\text{CO}_2}^{\text{model}}$. It is used as a best-case scenario for the proxy method. In contrast, $X_{\text{CO}_2}^{\text{model}}$ for PRICO2 was calculated using prior CO_2 fluxes transformed directly into observations using TM5 without optimization using CO_2 surface measurements. This inversion represents a worst case scenario for the proxy method. The RATIO inversion uses our new ratio method, assimilating surface CH_4 and CO_2 observations, and X_{ratio} for optimizing surface CH_4 and CO_2 fluxes. PROXY represents the common use of proxy retrievals in atmospheric inverse modelling. In PROXY, the same amount of measurements are assimilated in a series of two linear inversions: (1) optimization of CO_2 fluxes w.r.t. the surface data (SURFCO2), (2) an inversion using surface CH_4 and $X_{\text{CH}_4}^{\text{proxy}}$ (PROXY). We use 50 CONGRAD iterations for both of these inversions. In RATIO, all the information is assimilated in a single inversion using 100 M1QN3 iterations.

2.5 Analysis

In Sect. 3, we analyze the monthly time series of posterior fluxes from different inversions using Taylor plots (Taylor, 2001) and mean annual departures from the true fluxes aggregated over the land Transcom regions. We only show the analysis of the fluxes over the land as the fluxes of CH₄ are negligible over the oceans. We define the following parameters to represent the average deviation of the posterior fluxes from the truth over all the land Transcom regions:

$$\begin{aligned}\kappa &= \overline{|\text{cor} - 1|}, \\ \gamma &= \overline{|\sigma/\sigma_{\text{truth}} - 1|}, \\ \beta &= \overline{|\text{bias}|},\end{aligned}\tag{4}$$

where cor is the cross-correlation between the posterior and true monthly flux time-series for a Transcom regions, and $\sigma/\sigma_{\text{truth}}$ is the relative SD of the posterior and true monthly flux timeseries of a Transcom region. In the Taylor plots, $\sigma/\sigma_{\text{truth}} = 1$ and cor = 1 represent the true fluxes and therefore, we subtract 1 from both the values in Eq. (4) to represent the deviation of prior or posterior fluxes from true fluxes. Finally, bias is the difference of the posterior and true net annual flux of a Transcom region. It should be noted that κ and γ are dimensionless, and β has a unit of Tgyr⁻¹ for CH₄ and PgCyr⁻¹ for CO₂. Table 3 lists the values of these parameters for the inversions performed in this study. The closer these values are to zero for an inversion, the better it is performing. With each parameter at zero the agreement between the true and inversion-optimized fluxes is perfect.

3 Results

3.1 Ratio method implementation

Figure 3 summarizes the performance of RATIO (see also Table 2). The pseudo X_{ratio} measurements have typical values in the range of 4.4 to 4.8 ppb ppm⁻¹. We observe that the latitudinal gradient of CH₄ atmospheric concentration is a dominant mode of variation in X_{ratio} . The randomly generated globally and annually integrated a priori CO₂ flux, combining land and ocean, is 2.01 Pg Cyr⁻¹ larger than the true flux (truth = -4.65 Pg Cyr⁻¹, prior = -2.640 Pg Cyr⁻¹). As a result of this, the a priori fluxes overestimate the global CO₂ increase. The global annual prior CH₄ flux is only 6.85 Tgyr⁻¹ lower than the truth (truth = 541.764 Tgyr⁻¹, prior = 534.905 Tgyr⁻¹), which is a much smaller relative deviation from the true fluxes compared to CO₂. Hence, the percentage mismatch between the modeled prior and measured X_{ratio} is mostly positive over the globe (Fig. 3c). The figure also compares the prior and posterior misfits of RATIO to the “true” X_{ratio} . The measurement uncertainty of X_{ratio} increases towards higher latitudes. We find a gradient norm reduction of ≈ 2000 for 100 M1QN3. As expected, the posterior mismatches are strongly reduced in-comparision to the prior, demonstrating that the ratio inversion system works mathematically and that it is reasonably efficient in minimizing the cost function. The improved fit of measurements also leads to a convergence of the posterior fluxes towards the true fluxes, as will be discussed in detail in Sects. 3.3 and 3.4.

