Abstract

Continuous measurements of dry aerosol light scattering (Bsp) were made at two sites in the Klang Valley of Malaysia between December 1998 and December 2000. In addition 24-h PM_{2.5} samples were collected on a one-day-in-six cycle and the chemical composition of the aerosol was determined. Periods of excessive haze were defined as 24-h average Bsp values greater than 150 Mm⁻¹ and these occurred on a number of occasions, between May and September 1999, during May 2000, and between July and September 2000. The evidence for smoke being a significant contributor to aerosol during periods of excessive haze is discussed and includes features of the aerosol chemistry, the diurnal cycle of Bsp, and the coincidence of forest fires on Sumatra during the southwest (SW) monsoon period, as well as transport modelling for one week of the southwest Monsoon of 2000. The study highlights that whilst transboundary smoke is a major contributor to poor visibility in the Klang Valley, smoke from fires on Peninsular Malaysia is also a contributor, and at all times, the domestic source of secondary particle production is present.

1. Introduction

In recent times, reduced visibility has become a recurrent phenomenon across areas of Southeast Asia, resulting from biomass burning in Kalimantan and Sumatra. Haze events have been recorded in 1983, 1990, 1991, 1994, 1997 and 1998 (Radojevic and Hassan, 1999; Muraleedharan et al., 2000). Koe et al. (2001) noted that reduced visibility in Malaysia during the 1997 haze episode was the result of long range transport of smoke from Sumatra. Historically, major smoke hazes have been observed in the region, at times impeding shipping, as early as the 1800s (McDonald, 1938). Episodes like the 1997 haze events prompt the need for a thorough understanding of the factors regulating the severity of haze in Kuala Lumpur (KL) and the surrounding Klang Valley region, including the source and transportation of particles.

While severe and disastrous, such events are episodic. Perhaps more insidious is the constant lower level of haze present in cities like KL where primary sources of particles such as vehicle emissions, industrial emissions and domestic biomass burning all contribute to haze. Secondary photochemical particle production can also be a major contributor to haze development. This occurs when gases from vehicle, industrial and biomass burning emissions undergo gas to particle conversion forming low vapour-pressure products that nucleate to form new particles, or condense on the surfaces of existing particles (Finlayson-Pitts and Pitts, 2000).

Primary particles produced by combustion processes such as vehicle emissions, industrial emissions and domestic biomass burning and secondary photochemical production overwhelmingly result in particles in the fine particle range (i.e. less than $2.5 \mu\text{m}$ in aerodynamic diameter). These particles are important in the development of haze because they are within the size range that scatters light most efficiently. Particulate haze is a major environmental hazard. Besides impairing visibility, other potential problems associated with elevated particle loadings include impacts on human health (Vedal, 1997) and impacts on atmospheric radiative transfer, with the potential to significantly affect climate in the region (Seinfeld and Pandis, 1998).

At present, knowledge of the factors regulating the severity of aerosol haze in KL and the surrounding Klang Valley region is incomplete. Two previous investigations into haze in Malaysia have focused on aerosol chemistry (JICA, 1993; NERI, 1998), using the chemical composition of particles to determine the sources of haze. Neither study involved a direct measurement of haze intensity, i.e. aerosol scattering coefficient (Bsp). In the Malaysian Haze Study (MHS), a new study documented herein, the parameter Bsp was measured continuously over two years (December 1998 to December 2000) at two sites in the Klang Valley region to provide a real-time record of haze intensity. Bsp is the integrated aerosol light scattering coefficient, a direct measure of the reduction of light transmission through the atmosphere due to scattering by atmospheric particles. The previous studies also focused only on PM₁₀ (particles smaller than $10 \mu\text{m}$ in aerodynamic diameter) or SPM (suspended particulate matter

Haze in the Klang Valley of MalaysiaM. D. Keywood et al.

© EGU 2003

or particles of all sizes), whereas the MHS set out to explain and find the fraction of the aerosol responsible for most visibility and health effects, i.e. PM_{2.5} (particles smaller than 2.5 μm in aerodynamic diameter).

