Abstract

Raman lidar data obtained over a one year period has been analyzed in relation to aerosol layers in the free troposphere over the Highveld in South Africa. In total, 375 layers were observed above the boundary layer during the period 30 January 2010 – 31 January 2011. The seasonal behavior of aerosol layer geometrical characteristics, as well as intensive and extensive optical properties were studied. In general, layers were observed at higher center heights during the South African spring (2520 ± 970 m A.G.L.). The geometrical layer depth was found to be maximum during spring, while it did not show any significant difference for the rest of the seasons. The variability of the analyzed intensive and extensive optical properties was high during all seasons. This was attributed to the mixing state of aerosols and the different transport paths of the aerosol layers. Layers were observed at a mean altitude of 2100 ± 1000 m A.G.L. with an average lidar ratio of 67 ± 25 sr (mean value with one standard deviation) at 355 nm and a mean extinction-related Ångström exponent of 1.9 ± 0.8 between 355 and 532 nm during the period under study. During southern hemispheric spring, the biomass burning activity is clearly reflected in the optical properties of the observed free tropospheric layers. Specifically, lidar ratios at 355 nm were 57 ± 20 sr, 65 ± 23 sr, 59 ± 22 sr and 89 ± 21 sr during summer (December – February), winter (June – August), autumn (March – May) and spring (September – November), respectively. The extinction-related Ångström exponents between 355 and 532 nm measured during summer, winter, autumn and spring were 2.41 ± 0.9, 1.78 ± 0.6, 1.81 ± 0.9 and 1.79 ± 0.6, respectively. The contribution of free tropospheric aerosols on the optical depth had a wide range of values with a mean contribution of 46%.

1. Introduction

Atmospheric aerosols from natural and anthropogenic origin contribute substantially to global climate variability (IPCC, 2013). A detailed understanding of the regional geometrical characteristics and optical properties of aerosols, as well as their temporal and spatial distribution is required before we can accurately evaluate aerosol effects in the climate system (Hsu et al., 2000). However, high-quality aerosol measurements in the southern hemisphere are rather limited. South Africa is located at the southernmost tip of the African continent, extending from 22°S to 34°S latitude and from 16°E to 32°E longitude. Previous studies have indicated that South Africa is one of the most affected countries with regard to aerosol load, due to various natural and anthropogenic activities (Piketh et al., 2000; Piketh et al., 2002; Formenti et al., 2002, 2003; Campbell et al., 2003; Eck et al., 2003; Freiman and Piketh, 2003; Ichoku et al., 2003; Ross et al., 2003; Winkler et al., 2008; Queface et al., 2011; Tesfaye et al., 2011; Venter et al., 2012; Tiitta et al., 2014).

According to Giglio et al. (2010), 70% of the total area burned worldwide annually occurred in Africa. In order to assess the influence of wildfire aerosols on the climate system, it is important to know their altitude distribution. If wildfire aerosols are for example involved in cloud activation processes, it can alter cloud development through indirect and semi-direct aerosol effects (Ramanathan et al., 2001; Andreae et al., 2004; Koren et al., 2004; Koren et al., 2008; Rosenfeld et al., 2008). In addition, vertical transport can change the residence time and horizontal transport patterns of the absorbing aerosols. Vakkari et al. (2014) also recently showed that in biomass burning plumes in South Africa secondary aerosol formation increases significantly the aerosol mass and number concentrations during plume transport.

72 The Southern Hemisphere is relatively devoid of major dust activity (Prospero et al.,

73 2002). In southern Africa one source of mineral dust is located in Botswana in the

74 region centered at 21^oS, 26^oE with highly variable activity from year to year, while a

75 second small but persistent source is centered at 16^oE, 18^oS over the Etosha Pan, an

76 extremely flat salt pan in northern Namibia (Prospero et al., 2002; Bryant et al., 2007).

77 Robles-Gonzalez and Leeuw (2008) have measured aerosol optical depths of up to

78 0.75 at 555 nm over Namibian and Kalahari deserts during SAFARI-2000.