3.2 TRU-DAT and PRICO2

As explained in Sect. 2.4, TRU-DAT and PRICO2 represent best and worse case scenarios of the impact of errors in $X_{\text{CO}_2}^{\text{model}}$ on the results of a proxy inversion. Here we analyze the differences between these inversions, which inform us about the sensitivity of the proxy method to errors in $X_{\text{CO}_2}^{\text{model}}$. Figure 4 compares the performance of PRICO2 and TRU-DAT using Taylor plots. In these plots, each point represents a 12

month timeseries of CH₄ fluxes integrated over a land Transcom region. Compared to the prior ($\kappa = 0.286$ and $\gamma = 0.211$), the posterior fluxes of TRU-DAT shows much better agreement with the true fluxes ($\kappa = 0.024$ and $\gamma = 0.042$). PRICO2 ($\kappa = 0.210$ and $\gamma = 0.258$), on the other hand, performs even worse than the prior in terms of γ .

Figure 5 shows how well the TRU-DAT and PRICO2 inversions are capable of reproducing the true annual fluxes integrated over land Transcom regions. The β values are 2.370, 2.409 and 0.621 Tgyr⁻¹ for PRIOR, PRICO2 and TRU-DAT, respectively. Again, we observe that on average the results of TRU-DAT are closest to the truth, and that the results for PRICO2 are further away from truth than the a priori fluxes. This tells us that the performance of inversions assimilating proxy data is sensitive to our knowledge of the CO₂ fluxes. In practical applications, however, the CO₂ fluxes will first be optimized using surface measurements to obtain a better representation of atmospheric CO₂ concentrations. Inversions representing this approach will be discussed in the next section.

3.3 PROXY, RATIO and SURFCH4

Next we analyze the difference between the proxy inversion (PROXY), using optimized CO₂ concentrations from SURFCO2, and our new ratio method (RATIO). For comparison, we also include results of SURFCH4 using only surface CH₄ measurements. The performance of these inversions is analyzed as in Sect. 4.2, and the results are summarized on Figs. 6 and 7. All three inversions improve the cor of the posterior fluxes with the truth compared to the prior but have varied performance in improving $\sigma/\sigma_{\text{truth}}$. The prior fluxes of Boreal North America are closer to the truth than any of the posterior fluxes. However, it should be realized that the prior fluxes were created by adding random noise to the truth, which happens to be a small perturbation occasionally. This is why we average results over all land Transcom regions to derive meaningful comparisons. The κ and γ values, representing the average performance over land Transcom regions, are shown in Table 3. We observe that RATIO and PROXY perform better than

SURFCH4, confirming the importance of information provided by the satellite measurements.

Figure 7 shows the departures of the annual fluxes from the truth aggregated over land Transcom region. β values are 2.37, 1.40, 1.43, and 1.96 Tgyr⁻¹ for PRIOR, RATIO, PROXY and SURFCH4, respectively (see Table 3). Overall, we find that the performance of RATIO and PROXY is similar. RATIO performs better than PROXY in 6 regions, and PROXY is better in the other 5 regions. The PROXY inversion shows the worst performance in Boreal North America, Temperate North America and Boreal Eurasia, and RATIO has the worst performance in Southern Africa.