The Malaysian Haze Study (MHS) aimed to improve understanding of the haze phenomenon by investigation of the chemical composition and other properties of aerosol haze at two sites in the Klang Valley region near Kuala Lumpur (see Fig. 1). By combining this information with direct measurements of aerosol light scattering coefficient at both sites, and taking into account meteorological conditions throughout the measurement period, the MHS aimed to identify the sources of aerosol material and controlling meteorological factors on days of excessive haze.

This paper provides an overview of the MHS and focuses on the broad features of the aerosol scattering coefficients and aerosol composition over two years of measurements in the Klang Valley. The nearly complete continuous two-year record of hourly Bsp values, combined with the coincident two-year record of PM_{2.5} chemical composition, allows a unique analysis of haze development on seasonal and diurnal timescales. In this work, two major sources of particles, smoke and secondary production, are discussed in terms of their contribution to the seasonal and diurnal patterns of haze development.

2. Methods

2.1. Measurement sites

Aerosol measurements were carried out at two sites in the Klang Valley region: Petaling Jaya (03°06' N, 101°39' E) and Gombak (03°15.7' N, 101°39' E). The Petaling Jaya site, which is 10 km west of Kuala Lumpur, was situated on the roof-top of the Malaysian Meteorological Service (MMS) building (≈ 18 m above the ground), alongside equipment operated by MMS. The closest building is 50 m to the southwest of the MMS building and is currently two levels higher. Petaling Jaya may be considered an ur-

ban/commercial area. During the course of the MHS, construction began on a large building 20 m to the west of the MMS building.

The Gombak site, which is 15 km north of Kuala Lumpur, was at the Department of Environment, Gombak air quality monitoring station operated by Alam Sekitar Malaysia (ASMA). This is located in the grounds of the Gombak office of Jabatan Bekalan Air (Water Department, Gombak). The station is located in a valley at the edge of bordering highlands. The area surrounding the station is vegetation-covered and there are no tall buildings in the immediate vicinity of the station. The Gombak site may be considered semi-urban, bordering rural.

2.2. Measurement methods

Aerosol scattering coefficient, Bsp, at a wavelength of 530 nm was determined at each site using a Radiance Research M903 nephelometer. The nephelometer was operated with a heated inlet and heated chamber to minimise effects of hygroscopic growth on scattering of the aerosol, thus giving a measure of dry aerosol scattering coefficient. Calibration of the nephelometer was performed using zero air and CO₂ as a span gas. Automatic span and zero checks were carried out daily at Petaling Jaya and Gombak. In addition, weekly manual checks were carried out at Petaling Jaya for most of the sampling program and any drifts in the zero and spans are adjusted. At Gombak weekly manual calibration checks were carried out from December 1999. Where applicable, Bsp data were corrected for drift and offsets. All corrections were minor.

The aerosol samplers used in this study were Ecotech Dual Flow 1500 Aerosol Samplers. These samplers collect particles less than 2.5 μm in aerodynamic diameter (PM2.5), collecting two samples in parallel on separate filters. Flow rate through the inlet was 16.7 l min⁻¹ with half the flow directed to each of the two filters. Filter media used for sample collection are described in Table 1. Three out of every four samples were collected on the combination of Teflon (TEF) and polycarbonate (PC) filters. One out of every four samples was collected on the combination of TEF and quartz fibre (QF) filters. Samples were collected for a 24-h period on a one-day-in-six

cycle, except during periods of excessive haze when daily samples were collected.

Continuous PM₁₀ concentrations were determined at Petaling Jaya and Gombak using a Beta Attenuation Gauge operated by ASMA.

