8 **Abstract**

9 Himalayan mountain glaciers and the snowpack over the Tibetan Plateau provide the headwater of several major
10 rivers in Asia. In-situ observations of snow cover extent since the 1960s suggest that the snow pack in the region
11 have retreated significantly, accompanied by a surface warming of 2-2.5°C observed over the peak altitudes
12 (5000 m). Using a high-resolution ocean-atmosphere global climate model and an observationally constrained
13 black carbon (BC) aerosol forcing, we attribute the observed altitude dependence of the warming trends as well
14 as the spatial pattern of reductions in snow depths and snow cover extent to various anthropogenic factors. At the
15 Tibetan Plateau altitudes, the increase of atmospheric CO₂ concentration exerted a warming of 1.7°C, BC 1.3°C
16 where as cooling aerosols cause about 0.7°C cooling, bringing the net simulated warming consistent with the
17 anomalously large observed warming. We therefore conclude that BC together with CO₂ has contributed to the
18 snow retreat trends. Especially, BC increase is the major factor in the strong elevation dependence of the
19 observed surface warming. The atmospheric warming by BC as well as its surface darkening of snow are
20 coupled with the positive snow albedo feedbacks to account for the disproportionately large role of BC in high-
21 elevation regions. These findings reveal that BC impact needs to be properly accounted for in future regional
22 climate projections, in particular on high-altitude cryosphere.

1 **1 Introduction**

2 Himalayan mountain glaciers and snow packs have a major impact on the water systems of major rivers
3 throughout Asia and the people living in the river basins. Recent observations suggested a continuing decline in
4 Himalayan mountain glaciers and snow cover. Bajracharya et al. (2008) observed that the Himalayan glaciers are
5 retreating at rates ranging from 10 to 60 m per year, and many small glaciers have disappeared. Gardner et al.
6 (2013) also showed with satellite observations the steady reduction of Western China glaciers with the most
7 rapid decline observed in the Himalayan mountain regions. Changes in the cryosphere are accompanied by
8 documented surface warming trends over Tibet, which reveals a strong altitude dependence of surface warming
9 with peak warming trends of 2-2.5°C at 5000 m from 1961 to 2006 (Liu et al., 2009).

Yangyang 12/28/2015 3:21 PM
Formatted: Indent: First line: 0"

10 The last few decades also witnessed rapid growth in human population and economic activities, causing intense
11 air pollution over the Asian region. Among the many air pollutants, black carbon (BC) aerosols have been shown
12 to have a significant impact on global and regional climate change (Ramanathan and Carmichael, 2008). Many
13 previous studies have linked Asian aerosols (including sulfates and BC) with monsoon systems and have
14 demonstrated the aerosol impact on the summer rainfall (Ramanathan et al., 2005; Lau et al., 2006; Lau and Kim
15 (2006); Meehl et al., 2008). The BC aerosols have also been shown to have impact on warming trends over the
16 Himalayan/Tibetan region (Ramanathan et al., 2007), on the retreat of Himalayan glaciers (Menon et al., 2010;
17 Qian et al., 2011), and on Eurasian snow cover (Flanner et al., 2009). Observationally, using ice-core samples to
18 reconstruct historical BC content over Tibet, Xu et al., (2009) suggested BC is a significant contributing factor in
19 causing the glacier change.

Deleted: impact of

20 To date global climate models forced by historical radiative forcing scenarios (such as those in Coupled Model
21 Intercomparison Project Phase 5, CMIP5) have difficulty in simulating the observed record surface warming
22 (You et al., 2015) or its anomalously strong altitude dependence in Tibet/Himalaya region. One possible
23 explanation as we will investigate here is that few of these earlier studies of the Himalayan and Tibetan climate
24 change have considered the combined effects of all the following factors: BC direct heating of the atmosphere,
25 the heating of snow packs and glaciers by BC darkening the snow and ice, the greenhouse effect of CO₂ and the
26 surface cooling effects by aerosols other than BC.

27 In this study, we used a state-of-the-art global climate model to conduct a suite of model experiments to
28 understand BC's role in the cryosphere change over the Himalaya and Tibetan region. A unique feature of the
29 present study, compared with earlier studies, is that BC radiative forcing is constrained with multiple sources of

1 observations (satellite observed aerosol optical depths and ground network of spectral sunphotometer
2 measurements). We also used a newly developed method to separate the BC contribution to solar absorption
3 from other aerosols (sulphates, organics and brown carbon) and calculate its direct radiative forcing (Bahadur et
4 al., 2012; Xu et al., 2013). Previous studies (Ramanathan et al., 2007; Lau et al., 2010; Menon et al., 2010; Qian
5 et al., 2011) included the effects of BC on the atmosphere and the cryosphere, but the simulated BC radiative
6 forcing by these “standard” models used in CMIP5 is strongly biased to low values (Bond et al., 2013) due to
7 emission inventory biases and missing physical treatments (Jacobson, 2012). As shown in Bond et al. (2013),
8 current models are underestimating BC solar absorption over South Asia by a factor of two to five. In this study,
9 we scaled the simulated BC forcing in the climate model by factors ranging from two to four to bring the
10 simulated values closer to the observationally constrained values (Xu, 2014). Another improvement in this study
11 is that the simulations were conducted using a fully coupled ocean-atmosphere-land model at a high resolution of
12 1° by 1°, in which a new land snow module is adopted (Lawrence et al., 2011) to account for BC deposition
13 effect on snow and ice.