Overall, we find that with the additional information provided by the satellite measurements RATIO and PROXY are able to reproduce the true fluxes better than SURFCH4. However, it is difficult to conclude if RATIO or PROXY performs better, as their relative performances vary across the regions. As can be seen in Figs. 6 and 7, PROXY clearly has a poor performance over Temperate North America. Similarly, RATIO performs worse in Southern Africa than PROXY. These varying relative performances is further investigated in the next subsection. Annual flux uncertainties of the fluxes are shown as error bars in the Fig. 7. It should be noted that unlike PROXY and SURFCH4, RATIO does not estimate posterior uncertainties. This drawback of RATIO will be further discussed in the Sect. 4. The reduction in uncertainty is larger for PROXY than SURFCH4 in the regions where we have less surface measurements (in Tropical South America, Temperate South America, Northern Africa). This can be attributed to the larger number of satellites observations in comparison to surface measurements in these regions. In other regions, both inversions show similar uncertainty reductions due to a higher gradient norm reduction achieved by SURFCH4 (3.1×10^{10}) compared to PROXY (3.9×10^3). Both inversions are run for 50 iterations, but PROXY has a larger number of data to assimilate than SURFCH4, and therefore, it achieves a lower gradient norm reduction.

Interactive Discussion

3.4 CO₂ fluxes

As explained in Sect. 1, the motivation for our ratio technique is to obtain a more consistent representation of the CO₂ concentration fields in the atmosphere. In this subsection, we address the question whether RATIO optimized CO₂ fluxes are indeed closer to the truth than those obtained using SURFCO2 (which are used for PROXY). Figure 8 shows the deviations of posterior CO₂ fluxes from the truth for RATIO and SURFCO2. In general, annual a priori CO₂ fluxes show large relative deviations from the truth compared to CH₄. This is a direct consequence of the assumed a priori flux uncertainties (see Table 1). The β values (Table 3) are 0.327, 0.185 and 0.134 PgCyr⁻¹ for PRIOR, SURFCO2 and RATIO, respectively. RATIO is able to constrain CO₂ fluxes better than SURFCO2. The difference between SURFCO2 and RATIO is explained by regions such as Temperate North America and Temperate South America, which are relatively poorly constrained by SURFCO2. RATIO is performing better in these regions with the help of satellite measurements. This difference in the performance can also be attributed to the high model representation error associated with the point measurements in Temperate North America and a lack of surface measurement stations in Temperate South America.

Figure 9 shows how well the inversion-derived CO₂ fluxes reproduce the true seasonality. Compared with CH₄, the prior fluxes correlate well with the truth, despite their relatively large a priori uncertainties. This reflects the large seasonal variation in the biospheric CO₂ fluxes. For CO₂, the differences in the Taylor diagrams are dominated by variations in $\sigma/\sigma_{\text{truth}}$. Overall, RATIO ($\kappa = 0.125$, $\gamma = 0.225$) performs better than SURFCO2 ($\kappa = 0.180$, $\gamma = 0.241$). RATIO is able to reproduce the true seasonality for most regions except Northern Africa, Temperate Eurasia and Tropical Asia. In Temperate Eurasia, SURFCO2 performs very well. However, it performs worse than RATIO in Tropical Asia. In Tropical South America and Temperate South America, we find a similar performance of RATIO and SURFCO2. The prior for Europe does not deviate

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

much from the truth, so the relative performance for the two methods cannot be judged adequately.

3.5 The link between CO₂ and CH₄

In principle, the performance of PROXY should improve with the performance of SURFCO₂. If SURFCO₂ reproduces the true CO₂ fluxes exactly, then the only source of error in $X_{\text{CH}_4}^{\text{proxy}}$ due to $X_{\text{CO}_2}^{\text{model}}$ will be the representation error of the finite resolution model used for generating spatio-temporal fields of CO₂. Also in the case of RATIO, the correctness of posterior CH₄ fluxes is dependent upon the correctness of CO₂ fluxes and vice-versa. For example, Figs. 8 and 9 show that Southern Africa has a poor performance of RATIO, and that SURFCO₂ has a poor performance in Temperate North America for constraining CO₂ fluxes. This is also reflected in the poor performance of RATIO and PROXY in constraining CH₄ fluxes in these regions (Sect. 3.3). The performance of SURFCO₂ varies regionally, which causes a corresponding pattern in the performance of PROXY. The same relation should hold for the posterior CO₂ and CH₄ fluxes calculated with RATIO. To quantify this relation, we define p_{CH_4} as a measure of the relative accuracy of RATIO and PROXY derived CH₄ fluxes, and p_{CO_2} as a measure of the relative accuracy of RATIO and SURFCO₂ derived CO₂ fluxes for each Transcom region. They are defined as