79 Long-term studies of atmospheric aerosols over the continental Southern Hemisphere

80 are limited. In general, previous studies pointed out the importance of regional

81 circulation and seasonal pollutant variation. In these long-term investigations the

82 optical properties of aerosols have been studied by means of sun photometers (e.g.

83 Queface et al., 2011), *in situ* data (e.g. Laakso et al., 2012) and satellite observations

84 (e.g. Tesfaye et al., 2011). Sun photometers only provide column optical and

85 microphysical particle properties. Although *in situ* surface observations provide

86 detailed optical, chemical and microphysical characterization of particles, it only

87 delivers a point-like description of the particle conditions in space. Optical properties

88 of boundary layer aerosols that originate from local sources and regionally transported

89 aerosols are usually different from free tropospheric aerosols that generally originate

90 from long-range transport.

91 Considering the above mentioned, there is a clear need for vertically resolved

92 observations with advanced multiwavelength lidars. Lidar systems provide vertical

93 profiles of atmospheric aerosols with a high temporal and spatial resolution. They are

94 powerful tools for the geometrical characterization of free tropospheric aerosols and

95 for the analysis of aerosol optical properties, which are the key factors in determining

96 the impact of aerosols on solar radiation. The optical characterization of aerosols is

97 made possible with the independent detection of particle extinction and backscattering

98 properties by the use of the Raman-lidar technique (Ansmann et al., 1992). Modern

99 lidars are able to measure volume extinction coefficient profiles at two wavelengths

100 and therefore determine the extinction-related Ångström exponent (Ångström, 1964),

101 which contains information on particle size. Numerous studies (e.g. Ansmann et al.,

102 2002; Müller et al., 2007; Groß et al. 2013; Mona et al., 2006) have demonstrated that

103 the lidar ratio is a valuable parameter for aerosol characterization since it depends on

104 the particles microphysical and chemical properties and therefore varies significantly

105 for different aerosol types. Based on 10 years of lidar observations around the globe,

106 intensive optical properties of several aerosol types were presented by Müller et al.

107 (2007). However, long-term lidar studies often reveal high variability in the optical

108 properties measured (Balis et al., 2004; Papayannis et al. 2008; Amiridis et al., 2009;

109 Giannakaki et al., 2010, Hänel et al., 2012; Komppula et al. 2012; Baars et al. 2012)

110 due to the high temporal and spatial variability of the aerosol occurrences.

111 The measurements presented in this paper were performed within the framework of

112 the EUCAARI project (Kulmala et al., 2011). Four key regions outside Europe were

113 chosen to perform at least one year of Raman lidar measurements for greater insight

114 into aerosol effects on global climate. Apart from the South African measurements

115 (Laakso et al., 2002), measurements took place in the Amazon Basin (Baars, 2012),

116 India (Komppula, 2012) and China (Hänel, 2012).

117 In this study we summarize one year of Raman lidar observations over South Africa.

118 The analyses of lidar measurements presented here could assist in bridging existing

119 gaps on the knowledge of vertical distribution of aerosols above South Africa, since

120 limited long-term data of this type is available for this region. For the first time, we

121 have been able to cover the full seasonal cycle on geometrical characteristics and

122 optical properties of free tropospheric aerosol layers in the region.

123 **2. Site description**

124 The lidar measurement site was located on a hill top at Elandsfontein ($26^o15´$S, $29^o26´$

125 E, 1745 m a.s.l.) in the Highveld region of South Africa. The station was located

126 approximately 150 km east from the Johannesburg-Pretoria megacity, which is the

127 largest metropolitan area in South Africa with a population of over 10 million people

128 (Lourens et al., 2012).