1 **2 Methods**

2 **2.1 The global climate model**

3 CESM1 (Community Earth System Model 1) is a coupled ocean-atmosphere-land-sea-ice model. CESM1
4 climate simulations have been documented extensively (Meehl et al., 2013). The CESM1 (CAM5) used in this
5 study is a version with a finite volume nominal 1-degree horizontal resolution (0.9° by 1.25°) and 30-level
6 vertical resolution. The highest model level is about 36 km (4 hPa) in the stratosphere, and lower levels close to
7 surface (boundary layers) have vertical resolutions of about 100-200 m.

8 CESM1 (CAM5) includes forcings from greenhouse gases (GHGs) as well as concentrations of tropospheric
9 ozone and stratospheric ozone (Lamarque et al., 2010). The concentrations of various gases were calculated off-
10 line and prescribed into model simulations, unlike the aerosol loading calculated online from the emissions. The
11 three-mode modal aerosol scheme (MAM3) has been implemented (Liu et al., 2012) and provides internally
12 mixed representations of number concentrations and mass for Aitken, accumulation, and coarse modes of
13 various aerosol species (sulfates (SO₄), BC, organic carbons, dust, sea salt). The new cloud microphysics scheme
14 (Morrison and Gettelman, 2008) allows the number concentration of cloud drops and ice crystals to be affected
15 by aerosol concentrations and therefore accounts for the “indirect radiative forcing” of aerosols.

16 The land model (Community Land Model, CLM4) also includes major updates, making it more versatile in
17 simulating snow packs (Lawrence et al., 2011). The sub-grid processes including melting, metamorphism,
18 deposition and redistribution are considered in a snow cover fraction parameterization (Niu and Yang, 2007).
19 Other parameterizations include snow compaction (Lawrence and Slater, 2010) and the albedo calculations for
20 snow on or around vegetations (Wang and Zeng, 2009). Compared to the previous model versions, the albedo
21 contrast between snow-covered and non-snow-covered area is more consistent with observations.

22
23 **2.2 BC treatment in the model**

24 (a) BC effects on surface albedo. The deposition of BC particles, due to gravity or rainfall removal, is a
25 mechanism to remove aerosols from the atmosphere, and therefore a sink term for the atmospheric BC mass
26 balance. BC particles deposited onto surface of high-albedo snow or ice would reduce surface albedo. The snow
27 model of CLM4 is significantly modified via the incorporation of SNICAR (Snow and Ice Aerosol Radiation)

1 module, which represents the effect of aerosol deposition (BC, organic carbon and dust) on albedo, introduces a
2 grain-size dependent snow-aging parameterisation, and permits vertically resolved snowpack heating (Flanner et
3 al., 2007). This new module considers the albedo change by counting the surface concentration of BC and it
4 calculates the surface radiative energy flux at multiple wavelengths. The surface albedo change will
5 consequently alter the energy balance at the surface and in the atmosphere.

6 (b) BC atmospheric radiative forcing. The present-day BC emission is adjusted from the standard model
7 emission inventory (Lamarque et al., 2010) to account for the potential model underestimation of BC forcing.
8 Emissions over East Asia regions are increased by a factor of two and South Asia regions by four. The emissions
9 are adjusted by the same ratio in all economic sectors (energy, industrial, etc.) and all seasons by the same ratio.
10 Our previous analysis showed that such a correction would improve model-simulated radiative forcing compared
11 with direct observations (Xu et al., 2013; Xu, 2014). Without the observationally constrained values, the
12 modeled forcing and simulated temperature change would be lower by about a factor of two to four.

14 2.3 Model experiments

15 To isolate the climate impact of individual forcing agents, we contrasted the perturbed model simulations with
16 present-day forcing (b) to the long-term pre-industrial control simulations (a). The approach is similar to the
17 classical instantaneous CO₂ doubling experiment (Manabe and Wetherald, 1975). Additionally we conducted
18 fixed-SST experiment for radiative forcing diagnostics (c) and the 20th century transient runs to better attribute
19 the observational changes (d). The details of these simulations are given below.