$$\begin{aligned}
 p_{\text{CH}_4} &= \left| x_{\text{CH}_4}^{\text{PROXY}} - x_{\text{CH}_4}^{\text{truth}} \right| - \left| x_{\text{CH}_4}^{\text{RATIO}} - x_{\text{CH}_4}^{\text{truth}} \right|, \\
 p_{\text{CO}_2} &= \left| x_{\text{CO}_2}^{\text{SURFCO}_2} - x_{\text{CO}_2}^{\text{truth}} \right| - \left| x_{\text{CO}_2}^{\text{RATIO}} - x_{\text{CO}_2}^{\text{truth}} \right|,
 \end{aligned} \tag{5}$$

where the x 's denote timeseries of monthly fluxes integrated over land Transcom regions. The subscripts indicate the tracer, and the superscripts indicate whether the fluxes refer to the truth or inversion estimates. p_{CH_4} and p_{CO_2} are arrays of 12 month timeseries for each land Transcom regions. They are defined such that: (1) $p_{\text{CH}_4,i} > 0$ implies that RATIO is performing better than PROXY for CH₄ fluxes in the month i . (2)

$p_{\text{CO}_2,i} > 0$ implies that RATIO is performing better than SURFCO2 for CO_2 fluxes in month i . (3) For values of $p_{\text{CH}_4,i}$ and $p_{\text{CO}_2,i}$ less than 0 the reverse of (1) and (2) is true.

The upper panel of Fig. 10 shows p_{CO_2} and p_{CH_4} series for Boreal North America. Lower panels of Fig. 10 shows the cross-correlations between p_{CH_4} and p_{CO_2} for each land Transcom region. As it can be seen, this value is above 0.7 (mean = 0.809) for all regions except for Australia (0.202) and BEr (0.539). A lack of surface measurement in these two regions can be the reason for the low correlation as surface measurement stations are needed for good performance of both RATIO and PROXY (Sect. 4). Overall, we conclude that the relative performance of the proxy and ratio methods depends strongly on the relative performance of the surface-only and ratio CO_2 inversions.

4 Discussion

We have developed the “ratio” method. It is an inversion system for assimilating the ratio of satellite-retrieved total columns of CH_4 and CO_2 along with surface measurements for constraining their surface fluxes. The main advantage of the method over the traditional proxy method is that it does not impose model-derived CO_2 concentrations as a hard constraint on the CH_4 flux optimization. Instead, our method allows optimization of CO_2 and CH_4 fluxes within a single consistent framework. This way we can benefit from the proxy retrieval, which has proven to be highly efficient in reducing the errors due to light-path modification by atmospheric scattering (Sect. 1), but at the same time, avoid projection of errors in $X_{\text{CO}_2}^{\text{model}}$ on the inverted CH_4 fluxes. The method requires assimilation of surface measurements of CH_4 and CO_2 as an additional constrain, since, a ratio alone is not a sufficient constrain for absolute values of CH_4 and CO_2 fluxes. For example, the inversions can reduce the absolute CH_4 and CO_2 modeled columns by the same factor and can still fit their ratio column to give a lower value of the cost function (Eq. 3).

Interactive Discussion

The performance of the ratio method is tested in comparison with the traditional proxy method and surface-only inversions in an OSSE using the TM5-4DVAR atmospheric inversion system. Overall, we observe that the ratio method is capable of reproducing the true CH₄ and CO₂ fluxes better than the surface-only inversion. The performance of ratio method in comparison to the proxy method varies among land Transcom regions.