129 One significant source of atmospheric pollutants in the region is biomass burning

130 through wild and agricultural fires (Tummon et al., 2010; Swap et al., 2003). In

131 addition, the burning of solid fuels such as wood, dung and residual crops for

132 domestic cooking and space heating is also an important source of emissions into the

133 atmosphere in southern Africa. These emissions (from wild fires and domestic

134 burning), when transported above boundary layer, are difficult to distinguish from one

135 another. Marufu et al. (2000) have estimated that household emissions account for at

136 least as much as wild fire burning and industrial emissions. Another source of

137 aerosols in the region investigated is anthropogenic emissions from industrialized

138 regions in South Africa. The major industrial pollution sources within a 50 km radius

139 of the measurement site include ten coal-fired power plants, a petrochemical plant and

140 some metallurgical plants (Laakso et al., 2012). Desert dust aerosols emitted from

141 Botswana and Namibia deserts might be also possible sources of aerosols in this

142 region. The shortest distance to the Indian Ocean is approximately 350 km, therefore

143 marine air masses can also have an impact on atmospheric aerosols at Elandsfontein.

144 There are variations in the definition of climatic seasons in South Africa since South

145 Africa does not really experience four distinct seasons. For example, in the study of

146   Tesfaye et al. (2011) spring is defined from August to October, while in the study of

147   Queface et al. (2011), spring is defined from September to November. According to

148   actual weather conditions, spring can be rather short, lasting only two months, while

149   the summer is usually relatively long. In this study we accept the definition used in

150   Tyson, P.D. and Preston-Whyte, R.A (2004), Each season lasts for a period of three

151   months with summer being from December to February, autumn from March to May,

152   winter from June to August and spring from September to November. In addition, we

153   present statistical results for the wet (October to March) and dry periods (April to

154   September), as well as for the "intense" biomass burning period (August to October).

3. Instrumentation and methodology

3.1. Multi-wavelength Raman lidar

159   A multi-wavelength Raman lidar Polly^{XT} (Althausen et al., 2009) supplied by the

160   Finnish Meteorological Institute (FMI) was operated remotely at Elandsfontain in

161   South Africa. Polly^{XT} works with a Nd:YAG laser emitting at its primary wavelength

162   of 1064 nm, which after frequency doubling and tripling emits at the wavelengths of

163   532 and 355 nm, respectively. The receiver consists of a Newtonian telescope with a

164   diameter of 300 mm and a field of view of 1 mrad. Photomultiplier tubes (PMT) are

165   used for the detection of the elastically backscattered photons at 355, 532 and 1064

166   nm, as well as the in-elastically backscattered photons at 387 and 607 nm that

167   corresponds to the Raman-shift by nitrogen molecules at 355 and 532 nm,

168   respectively. Additionally, the cross polarized component at 355 nm is detected that

169   consequently allows the determination of the linear particle depolarization ratio. The

170   vertical resolution is 30 m and the raw data is typically stored as average values

171   calculated over 30 s. Data was collected on the web page of PollyNet

172   (http://polly.tropos.de) where the "quicklooks" of all measurements are available.

173 The Polly^{XT} of FMI had also been deployed in a long-term aerosol experimental

174 campaigns at Gual Pahari, India (March 2008 – March 2009) (Komppula et al., 2012)

175 and is currently operating at Vehmasmäki, Finland (62°44'17" N, 27°32'33.5" E, 190

176 m a.s.l.). The lidar system has been recently upgraded (Engelmann et al., 2012) and is

177 now part of the European Aerosol Research Lidar Network (EARLINET) (Bösenberg

178 et al., 2003; Pappalardo, et al., 2014) and the Finnish lidar network (Hirsikko et al.,

179 2014).

3.2. Auxiliary data

182 Moderate Resolution Imaging Spectroradiometer (MODIS) collection 5 active fire

183 product data was used in this study to determine the number of wild fire hotspots in

184 the region (http://earthdata.nasa.gov/data/near-real-time-data/firms/active-fire-data,

185 Roy et al., 2008).

186 Basic meteorological parameters were measured with a Vaisala WXT510

187 meteorological station (Vaisala, WXT510 specification sheet, 2010) at the site.

188 Measurements included wind direction and speed with an acoustic anemometer,

189 temperature, relative humidity and rain density (Laakso et al., 2012).