20 (a) Control simulation for pre-industrial climate. We have a 319-year-long pre-industrial control run, and
21 extended it with an additional 75-year run to test if there was any discernible drift in the mean climate state. The
22 Northern Hemisphere temperature does not show any statistically significant drift. Therefore, we lay the
23 foundation for our analysis by employing the original 319-year run and the extended 75-year run (394 years in
24 total) as a control case. Natural variability of the climate system can be examined from the unforced 394-year
25 pre-industrial simulations.

26 (b) Four sets of perturbed simulations with instantaneously imposed present-day forcing: BC, SO₄, CO₂ and all
27 three forcing combined. The forcings were imposed by instantaneously increasing the emissions of BC, or the
28 emission of SO₄'s precursor sulfur dioxide, or by increasing CO₂ concentration to present-day level (400 ppm).

Deleted: (b) Perturbed simulations with instantaneously imposed present-day BC, SO₄ and CO₂. We ran

1 | Except for the adjusted BC present-day emission as detailed in section 2.2(b), all other emissions are from the
2 | standard inventory adopted by CMIP5 models, as described in Lamarque et al., (2010). We run the perturbed
3 | simulations in fully coupled mode for 75 years, starting from the end of the 319th year of the control simulation.
4 | The difference between the last 60 years (allowing the first 15 years for model spin-up) and the long-term
5 | control simulation provide the response signal due to the imposed forcing. With the concern that BC signal is
6 | potentially small compared with natural variability, five ensemble members of BC forced simulations are
7 | conducted to increase signal-to-noise ratio. Each model year costs about 2000 processor-hours in a high-
8 | performance computing system.

9 | (c) Three sets of perturbed simulations but with fixed sea surface temperature. These are also forced by the
10 | instantaneous increase of BC, SO₄ and CO₂, separately, but the model runs in atmosphere and land only mode
11 | with sea surface temperature fixed at pre-industrial level. These simulations are used only for diagnosing the
12 | radiative forcing due to various species.

13 | (d) The 20th century transient single-forcing simulations. The simulations as part of CMIP5 experiments were
14 | conducted using the same model configuration as above, except with time-evolving transient forcing of
15 | individual species (All forcing, GHGs, aerosols, and BC). Three ensemble members are available for each single
16 | forcing run. In addition to the standard BC runs, we also conducted a new BC single forcing simulation with
17 | adjusted BC emission factor as described in section 2.2(b).

19 | 2.4 Observations

20 | The key model output in this high altitude region to be compared with observations is surface temperature and
21 | snow cover. For temperature trend, we adopted both in-situ data recorded at meteorological sites as reported in
22 | previous studies (a) and a high-resolution temperature reanalysis dataset (b). For snow cover, we adopted a long-
23 | term dataset (c) as well as the direct satellite measurement but only dated back to 2000s (d). The details of these
24 | observational dataset are below.

25 | (a) Ground-based temperature record. Monthly mean daily-minimum temperatures from 116 weather stations in
26 | the eastern Tibetan Plateau and its vicinity (with elevations ranging from 300 m to 5000 m) during 1961–2006
27 | are reported in Liu et al. (2009). Liu et al. (2009) only analysed daily-minimum temperature because a well-
28 | recognized feature associated with climatic warming is less warming observed in maximum temperatures and

1 substantially more warming in minimum temperatures (Easterling et al., 1997). Previous studies also show such
2 asymmetric changes in maximum and minimum temperatures are particularly true for the Tibet (Liu et al., 2006)
3 and the Alps (Weber et al., 1997).

4 (b) Surface temperature reanalysis dataset. Global Historical Climatology Network (GHCN) is a high-resolution
5 (0.5° by 0.5°) analysed global land surface temperatures from 1948 to near present (Fan and van den Dool, 2008).
6 The dataset uses a combination of two large individual data sets of station observations collected from the
7 Global Historical Climatology Network version 2 and the Climate Anomaly Monitoring System. Data are
8 downloaded from http://www.esrl.noaa.gov/psd/data/gridded/data_ghcnams.html.

9 (c) NOAA Climate Data Record of snow cover extent (Robinson et al., 2012). Prior to 1999 the NH snow cover
10 extent is based on satellite-derived maps produced weekly by trained NOAA meteorologists. After 1999 NOAA
11 NH snow cover extent maps were replaced by output from the Interactive Multi-sensor Snow and Ice Mapping
12 System (IMS) processed at Rutgers University. Data are downloaded from
13 <http://climate.rutgers.edu/snowcover/docs.php?target=datareq>.

14 (d) Moderate Resolution Imaging Spectroradiometer (MODIS) snow cover observations. The MODIS snow
15 products are an 8-day global-gridded product The MOD10CM product is a climate modeling grid product at a
16 0.05° resolution with global coverage and monthly availability. Pixel values depict the percentage of snow cover
17 (Hall et al., 2006). For the period March 2000 to December 2006, the algorithm version 4 is used and after that
18 version 5 of the algorithm is used. Snow cover products derived from MODIS are based on a ratioing of MODIS
19 band 4 (green) (0.545–0.565 μm) and band 6 (near-infrared) (1.628–1.652 μm). Data are downloaded from
20 <http://nsidc.org/data/MOD10CM>.