The ratio method is a more complicated inversion to solve than a proxy inversion as it is a non-linear inversion problem, and therefore the widely used CONGRAD optimizer cannot be used. In our setup, we use the M1QN3 optimizer, which is capable of handling the non-linearity. However, to inter-compare inversions using different optimizers requires attention as mathematically their mode of operation is different. For example, CONGRAD constrains the largest spatial and temporal scales in the first few iterations, gradually adjusting finer scales in subsequent iterations. M1QN3 works in similar manner, however, it has a much slower convergence rate for the finer scales than CONGRAD. Hence the overall convergence rate of M1QN3 is slower than CONGRAD, and to achieve the same gradient norm reduction it takes more iterations (Krol et al., 2013).

Another drawback of M1QN3 compared to CONGRAD is that no information is obtained about posterior flux uncertainties, since the method does not collect information about Hessian of the cost function like CONGRAD. Posterior uncertainties are essential for inverse modeling applications using real data to quantify the constraints on the fluxes imposed by measurements. This is true, despite the fact that several important sources of uncertainty, such as transport model uncertainties, are difficult to account for. Furthermore, the accuracy of CONGRAD's uncertainty approximation may be rather poor for large optimization problems, limiting its use. An alternative method for calculating posterior uncertainties is to use a Monte Carlo approach (Chevallier et al., 2007). This method can be applied also to inversions using M1QN3, although the method is computationally expensive. So far we have not investigated possible alternatives for M1QN3. However, we would like to stress that there is a scope to find

a more efficient optimizer for solving this non-linear optimization problem, and future studies into the application of the ratio method should put an effort in this direction.

Now that we have demonstrated that the ratio method works in a synthetic environment the next step is the application of the method to real satellite data. A first step in this direction is to validate GOSAT observed X_{CH_4} over X_{CO_2} ratios with TCCON. After that we plan to apply the ratio method to real satellite data, and compare the outcome with inversions using the GOSAT proxy and full-physics retrieval products. With improved constraints on the CO_2 side of problem, as more space borne CO_2 measurements becoming available from GOSAT and OCO-2, the proxy method is expected to perform better for methane. In this case one would expect the results of the proxy and ratio methods to converge. Whether or not this will really happen depends on the mutual consistency of the various data streams. The ratio method provides an internally consistent setup (i.e within a single inversion system) to test this and to identify remaining biases. It should be noted that computationally, the ratio method has the advantage that it optimizes CH_4 and CO_2 fluxes together. This method can also be applied to other pairs of tracers, which are retrieved from close-by spectral ranges in the satellite measurement spectra. For example, CO total columns will be retrieved from TROPOMI (to be launched in 2016) using CH_4 as the proxy for atmospheric scattering, and there is a possibility, that our ratio method can be applied successfully to this pair of tracers.

5 Conclusions

We developed a new inverse modeling method within the TM5-4DVAR inverse modeling framework for direct assimilation of satellite observed ratios of total column CH_4 and CO_2 . The dual tracer inversion solves for surface fluxes of CH_4 and CO_2 . Our current implementation also assimilates surface measurements of CO_2 and CH_4 to further constrain the two tracer inverse problem. To deal with the weak non-linearity introduced by the optimization of tracer ratios we make use of the M1QN3 optimizer, instead of the CONGRAD optimizer, which was used so far for inversions using proxy retrievals.

Interactive Discussion

Although the optimization of the ratio inversion using M1QN3 is about a factor 2 less efficient than the corresponding proxy inversion using CONGRAD, we nevertheless find satisfactory gradient norm reductions (by a factor of ≈ 2000 in 100 iterations). We tested our method in an OSSE setup. We observe good convergence of posterior model columns toward the true ratio columns, and the ratio method is able to reproduce the true CH₄ and CO₂ fluxes from randomly perturbed prior fluxes.