3.3. Lidar data evaluation

192 Lidar measurements commenced on 11 December 2009 and were conducted up until

193 31 January 2011. The measurements were carried out continuously, with the

194 exception of two periods during which maintenance was performed, i.e. from 23rd

195 December 2009 to 26th January 2010 and from 23rd October 2010 to 23rd November

196 2010. Polly^{XT} collected measurements on 310 days for a total of 4935 h. In order to

197 determine the optical profiles, the data was hourly averaged every three hours, when

198 the atmospheric conditions were homogeneous and free of low and medium height

199 clouds. Only night-time measurements are analyzed in this investigation since Raman

signals are too weak to be detected with the Polly^{XT} during daytime. The main objective is to study the extensive (backscatter and extinction coefficients) and intensive (lidar ratio, Ångström exponents) optical properties of free tropospheric aerosol layers in the region. The extinction and the backscatter coefficient profiles at 355 and 532 nm have been obtained with the Raman method (Ansmann et al., 1992), while the backscatter at 1064 nm has been determined using the Klett method (Klett, 1981). An overlap correction has been applied on the basis of a simple technique proposed by Wandinger and Ansmann (2002). The depolarization ratio profiles are not analyzed in this study.

The range-resolved elastic backscatter signal contains information that can be used to derive the height of aerosol layers. The gradient method, also used in the EARLINET community, was applied to determine the bottom and top layer heights of the aerosols in the free troposphere (Flamant et al., 1997; Bösenberg et al., 2003; Mattis et al., 2008). In general, the local maximum in the first derivative of backscatter at 1064 nm is considered to be the bottom of a layer, while the local minimum is considered to be the top of the layer. In order to verify the gradient method, we checked whether the layer boundaries identified by the gradient method coincide with the bottom and top heights that we recognize in coherent structures of the height time displays of the range-corrected lidar signal.

In this work we analyzed the geometrical characteristics of the free tropospheric aerosol layers above the measurement site. Layers observed inside the boundary layer are not analyzed in this study. This involved determining the top of the planetary boundary layer as presented by Korhonen et al. (2014). Planetary boundary layer top heights were retrieved from the lidar backscatter signal at 1064 nm using the Wavelet Covariance Transform method (Brooks, 2003). Subsequently, 7-day back-trajectories

225 were calculated by means of the HYSPLIT model (Draxler and Hess, 1997; Draxler

226 and Hess 1998) for the center height of each elevated layer.

227 In this paper we present the statistics on the seasonal behavior of free tropospheric

228 aerosol layers above South Africa. Our initial aim was to attribute each aerosol layer

229 to a certain aerosol type, since different sources emit different types of aerosols.

230 However, this was not possible because the aerosol layers were often observed to be

231 in a mixing state rather than as one single pure aerosol type. Detailed analysis with

232 respect to optical and microphysical aerosol properties for selected aerosol layers that

233 have been assigned to specific aerosol types will be presented in a subsequent article.

234 **4. Results and discussion**

235 The percentage of the night-time measurements performed each month in terms of

236 hourly averaged profiles every three hours is presented in Figure 1(a) (blue bars),

237 which varies between 3 and 72 % for all the months. The percentage was calculated

238 by taking into account the not sunny hours for each month. Analysis could not be

239 performed during unfavorable weather conditions, such as the presence of low clouds

240 and rain (shaded bars) or due to the scheduled shutdowns (grey bars). In Figure 1(b)

241 we present the percentage of the measurements in which at least one free-tropospheric

242 aerosol layer was observed (green bars). The total number of the observed layers per

243 month is presented with red stars in the same figure. In total, 375 aerosol layers were

244 observed above the boundary layer during the period studied.

245 In this region, approximately 90% of the annual precipitation falls during the wet

246 season (October - March) (Laakso et al., 2012 and references therein), as indicated in

247 Figure 1 (c). Fewer measurements were performed during the wet period. The

248 seasonal precipitation cycle should not only affect the number of measurements that

249 could be performed but also the total number of layers observed. Therefore it is

250   expected that the fraction of measurements of free-tropospheric aerosol layers in

251   relation to the total number of observations should be less during the wet season due

252   to wet scavenging. However, our results indicate that during the wet period a

253   relatively large number of layers are still observed in the free troposphere. According

254   to Cosin and Tyson (1996) the general anticyclonic nature of atmospheric circulation

255   over the region, results in the formation of absolutely stable layers of air throughout

256   the year.