3 Observed snow cover reduction linked with BC

The observations (Robinson et al., 2012) show that the snow cover extent over the Himalayan mountain range has declined at a rate of more than 10% per decade since the 1960s (Fig. 1). The snow cover retreat along the Himalayan mountain range is greater than in Eurasia during the same period. In-situ studies on regional glaciers and snow pack also reported strong declining trends. For example, Ma and Qin (2012) used 754 stations in China to document statistically significant declining trends of spring snow for the Qinghai-Tibet Plateau for the 1951-2009 period. Consistently, permafrost degradation has been reported on the Tibet Plateau (Cheng and Wu, 2007; Li et al., 2008).

Several satellite observations since the year of 2001 provided additional record in snow cover extent. The observed trend over this shorter period (2001-2012), is less significant (Fig. S1a) and negative trends are only found along some portion of Himalaya range. Consistently, the 5-km MODIS dataset (Fig. S1b) also shows that the snow cover extent averaged over the entire Tibet region only has a slight decrease. But as other studies have pointed out (Pu et al., 2007; Pu and Xu, 2009), the highest altitudes of 5750–6000 m exhibits larger negative trends (–6%/decade). We note that at shorter time-scale (10 years), the snow cover trend is heavily influenced by natural variability and less significant. For example, during 1980-1991 (Fig. S1c) or during 1990-2001 as shown in Fig. 5 of Menon et al. (2010), the declining trends are much larger. Nevertheless, the declining trend in the 40-50 year timescale (Fig. 1) is more robust and warrants further investigation on its causes, which is the main objective of this study.

To understand the causes of the observed trends of snow reduction over the multi-decadal timescale, we conducted global climate model simulations, in which BC emissions, CO₂ concentration or SO₄ emissions are increased instantaneously from pre-industrial to present-day levels. Fig. 2 (left column) shows the simulated change of snow fraction due to the increase of BC, CO₂ and SO₄ aerosols. The pattern of snow cover decline in the BC model simulation captures the broad features of the observed decline (Fig. 1), with the largest snow reduction along the mountain range. The Tibetan Plateau on average showed a reduction in snow fraction of 1.9% due to BC. The snow fraction shrinks by 2.9% due to present-day CO₂. Along the Himalayan mountain range, where the near-permanent snow cover exists, the reduction of snow fraction exceeds 10% in both BC and CO₂ cases.

Menon et al. (2010) attempted to simulate the snow reduction trends during 1990s but the spatial distribution of the observed trend was not well captured mainly due to the coarse resolution of the model. Qian et al. (2011)

1 also acknowledged their model's limitation in representing the snow cover climatology and therefore may have
2 biases in estimating BC impact on snow. It is well known that global models tend to overestimate the snow cover
3 of the Tibetan Plateau, and one potential reason is that the blocking effect for the moisture transport crossing the
4 Himalayas is too small due to the coarse resolution of the global models and too much snowfall is simulated
5 (Ménégoz et al., 2013). This limitation can partly be overcome with models using higher spatial resolutions. The
6 modelling work presented here is a major step forward in terms of spatial resolution (about 1° by 1°), as opposed
7 to earlier studies [2.8° by 2.8° in Flanner et al. (2009) and Qian et al. (2011); and 4° by 5° in Menon et al. (2010)],
8 which helps better resolving the complex topography in this region. As a result of increased spatial resolution
9 and also the improved land scheme, the biases in snow cover simulation is significantly reduced from its earlier
10 model versions [Lawrence et al., (2011), also contrast Fig. S2c with Fig. 2 of Qian et al., (2011)]. However, we
11 note that the precipitation over the Tibet Plateau is still overestimated (Fig. S2b), and future studies, especially
12 using regional climate models with even higher resolutions, are needed to improve the fidelity of model
13 simulations of snow pack and glaciers over this topography-complicated region.

14 One consequence of the snow cover reduction is the decrease in surface albedo, which provides a positive
15 feedback mechanism to localized warming. Such a surface albedo change in response to sea ice loss has been
16 observationally detected (Kay and L'Ecuyer, 2013; Pistone et al., 2014) and is important in explaining amplified
17 Arctic warming. Flanner et al. (2011) also used observations during recent decades to calculate the surface
18 albedo feedback in Northern Hemisphere large-scale snow-covered regions. Our simulations show that surface
19 albedo over the Tibet region decreased by over 2% (Fig. 2, right column) in response to BC. The maximum
20 reduction occurs right along the Himalayan mountain range and part of the Tibet-Sichuan mountain regions.