2.3. Analytical methods

TEF and PC filters were weighed using a Mettler UMT2 ultra-microbalance. Electrostatic charging was reduced by the presence of radioactive static discharge sources within the balance chamber. The balance was calibrated before each weighing session. The resolution of the balance is 0.0001 mg (0.1 μg). Each filter was weighed repeatedly until three weights within 0.001 mg were obtained. Before weighing, filters were dried in a desiccator for 24 h at humidity of ≤20%, and this humidity was maintained during the weighing procedure. The filters were weighed in this fashion both before and after exposure and the gravimetric mass determined as the difference between the two measurements. For the average masses measured for this work, uncertainties were 7% (at 95% confidence) for masses derived from TEF filters and 21% (at 95% confidence) for masses derived from PC filters.

Elemental carbon (EC) was determined by light absorption using the integrated plate method modified from Lin et al. (1973). The system was calibrated for elemental carbon using an aerosol produced by pyrolysis of acetylene (Gras, 1996), which yielded a specific mass absorption of 10.4 m² kg⁻¹.

Total carbon (TC) was determined from the samples collected on the QF filters. A sample and blank was determined for each sample. The blank concentration was determined from a second quartz filter placed in series behind the sample filter in a single filter holder and was on average 5% of the sample. TC was determined using thermal decomposition to CO₂ in CO₂-free air in a tube furnace, with a copper catalyst to oxidise any CO formed by partial oxidation. A Licor 6262 analyser was used to determine the evolved CO₂. The carbon analyser was calibrated by injection of known quantities of CO₂ into the flowing air stream. The reproducibility of the TC measurement was 15% (at 95% confidence). Ion chromatography (IC) was used to measure soluble ions

in aqueous extracts of the samples collected on the TEF filters. Ions determined were: Na^+ , NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , Cl^- , NO_3^- , SO_4^{2-} , Br^- , NO_2^- , PO_4^{3-} , F^- , acetate, formate, oxalate and methanesulfonic acid (MSA). The substrates were wetted with methanol before being extracted in 12 ml of Milli-Q HPLC grade (high purity de-ionised) water, and a bactericide (120 μl of chloroform) was added to preserve the extracted sample from biological degradation. The ionic concentrations were determined using a Dionex DX500 gradient ion chromatograph employing Dionex IC columns, an AS11 column and ARS1 suppressor for anions, a CS12 column and CRS1 suppressor for the cations. Quality control assessment procedures for the IC measurements included measurement of duplicates, and ionic balances and comparison of calculated and measured conductivity compliance to USEPA criteria (USEPA 1994). Proton induced x-ray emission (PIXE) was used to determine concentration of elements including Na, Al, Si, P, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Cu, Co, Ni, Zn, Br and Pb. PIXE analyses were conducted by the Australian Science and Technology Organisation (ANSTO) and involved bombarding the sample with 2.6 MeV proton beams. An 8-mm diameter beam with an incident proton charge of 3 μC is used to bombard the sample. Comparability of the two chemical datasets was assessed by comparison of S determined by PIXE and SO_4^{2-} determined by IC.

2.4. Modelling – the Air Pollution Model (TAPM)

Modelling was carried out using the CSIRO coupled meteorological and air pollution model, TAPM (Hurley, 1999). TAPM uses databases of terrain, vegetation, soil types, sea-surface temperature and synoptic-scale meteorological analyses to derive the meteorological component. The pollution component is derived using point source emission data or gridded emission inventories of air pollutants. In this work, TAPM was run with three 40 \times 40 nested grids with spacings of 30 km, 10 km and 3 km (i.e. domains of 1200 \times 1200 km, 400 \times 400 km and 120 \times 120 km), centred on Petaling Jaya. TAPM was used to simulate the transboundary transport of smoke to the Klang Valley and the

© EGU 2003

3. Observations

3.1. Aerosol scattering coefficient

Time series of daily-averaged Bsp and local visual distance (LVD) at Petaling Jaya and Gombak are shown in Fig. 2. LVD is a measure of visual range usually defined as the distance at which a black object can be distinguished against the horizon. LVD therefore depends upon contrast and visual sharpness, and is related to the volume extinction coefficient B_e by the Koschmeider relationship (Griffing, 1980), where A is the Koschmeider constant and

$$LVD = A/B_e. \quad (1)$$

The extinction coefficient B_e is approximated by the dry scattering coefficient Bsp and the molecular scattering coefficient of atmospheric gases. LVD is only an approximation to actual visual range because Bsp is measured at a point, rather than integrated over an atmospheric light path, and Bsp is the measured scattering efficiency of dry aerosol particles, not the aerosol droplet population that typically results at ambient humidity.