257   4.1. Geometrical characteristics and optical depth of free tropospheric aerosol

258   layers

259   Figure 2 shows our complete data set of lidar measurements in terms of geometrical

260   characteristics. The vertical lines present the observed height ranges of free

261   tropospheric aerosol layers. Out of 429 hourly analyzed lidar observation, we observe

262   free tropospheric pollution events on 223 (i.e. 52 %). In total 375 free tropospheric

263   aerosol layers were observed. Pollution events are observed as single layer on 52% of

264   the cases, while they are often characterized by two (32 %), three (13 %) or more

265   particle layers (3%). Up to five layers were observed simultaneous. The maximum top

266   height observed was 5730 m A.G.L. on 22 August 2010, while the minimum bottom

267   height was 400 m A.G.L. and observed on 21 of July 2010. The geometrical depth of

268   the free tropospheric layers varies from a few hundred meters to several kilometers

269   throughout the period under investigation. Figure 2 already indicates that higher

270   layers are observed during the second half of the year.

271   Monthly averaged lidar measurements analyzed in terms of center height (a),

272   geometrical depth (b), and aerosol layer optical depths (c) at 355 and 532 nm for the

273   period investigated are presented in Figure 3. The aerosol optical depth measured is

274   the integrated extinction coefficients at 355 and 532 nm for each layer identified.

275   From the total number of free-tropospheric layers observed, 72% occurred at heights

276   higher than 1500 m A.G.L. The higher and thicker layers were observed during the

277   second half of the year. According to the MODIS fire product in year 2010 the

278   biomass   burning   activity   started   in   July   and   lasted   until   October

279   (https://firms.modaps.eosdis.nasa.gov/animations/2010_animation.gif),   which   is   a

280   typical seasonal pattern in southern Africa (e.g. Ito et al., 2007). The increase in

281   biomass burning activity most probably contributes to higher and more frequent

282   aerosol layer observations from August to October. During winter the well-defined

283   inversion layers can trap low level emissions. The layers during this season reach up

284   to 3000 m which is consistent with power station plumes over the region.

285   Due to low signal-to-noise ratios, analysis of the optical properties could not be

286   performed for the entire dataset. For this reason the number of geometrically observed

287   layers (Fig. 3a) is larger (or equal) than the number of layers for which layer aerosol

288   optical depth could be calculated (squares in Figure 3(c)). Mean extinction

289   coefficients and thus layer aerosol optical depths show large variations both at 355

290   and 532 nm. On average, aerosol layer optical depths at both wavelengths were below

291   0.1. Only during late winter and spring the mean aerosol optical depth of free

292   tropospheric layers at 355 nm was above 0.1. Maximum values of layer aerosol

293   optical depth of up to 0.3 at both wavelengths were reached, which is a significant (in

294   the order of 85%) contribution to the columnar aerosol optical depth. The larger

295   extinction coefficients at both wavelengths during May and June are observed for

296   lower layers. However, the corresponding aerosol optical depths are low due to small

297   geometrical depths of these layers.

298   In order to further investigate the contribution of the free tropospheric aerosol load to

299   the columnar optical depth we studied the columnar, free tropospheric and boundary

300 layer optical depths in more detail. For each of the lidar measurements analyzed,

301 columnar aerosol optical depth estimates were determined by integrating the aerosol

302 extinction coefficient at 355 nm and 532 nm. We assumed that the extinction value at

303 the height for which the overlap function is equal to 0.7 is representative down to the

304 surface to account for the incomplete overlap region. The value of 0.7 is reached

305 between 300 and 500 m. Therefore, this is a reasonable assumption and it is also a

306 common approach in lidar studies (e.g. Giannakaki et al., 2010). In Figure 4 we

307 present the columnar aerosol optical depth calculated from each of the hourly

308 analyzed lidar measurements. The mean columnar aerosol optical depth obtained from

309 lidar measurements was found to be 0.46 ± 0.35 at 355 nm and 0.25 ± 0.2 at 532 nm.