21 The surface albedo decrease due to CO₂ shares a similar spatial pattern with BC (Fig. 2, right column) but
22 with a smaller magnitude (Table 2b). Moreover, the snow depth reduction in response to CO₂ is only 30% of that
23 due to BC (Table 2c and Fig. 2), and this highlights the larger effect of BC in causing the regional cryospheric
24 change over the Himalayas and Tibet. Not surprisingly, in the simulations the snow cover and surface albedo are
25 increasing in response to cooling aerosols like SO₄ (Fig. 2), but in a smaller magnitude than that of the decreases
26 due to BC and CO₂.

1 4 Warming at high altitudes enhanced by BC

2 The Tibet region has witnessed increasing surface temperature by 0.3°C per decade—more than twice the
3 global average (Wang et al., 2008). One feature of the surface-warming trend over Tibet is that the warming
4 magnitude increases significantly with altitude (Liu et al., 2009). To understand this anomalous feature, we show
5 in Fig. 3 the tropospheric temperature responses (as a function of altitude and latitude) to BC as well as CO₂ and
6 SO₄. BC-induced heating rate (Fig. 3a) is more concentrated over the northern hemisphere (NH) due to larger
7 emissions there from industrial activities, consistent with radiative forcing distribution (Table 1). The notable
8 feature of BC response is the elevated warming at altitudes of 4000 to 8000 m and 30 to 60 °N (Fig. 3b), in
9 particular over the Tibetan Plateau. The CO₂ warming pattern (Fig. 3b) features an amplified warming at the
10 surface of the Arctic and in the upper tropical troposphere. CO₂ induced warming in the upper atmosphere (500
11 hPa) over Tibet is 1 °C, larger than BC induced warming of 0.5°C, but the vertical gradient is much smaller (Fig.
12 S3). SO₄ cooling features an even stronger north-south asymmetry (north cooling; south slightly warming) but is
13 more confined to the surface (Fig. S3). ~~The temperature response in the troposphere is associated with strong
14 meridional circulation change. The mechanisms behind the free atmosphere circulation change, especially for the
15 SO₄ case that does not have strong atmospheric forcing, are discussed in details in Xu and Xie (2015).~~

16 Ground based observations have shown that the last three decades were subject to a factor of two greater
17 warming in the high-altitude interior of the Tibetan Plateau than at the edge of the plateau and at lower altitudes.
18 The observations in Liu et al. (2009) were made between 1965 and 2006 from ground meteorological stations on
19 the Tibetan Plateau region, and they revealed clear altitude dependence in the daily-minimum surface
20 temperature (purple line in Fig. 4). The vertical profile of temperature change based on daily-average
21 measurement from another reanalysis dataset (Fig. 5) also reveals similar altitude dependence. What's driving the
22 larger warming at high-altitude regions?

23 Fig. 4 shows the model-simulated change of the daily-minimum surface temperature as a function of
24 elevation due to three different forcing agents (CO₂, SO₄ and BC). The surface temperature responses are
25 calculated from all of the model grid cells over the Tibetan Plateau and the surrounding region (20–50°N, 70–
26 110°E) to capture the altitude variation in this region. As shown in Fig. 4, the altitude dependence of the surface
27 warming is mostly determined by the response to BC forcing (red dots). At altitudes below 1000 m the warming
28 is minimal, but with increasing altitudes the magnitude of the warming increases up to 2°C at 5000 m. The

1 dependence of the surface warming on altitude is much smaller in the CO₂ case, which only increased from
2 1.2°C warming at low altitudes to 1.6°C warming at higher altitudes (yellow dots).

3 The combined temperature response (black triangles in Fig. 4) by adding the individual trends due to BC,
4 CO₂ and SO₄ is largely consistent with the observed trend. To test the additivity of the temperature response, we
5 conducted another simulation in which all of the three forcings were imposed simultaneously. The warming
6 profile simulated by the combined anthropogenic forcing experiment largely agree with the sum of the individual
7 responses within 30% (Fig. 5). Some non-linearity is expected as discussed in other modelling studies (Ming and
8 Ramaswamy, 2009). The agreement of the simulated and the observed warming profiles provides a qualitative
9 estimate of the relative contributions of BC, CO₂ and SO₄. Over the entire Tibetan Plateau, CO₂-induced surface
10 warming is 1.3°C, compared to the BC-induced warming of 0.84°C (Table 1b). Almost half of the surface
11 warming at the highest altitudes (around 5000 m) is due to BC.

12 A potential complexity arises due to the internal variability of the climate systems, which has been shown to
13 be important in determining decadal trends over individual regions (Deser et al., 2012). To examine the role of
14 natural variability, we calculated the temperature trend from all 350 consecutive 45-year period out of 394 years
15 simulations. The 80% (10th to 90th percentile) probability range of temperature change is shown in Fig. 5 (light
16 blue shading). The magnitude of the warming rarely exceeds 0.5°C in any 45-year period in the long-term pre-
17 industrial control simulations without any external forcing. Therefore we infer that the vertical gradient of the
18 temperature trend found in the simulations is very unlikely due to natural variability. One further concern is that
19 the internal variability deduced from the long-term pre-industrial control simulation can be model dependent.
20 However, comparing a 30-member ensemble of CESM1 simulation (the same spatial resolution and
21 configuration as in our control simulation) with the 38-member CMIP5, Kay et al., (2015) found that the
22 ensemble spread in the 30-year trend of surface temperature in CESM1 ensemble is statistically the same with
23 the spread in trends within CMIP5.