We performed additional inversions in our OSSE setup to compare the performance of inversions using proxy and ratio retrievals from GOSAT. In addition, we compare the performances of these inversions, which also use surface measurements, with inversions that use surface measurements. Additional inversions are performed to test the sensitivity of proxy inversions to the quality of the model derived CO₂ concentrations, which are used to translate the retrieved tracer ratios into total columns of CH₄. The performance of these inversions is evaluated by comparing the inversion-derived fluxes to a set of true fluxes from which the synthetic measurements were derived. The performance is assessed for monthly and annual fluxes integrated over the 11 land Transcom regions. Our results demonstrate that the estimation of CH₄ fluxes using the proxy inversion is sensitive to errors in the modeled derived CO₂ concentrations.

We conclude that for most Transcom regions the ratio method is capable of reproducing the true seasonality and annually integrated CH₄ fluxes. However, it should be noted that availability of surface measurements is important for good performance of the ratio method. The relative performance of the proxy and ratio methods shows a relationship with errors in CO₂, with ratio method performing better in regions where the CO₂ fluxes are poorly constrained. In our synthetic simulations, the ratio inversion is capable of improving the CO₂ fluxes compared with the use of CO₂ surface-only measurements, which explains why it outperforms the proxy method in certain regions. This points to the applicability of the ratio method for improving CO₂ fluxes in these regions. Further research is needed to test the performance of the ratio method in the applications using real satellite data.

Acknowledgements. This work is supported by the Netherlands Organization for Scientific Research (NWO), project number ALW-GO-AO/11-24. The computations were carried out on the Dutch national supercomputer Cartesius, and we thank SURFSara (www.surfsara.nl) for their support. We thank our data providers: NOAA/ESRL cooperative flask-sampling network surface observations were obtained from the website <http://www.esrl.noaa.gov/gmd/dv/ftpdata.html>; Access to the GOSAT data was granted through the 3rd GOSAT research announcement jointly issued by JAVA, NIES, and MOE. We would like to acknowledge Guillaume Monteil (IMAU) for his useful discussions.

Table 1. Covariance parameters of the a priori flux uncertainties per grid box per month used in the inversions. The uncertainty is expressed as a fraction of the a priori flux. Error correlations are defined by exponential (“e”) and Gaussian (“g”) correlation functions using the specified length scales (Basu et al., 2013).

Tracer category	Uncertainty (%)	Temporal (months)	Spatial (km)
CH ₄ Total	50	3.0-e	500.0-g
CO ₂ Biosphere	250	3.0-e	1000.0-g
CO ₂ Ocean	250	6.0-e	1000.0-g

**Table 2.** Summary of the inversions performed in this study.

Inversion	Measurements	Fluxes optimized	Optimizer (No of iterations)
RATIO	X_{ratio} , surface CH ₄ , CO ₂	CH ₄ , CO ₂	M1QN3 (100)
SURFCO2	surface CO ₂	CO ₂	CONGRAD (50)
PROXY	$X_{\text{CH}_4}^{\text{proxy}}$, surface CH ₄	CH ₄	CONGRAD (50)
SURFCH4	surface CH ₄	CH ₄	CONGRAD (50)
TRU-DAT	$X_{\text{CH}_4}^{\text{proxy}}$, surface CH ₄	CH ₄	CONGRAD (50)
PRICO2	$X_{\text{CH}_4}^{\text{proxy}}$, surface CH ₄	CH ₄	CONGRAD (50)

**Table 3.** κ , γ and β values of the inversions performed in this study (see Eq. 4 and Table 2). The β values have a unit of Tgyr⁻¹ for CH₄ and PgCyr⁻¹ for CO₂. κ and γ are unitless quantities.

Tracer	Inversion	κ	γ	β
CH ₄				
	PRIOR	0.286	0.211	2.370
	RATIO	0.122	0.129	1.396
	PROXY	0.119	0.137	1.432
	SURFCH4	0.218	0.162	1.959
	TRU-DAT	0.024	0.042	0.621
	PRICO2	0.210	0.258	2.409
CO ₂				
	PRIOR	0.232	0.392	0.327
	SURFCO2	0.180	0.241	0.185
	RATIO	0.125	0.225	0.134