310 The lidar derived columnar aerosol optical depth exhibits a seasonal variability, with

311 maximum values of 1.54 and 0.78 at 355 and 532 nm, respectively, measured in late

312 September. The same seasonal behavior is also observed with sun photometer data

313 (http://aeronet.gsfc.nasa.gov/cgi-

314 [bin/type_one_station_opera_v2_new?site=Elandsfontein&nachal=0&year=18&aero_](http://aeronet.gsfc.nasa.gov/cgi-)

315 [water=0&level=3&if_day=0&if_err=0&place_code=10&year_or_month=1](http://aeronet.gsfc.nasa.gov/cgi-)).

316 In an effort to explain the observed seasonality of the columnar aerosol optical depth,

317 we separately estimated the aerosol optical depth in the boundary layer and the free

318 troposphere at 355 nm, which are presented in Figure 5 (a). The boundary layer

319 optical depth is only indicative. As can be seen in Figure 5 (a), the same seasonal

320 pattern is observed for the aerosol optical depth at 355 nm in the boundary layer and

321 the free troposphere, i.e. larger aerosol optical depth values measured during late July,

322 August, September and October in the boundary layer and the free troposphere. This

323 is also found for the aerosol optical depth at 532 nm (not shown here). In Figure 5 (b)

324 we present the percentage contribution of free tropospheric aerosol optical depth to

325   the total aerosol optical depth. Large variations of the contribution of free

326   tropospheric aerosol optical depth to the total aerosol optical depth are observed for

327   the period investigated, with a mean value of 46%. The largest monthly contribution

328   of 92% is observed in October. The period with increases in columnar, free

329   tropospheric and boundary layer optical depths coincides with higher wind speeds as

330   presented in Figure 6(a) and an increase in biomass burning activity in South Africa

331   shown in Figure 6(b). Tesfaye et al. (2011) attributed the increase of columnar optical

332   depths mainly to local sources and enhanced wind speeds. Higher wind speeds could

333   lead to an increased transport of biomass emissions from regions further away from

334   Elandsfontein. The increase in biomass burning activity in South Africa also

335   contributes to enhance free tropospheric aerosol optical depth. This is supported by

336   the higher altitude of the observed aerosol layers during August, September and

337   October (Figure 2). The number of hotspots (active fire detections)

338   (http://earthdata.nasa.gov/data/nrt-data/firms/active-fire-data) that was observed in the

339   latitude range between 40°S and 20°S and longitude range between 20°E and 40°E

340   degrees are plotted in Figure 6 (b). The results are presented in two clusters of

341   medium (30-80%) and high confidence (80-100%). The number of hotspots with high

342   confidence, in the region under study, ranges from 10000 to 15000 during August,

343   September and October; while it is less than 2000 for the rest of the months.

344   The geometrical center height of the ~~elevated~~ particle plumes with bin intervals of 750

345   m are shown in Figure 7 for each of the seasons. In the same figure, the statistical

346   distribution for each season is also presented with box and whisker plots. High

347   variation in the geometrical characteristics is observed throughout the year. Mean

348   values of geometrical centers, as well as optical depths at 355 and 532 nm are

349   presented in Table 1. In general, free tropospheric aerosol layers were found at higher

350　altitudes in spring and summer. The peak of the frequency distribution of the

351　geometrical mean height of the observed free-tropospheric aerosol layers during

352　spring and summer were found to be between 2250 and 3000 m A.G.L., while for

353　autumn and winter the peak ranges between 1500 and 2250 m A.G.L. Only 35% of

354　the analyzed free tropospheric aerosol layers were observed below 2250 m A.G.L.

355　during spring, while in summer, autumn and winter 43, 74, and 75 % of the free

356　tropospheric aerosol layers were observed below 2250 m, respectively. The higher

357　free tropospheric aerosol layers during spring is possibly due to intensive biomass

358　burning activity in central and southern Africa and the transport of smoke above our

359　measurement site. Seven-days back-trajectories analysis together with superimposed

360　hotspots derived by MODIS for each of the layers identified reveals long range

361　transport of biomass burning aerosols over Elandsfontein in most of the cases

362　analyzed during spring.