24 Note that the climate simulations shown in Fig. 4 and Fig. 5 are driven by the instantaneous increase of
25 present-day forcing. Since the real forcing trends were time dependent, we further analysed a set of 20th century
26 transient simulation output from the same model (Fig. 6), as part of CMIP5. The relative contributions of CO₂
27 and SO₄ to the simulated warming are consistent between the two sets of simulations (the instantaneous forcing
28 and transient forcing). But the trends estimated from the 20th century transient forcing simulations are smaller
29 than the quasi-equilibrium response to instantaneous forcing (parenthesis in Table 1b). The reason is that only 70%

1 of SO₄ forcing and about 60% of CO₂ forcing in the transient simulation were applied after 1960. The standard
2 BC forcing (red solid line in Fig. 6) only lead to a weak warming, not exceeding the range of natural variability.
3 As a result, the combined all-forcing responses (black triangles) did not capture the altitude dependence in
4 observations very well.

5 Only when we adjusted historical BC forcing using the same scaling factors constrained by present-day
6 observations, transient BC forcing induced a robust warming and amplification over high altitudes (red dots in
7 Fig. 6), similar to what's shown in instantaneous forcing experiment. However, note that the historical time
8 dependence of the BC forcing is more uncertain, and also we were only able to produce one ensemble of
9 adjusted BC simulation, more subject to the influence of decadal variability. Therefore, the response to the
10 instantaneous present-day BC forcing seems a more reliable indicator of the BC effects. While the absolute
11 values of warming profile needs more model tests, our inference regarding the relative role of BC and CO₂ in the
12 observed decrease of snow cover as well as the major role of BC on the altitude dependence of the warming
13 trends is robust.

1 **5 Physical mechanisms of elevated warming due to BC**

2 Both CO₂ and BC contribute to the elevated warming at 5 km as shown in Fig. 4. However, BC is mostly
3 responsible for the vertical gradient of the simulated warming trend. Most of the BC aerosols in the region are
4 emitted over India and China and subsequently transported to the Tibetan Plateau and the Himalayan mountain
5 range. The physical mechanisms for the amplified warming at higher altitude due to BC are at least three-fold:

6 (1) Direct heating in the atmosphere.

7 BC absorbs a significant amount of solar radiation, as much as 25% in typical pollution events as directly
8 measured by multiple unmanned aircrafts over the Northern Indian Ocean (Ramanathan et al., 2007). The BC
9 layer placed at higher altitude is even more efficient in absorbing solar radiation than at sea level, due to stronger
10 solar radiation and the brighter underlying cloud surface. In our model simulation, the BC atmospheric heating
11 rate is concentrated in the Northern Hemisphere (maximum at 30°N), coincident with the location of the
12 maximum temperature change (Fig. 3). The elevated BC layer, due to the topography of the Tibetan Plateau and
13 the Himalayan mountain range, contributes to the elevated heating which is more than 0.1 °C/day and about 0.03
14 °C/day at 4 km (Fig. S3a). Such anomalous heating in the atmosphere over the elevated regions will contribute to
15 the loss of ice and snow in two ways: (a) it will increase melting of the glaciers and snowpack; and (b) more of
16 the precipitation will fall as rain instead of snow. CO₂ increase also induces longwave heating of the atmosphere
17 (Fig. 3c), but it is well known that warming enhancement at the upper tropical troposphere is mostly due to moist
18 convection processes (Manabe and Wetherald, 1975) and the warming enhancement at high altitudes is not
19 showing sharp gradient as in BC case (Fig. S3b and Fig. 4).

20 (2) Surface darkening by BC deposition.

21 Snow and ice have a high surface albedo and reflect as much as 50 to 90% of incoming solar radiation.
22 Transported BC aerosols over the Himalayas and the Tibetan Plateau are removed from the atmosphere due to
23 precipitation. When BC aerosols are deposited over the snow and ice, they increase the absorption of solar
24 radiation and cause surface warming (Wiscombe and Warren, 1980; Chýlek et al., 1983). Recent studies have
25 also suggested the influence of BC aerosols over regions like the Alps (Painter et al., 2013) and Eurasian land
26 (Flanner et al., 2009). Menon et al. (2010) found that when the model includes snow albedo change due to BC
27 the snow cover reduction is twice as large as the simulation with BC atmospheric heating effect only. Flanner et
28 al. (2009) also suggested that BC surface albedo darkening effects are important in causing Eurasian springtime
29 snow-cover decline and are comparable to that of CO₂.