CH₄ / CO₂ columns
assimilation

S. Pandey et al.

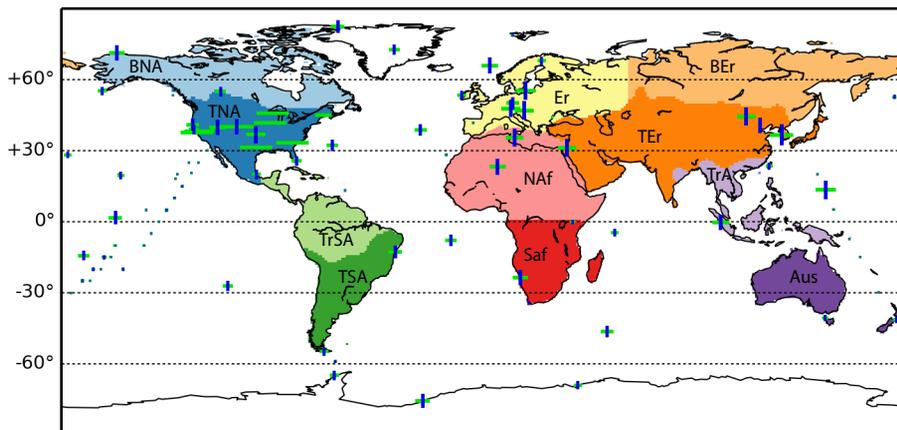

Figure 1. The dynamic symbols (blue-green crosses) show the location of the NOAA measurements sites included in inversions using surface measurements (see Table 2). The lengths of vertical blue and horizontal green bars are proportional to the number of CO₂ and CH₄ measurements, respectively. Continents are divided into 11 Transcom land regions (Gurney et al., 2002) which will be referred to in Sects. 4 and 3 as: Boreal North America (BNA), Temperate North America (TNA), Tropical South America (TrSA), Temperate South America (TSA), Northern Africa (NAf), Southern Africa (SAf), Boreal Eurasia (BEr), Temperate Eurasia (TEr), Tropical Asia (TrAs), Australia (Aus), and Europe (Eur).

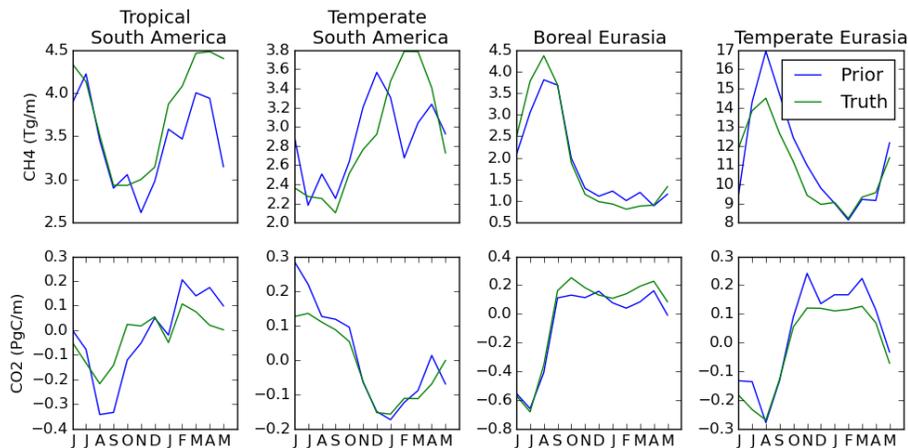

Figure 2. Timeseries of the true (green) and prior (blue) fluxes integrated over Tropical South America, Temperate South America, Boreal Eurasia and Temperate Eurasia.