363　4.2. Extensive and intensive optical properties of free tropospheric aerosol

364　layers

365

366　Detailed statistical information on the extensive aerosol properties is presented in

367　Table 2. It is evident that a wide range of extinction and backscatter coefficients for

368　the four seasons during the year is observed. In addition to seasonal values we also

369　present the values for wet, dry and biomass burning periods.

370　Mean Ångström exponents and lidar ratios were derived for the observed geometrical

371　layers in cases that the extinction and backscatter coefficients profiles could be

372　obtained. The monthly averaged lidar ratio at 355 and 532 nm, as well as the

373　Ångström exponents of free tropospheric layers are presented in Figure 8.

374　Between late winter and throughout spring high lidar ratios are observed at both

375　wavelengths. During this period a significant contribution of aerosol layers originates

15

376 from wild and controlled fires. Domestic biomass burning in informal settlements for

377 cooking and heating can also contribute, but these emissions are exclusively emitted

378 at ground level. It is therefore unlikely that such emission close to Elandsfontein will

379 have a significant impact to free tropospheric aerosol load measured. However,

380 household emissions are common across the entire southern Africa, which implies

381 that regional transport of such emission further away from Elandsfontein may results

382 in a contribution to the free tropospheric load measured over Elandsfontein. The

383 absorbing smoke aerosols, originating from all the afore-mentioned combustion

384 sources, can explain the large lidar ratio values observed. During this period the

385 Ångström exponents appear to have large variation, with smaller values observed for

386 lower aerosol layers. Ångström exponents appear to be lower from May to September.

387 This can be attributed to the lower precipitation (dry season). Therefore larger

388 particles stay longer in the atmosphere at lower layers, since they are not washed out.

389 The seasonal frequency distribution plots for the lidar ratio at 355 nm and the

390 Ångström exponent related to extinction between 355 and 532 nm are presented in

391 Figure 9 and 10, respectively. We present the frequency distribution plot only for 355

392 nm because observation of the lidar ratio at 532 nm was more often limited due to

393 detector problems. Additional information on the intensive optical properties for both

394 wavelengths is given in Table 3. An average lidar ratio of 67 ± 25 sr at 355 nm and a

395 mean extinction-related Ångström exponent of 1.9 ± 0.8 between 355 and 532 nm are

396 measured during the entire sampling period in South Africa.

397 Lower mean values of lidar ratio and larger Ångström exponents have been observed

398 during summer. One possible explanation is the removal of larger aerosols through

399 wet-scavenging during these wetter months. Most of the free-tropospheric aerosol

400 layers observed during this period were associated with an easterly air mass flow. The

major industrial pollution sources are located primarily either to the north, west or southwest of the lidar at Elandsfontein (Laakso et al., 2012). Therefore, the easterly flow that prevails during summer results in a less polluted free troposphere, compared to other seasons. Aerosols measured during this period could also include maritime aerosols with air masses moving from the Indian Ocean.

The distribution plots for autumn and winter are quite similar. However, 16% of elevated aerosols during autumn are associated with lidar ratios lower than 40 sr, while 12 % of lidar ratios were lower than 40 sr during winter. Seven-day backward trajectory analysis clearly indicated that these aerosol plumes (with lidar ratio lower than 40 sr), passed above the ocean. Wild fires in late July and August (see Figure 6(b)) are the mainly sources of absorbing smoke aerosols that result in aerosol layer plumes with high lidar ratios during these months. The intensive biomass burning activity in South Africa during spring is clearly reflected on the frequency distribution of the lidar ratio at 355 nm indicated by larger lidar ratio values, with a peak between 80 and 100 sr.

The frequency distribution plots of the extinction related Ångström exponent between 355 nm and 532 nm in Figure 10 reveal relatively evenly spread values during summer and autumn with no specific peak. This can most likely be attributed to atmospheric mixing processes. Ångström exponent distribution plot during winter and spring are similar, with a narrow distribution around 1.75.