1 The surface radiative forcing due to BC deposition over Tibet in this model is estimated to be 4.6 W/m²
2 based on the 5-year fixed SST (sea-surface temperature) simulation (Fig. S4b). Because of this strong positive
3 surface forcing associated with surface darkening, the shortwave forcing due to BC at the surface increased from
4 -1.5 W/m² (initially due to BC dimming effect) to a positive value of 3.1 W/m². This positive forcing imposed
5 directly at the surface is even larger than the adjusted atmospheric heating due to BC over Tibet (1.6 W/m²). A
6 recent modelling study (Ménégoz et al., 2014) also examined the role of BC deposition over snow in this region
7 (with smaller forcing estimates of 1 to 3 W/m²), but their study did not estimate the atmospheric heating effect
8 of BC.

9 However, we note that model estimates of radiative forcing due to BC deposition on snow have large
10 uncertainty. Using the same atmospheric and land model (but driven by realistic meteorological field in the year
11 of 2000), Zhang et al., (2015) showed that simulated BC concentration in snow is biased high with respect to in
12 situ sampling. Although the large spatial variations in BC deposition can affect the representativeness of BC-in-
13 snow measurements for the model evaluation purposes, this potential model bias should be kept in mind. In
14 addition to the uncertainty in BC loading, the forcing magnitude is also sensitive to model parameterization
15 (Yasunari et al., 2013), and also the simulated background snow cover because the wrongly simulated melting
16 dates of the snowpack can lead to an incorrect radiative forcing (Jacobi et al., 2015). Therefore, both in-situ
17 (Wang et al., 2013; Zhao et al., 2014) and laboratory measurements (Hadley and Kirchstetter, 2012) are needed
18 to constrain model representation of BC in snow.

19 (3) Snow albedo feedback. The melting snow in response to the two initial heating mechanisms discussed
20 above will further decrease surface albedo and increase solar absorption at the surface. The results based on the
21 60-year coupled model simulation suggest that the surface albedo will further decrease by 1.4% and effectively
22 impose an additional 3.2 W/m² shortwave forcing at the surface. In summary, the elevated heating and surface
23 darkening due to BC are simultaneously causing local warming and snow melting. The snow cover reduction
24 further reduces surface albedo and then provides a positive feedback. A look at the seasonality of snow depth
25 change suggests the early spring melting is important for this feedback. The net result of such a positive loop is
26 an amplification factor of four for BC-induced Tibet warming from the global average values and significant
27 snow and ice retreat.

28 Beyond the three main factors as we have discussed above, the changes of water vapour and clouds are also
29 possible mechanisms contributing to the elevation-dependent warming in the mountain regions. As shown in the

1 schematic of a recent review paper (Mountain Research Initiative EDW Working Group, 2015), in a warmer and
2 moister atmosphere, the latent heat release at the cloud condensation level may induce larger warming in high
3 altitudes (cloud feedback) and the downward longwave radiation increase particularly fast in higher and drier
4 atmosphere (water vapour feedback). It is difficult to identify or separate the contribution of these individual
5 feedbacks from our current experiment setup. However, we note that these feedback mechanisms are operating
6 regardless of forcing agents and therefore cannot explain the particularly large elevated warming in response to
7 BC.

8 Lastly, it is also worth commenting the role of other snow impurities. In this study we used BC, a strong
9 solar radiation absorber, to understand the climate response and the mechanisms due to absorbing aerosols that
10 also include dust (Painter, et al., 2007; Di Mauro et al., 2015; Gabbi et al., 2015) and organic aerosols (Qian et
11 al., 2015). Similarly, we used SO₄ to characterize all other reflecting aerosols. Any changes of dust and organics
12 may induced changes to the snow cover, as their atmospheric heating and surface deposition are readily captured
13 by this model, although the magnitude of response might be smaller since they are partially reflecting as well.

14

1 **6 Conclusions**

2 The observed surface warming over the Tibetan and Himalayan region of about 0.5°C at sea level to about 2-
3 2.5°C at 5000 m (from 1961 to 2006) has been an outstanding feature of climate trends. The more than 2°C
4 warming is close to the peak warming trend observed anywhere on the planet. For comparison, the Arctic
5 warming associated with large sea-ice retreat during this period is 1.2°C.

6 The high-resolution coupled ocean-atmosphere model in this study was able to attribute the observed
7 warming trends and their high altitude enhancement to imposed increases in CO₂, BC, and SO₄ aerosols. The
8 simulated changes with all forcing imposed were consistent with the observations. The key to the success is that
9 we obtained the BC forcing from the reconstruction of ground-based and satellite-based observations. The
10 imposed BC forcing was about two to four times (depending on the regions) larger than that simulated by the
11 models using bottom-up emission inventories. The analysis of model simulations highlights that the high-altitude
12 warming due to BC is as large as CO₂ warming over the Tibetan Plateau and the elevated warming profile is
13 unique in BC responses.