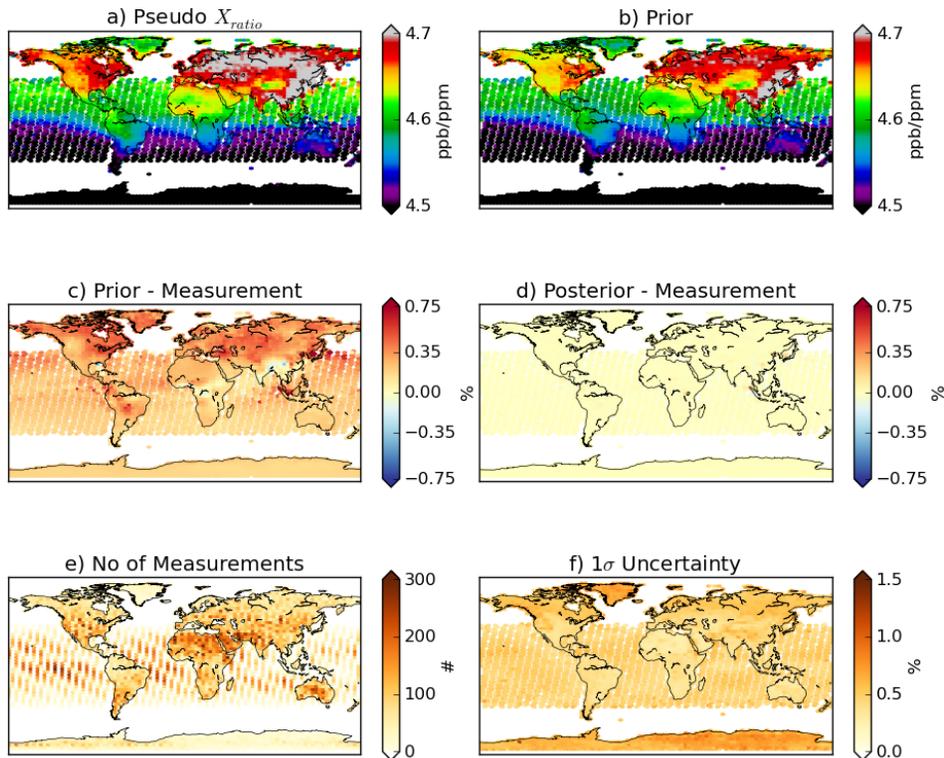

Figure 3. Fit of the RATIO inversion to the annually averaged “true” X_{ratio} pseudo measurements. **(a)** True pseudo X_{ratio} measurement, **(b)** a priori modeled X_{ratio} , **(c)** mismatch between the a priori model and the pseudo data, **(d)** the corresponding mismatch of the posterior model, **(e)** the number of GOSAT measurements, **(f)** the 1σ data uncertainty of X_{ratio} . The values represent yearly averages per $6^\circ \times 4^\circ$ (latitude \times longitude) grid box, except the bottom left panel which shows yearly integrals on $6^\circ \times 4^\circ$ (latitude \times longitude).

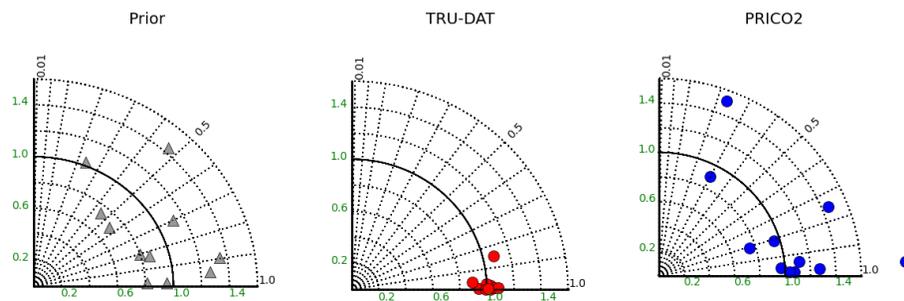

Figure 4. Taylor plots (Taylor, 2001) of monthly prior (grey triangles) and posterior CH₄ fluxes integrated over 11 land Transcom regions for the inversions TRU-DAT (red circles) and PRICO2 (blue circles). In these plots, each dot represents a seasonal cycle of a single Transcom region. The true fluxes are at the intersection point of the x axis and the bold arc (representing a $\text{cor} = 1$ and $\sigma/\sigma_{\text{truth}} = 1$).