Several statistics of lidar ratio and Ångström exponent are available for comparison. Mean lidar ratios at 355 nm vary from 21 to 67 sr, whereas 26 to 87 sr is found for the lidar ratio at 532 nm for aged Siberian forest fire smoke (Müller et al. 2005). Anderson et al. (2003) found a mean lidar ratio of 45 ± 10 sr at 532 nm during the ACE-Asia campaign in the spring of 2000 for east Asian haze over the Pacific Ocean

close to China. Murayama et al. (2003) analyzed ACE-Asia lidar and aircraft measurements over Japan. Mean lidar ratios in the polluted lower troposphere were 35-45 sr, and Ångström exponents were 1.5-2 in the wavelength range from 450 to 700 nm. Bösenberg et al. (2003) report an average lidar ratio of 55 sr at 351 nm for height range 2000 to 3000 m over Hamburg, Germany. Giannakaki et al. (2010) analyzed 7 years of EARLINET observations (2001 -2007). Lidar ratio at 355 nm of the order of 70 sr were found for biomass burning aerosols. Amiridis et al. (2009) found that backscatter related Ångström exponent for biomass burning aerosols over Southeastern Europe ranges between 0.5 and 2.4 indicating a variety of particle sizes. Giannakaki et al. (2010) found that Ångström exponent ranges from 1 to 3 both for biomass burning aerosols and European continental polluted aerosols, indicating the same size of aerosols for these types of aerosols. An Ångström exponent of 1.35 was measured for Siberian forest fire smoke at Tokyo (Murayama et al., 2004). Mean particle Ångström exponent between 355 and 532 nm varied from 0 to 1.3 for aged biomass burning aerosols observed over central Germany (Müller et al., 2005). A decrease of the Ångström exponent (450 – 550 nm wavelength), which is equivalent to an increase of particle size, was observed for fires in tropical forest and cerrado during SCAR-B campaign (Reid et al., 1998). In situ observations showed that Ångström exponents (355-532 nm wavelength) were on the order of 2.2 ± 0.2 for fresh smoke and 1.2 ± 0.2 for aged smoke. In this study, during spring which is the intense biomass burning activity, mean Ångström exponent found to be 1.8 ± 0.5, indicating relatively small and fresh particles. Moreover, different biomass fuel and burning processes certainly generate particles of different initial size, which in the end may lead to different growth mechanisms.

5. Summary and conclusions

The seasonal patterns of the geometrical characteristics and optical properties of elevated aerosol layers at a continental site in South Africa are presented. The elevated layers often "rest" on top of the planetary boundary layer. The geometrical depth of the free tropospheric layers varies from a few hundred meters to several kilometers. Pollution events are observed as single layer on 52% of the cases, while they are often characterized by two (32 %), three (13 %) or more particle layers (3%). Several aerosol sources may be responsible for a single free tropospheric pollution event. The classification of the aerosol layers relating to the season of occurrence revealed rather stable geometrical aerosol layer depths for winter, summer and autumn with higher aerosol layer depths during spring. During winter layers are observed up to 3000 m which is consistent with power station plumes over the region.

Except for the intensive biomass burning period from August to October, the lidar ratios and Ångström exponents are within the range of previous observations for urban/industrial aerosols (Müller et al., 2007; Giannakaki et al., 2010; Bösenberg et al., 2003). Considering that the Elandsfontein measurement station is located in the midst of large industrial plants 150 km east of the megacity of Johannesburg, this is reasonable. However, we observed large variability in both intensive and extensive aerosol properties of free tropospheric aerosol layers. From August to October, the lidar ratio of elevated layers is high, on average 89 sr, which is comparable to biomass burning smoke (Giannakaki et al., 2010; Amiridis et al., 2009). During this period also aerosol optical thickness is significantly increased, suggesting that similar to ground-based aerosol in the region (e.g. Vakkari et al., 2013) the seasonality of elevated aerosol layers is dominated by combustion sources. The mean free tropospheric contribution to the aerosol optical depth of aerosol layers is 46% which

475   can reach up to 96%. Mean Ångström exponent related to extinction was found to be

476   1.8 both for dry and biomass burning period indicating the same size of particles for

477   both biomass burning and polluted aerosols.