14 The observed record warming is accompanied by retreat of glaciers and snow cover as well as thinning of the
15 snow packs. In response to the pre-industrial to the present-day increase in BC emissions, the annual averaged
16 snow fraction over the Tibetan Plateau is reduced by more than 6% (relatively), and the snow depth by
17 approximately 19%. The surface albedo decreases by more than 5% along the Himalayan mountain range and
18 1.4% over the entire Tibet, providing a positive local feedback to the enhanced local warming. In stark contrast,
19 despite having five times larger effect in global mean temperature than BC, over Tibet CO₂ impact is only 1.5
20 times stronger in snow cover decrease, and only one-third in snow depth decrease. We conclude that BC is
21 instrumental in causing snow retreat and its effects are manifested simultaneously through a three-fold process: (i)
22 direct atmospheric heating; (ii) darkening of the snow surface and (iii) the snow albedo feedback. It is important
23 to note that, without the scaling factor we applied to bring the model BC forcing to the observationally
24 constrained values, the impact of BC on the observed temperature trends would have been marginal. This
25 perhaps explains why the models used in IPCC assessments have not simulated the role of BC in the large
26 warming trend over the Himalayas.

5

1 Table 1. (a) TOA (top-of-atmosphere) radiative forcing (W/m^2 , shortwave + longwave), due to BC (direct
2 radiative forcing; pre-industrial to present-day; not including snow albedo effect), CO_2 (pre-industrial to 400
3 ppm), and SO_4 (direct and indirect effect, so-called "adjusted forcing"; pre-industrial to present-day). The
4 radiative forcing is calculated by running the atmospheric model with fixed sea-surface temperature for 5 years.

5 The domain of the Tibet Plateau is 30 to 40°N and 80 to 100°E.

6 (b) Surface temperature change ($^{\circ}C$) in response to different forcings in (a). Surface temperature change is
7 calculated by averaging the last 60 years of a 75-year coupled model simulation. The values in parenthesis are
8 temperature change in the 20th century time-dependent forcing simulations (1960-2005). The linear trend
9 ($^{\circ}C/decade$) is first calculated and then multiplied by 4.5 to obtain the change with 45-year time frame. BC
10 responses include the range of using "standard" and adjusted emissions.

2 Fig. 4. The change of daily-minimum temperature (°C) as a function of elevation (km). The observation from
3 1961 to 2006 are from of Liu et al. (2006). The simulated temperature responses due to instantaneous increase of
4 forcings (CO₂, SO₄ and BC) are calculated from model grid cells over the Tibetan Plateau and its vicinity region
5 (20–50°N, 70–110°E) including low-lying regions and high-altitude regions. The standard deviation due to spatial
6 variation of temperature response is shown as error bars. The sum of CO₂, SO₄ and BC responses are shown in
7 black triangles.
8

1
 2 Fig. 5. Similar to Fig. 4, but with the following differences: (1) daily-mean surface temperature, not daily-
 3 minimum temperature, are shown; (2) the spread of five-ensemble member of BC simulations are shown in red
 4 lines; (3) the observations are from GHCN dataset (1961 to 2006); (4) the range of temperature change found in
 5 unforced pre-industrial control simulations is shown in blue shading and (5) the all forcing simulation (black line)
 6 is shown in comparison with the sum of individual responses (black triangles).

Fig S2. (Left) climatological surface air temperature (°C) in the model simulation in the top panel, and observed surface air temperature in the bottom panel. (Middle) total precipitation (rain and snow fall) (mm/day) (Right) snow cover fraction. The model results in the top row are the 1981-2005 averages of the transient simulations under all radiative forcing. The temperature and precipitation observations are from updated dataset of Willmott and Matsuura (2001). The snow cover observations are from NOAA AVHRR as compiled by Robinson et al., (2012). In terrain-complex regions (such as North American Rockies, South American Andes and Tibet Plateau), the model tends to overestimate the precipitation and consequently snow cover, a bias commonly found in global climate model with coarse resolutions (Ménégoz et al., 2013). More detailed land model evaluations can be found in Lawrence et al., (2011).

Fig. S4. (a) Change of surface albedo due to BC deposition on snow; (b) Change of net shortwave radiation (downward as positive, W/m^2). Over Tibet Plateau, the surface albedo is reduced by 2.2%, causing an increase in shortwave radiation reaching the surface by $4.1 W/m^2$ (heating). Globally, the radiative forcing at the surface is about $0.1 W/m^2$. The change of surface albedo in (a) is calculated with the five-year atmosphere-only simulation in which BC emission is increased. Therefore, the albedo change largely represents the surface darkening effects due to BC deposition, although we cannot completely rule out the associated melting during this period. As a result, the actual radiative forcing at the surface due to BC in snow should be smaller than that in (b).