In this work we define excessive haze as occurring when LVD falls below 20 km for a one-hour period. This translates to a Bsp value of greater than 180 Mm^{-1} over 1 h. An average Bsp over 24 h for days of excessive haze was determined by calculating the 24-h average Bsp on days when at least 1 h displayed LVD of lower than 20 km. Thus the average Bsp on days of excessive haze was calculated to be greater than 150 Mm^{-1} over 24-h, over the same interval for which aerosol chemical data (PM2.5 samples) were averaged.

The broad temporal variation in Bsp over the two-year measurement period was essentially the same at both sites, with excessive levels of aerosol scattering occurring

Interactive Discussion

between May and September 1999, during May 2000, and between July and September 2000.

Figure 3a shows the average diurnal pattern of Bsp at Petaling Jaya and Gombak. This pattern is a maximum Bsp overnight, decreasing through the early hours of the morning and increasing between 07:00 and 11:00. This increase is followed by a gradual decrease throughout the early afternoon and a sharp increase after about 18:00. Bsp continues to increase until midnight. This generalised pattern can be attributed to the diurnal changes in the source of particles (i.e. traffic peaks in the morning and late afternoon). In addition, mixing processes in the planetary boundary layer vent surface emissions to higher levels during the day, so diluting pollutants. However, at night pollutants are trapped in a shallow (near-surface) nocturnal boundary layer. Similar patterns in other cities have been reported, for example, by Cohen et al. (1997) for Jakarta.

Figure 3 also shows the diurnal patterns of Bsp and PM10 at Gombak when the Bsp data are selected for days with daily average Bsp greater than 150 Mm^{-1} (Fig. 3b). The number of days with average Bsp greater than 150 Mm^{-1} was 8% of the total number of days measured at Gombak. On these days the diurnal pattern shows a broad peak during the middle of the day. The diurnal patterns for Bsp when the daily average Bsp was lower than 150 Mm^{-1} for Gombak and Petaling Jaya are shown in Fig. 3c. These patterns of variation are similar to the average diurnal patterns displayed by all data (Fig. 3a). Also shown in Fig. 3b is the diurnal pattern for Bsp at Petaling Jaya for days when the daily average Bsp is greater than 150 Mm^{-1} (accounting for 5% of days). The pattern of variation is similar to the pattern displayed for days with Bsp less than 150 Mm^{-1} , except that a peak occurs during the middle of the afternoon (matched by a trough in the patterns for days less than 150 Mm^{-1}).

The diurnal plots in Fig. 3 reveal two patterns of variation, the first is the normal pattern with maximum Bsp (and PM10) overnight and minima during the day with peaks during the morning and afternoon traffic peaks (Figs. 3a and 3c). The second pattern is for a minimum overnight and peaks during the middle of the day (Fig. 3b). This

behaviour is distinctly displayed by PM10 and Bsp at Gombak on days of elevated scattering and less distinctly displayed at Petaling Jaya where a small peak is observed in the middle of the afternoon. Figure 3d displays the diurnal pattern for Bsp and PM10 at Gombak for a single day when the average Bsp was greater than 150 Mm^{-1} (13 July 2000). A peak in the Bsp and PM10 record is evident at both sites between 12:00 and 14:00, as well as at other times.

3.2. Aerosol mass

The time series of daily averaged PM10 measured at Petaling Jaya using a Beta Gauge is shown in Fig. 4. Also shown is the time series of PM2.5 determined from aerosol samples collected over a 24-h period on a one-day-in-six cycle, except between 16 and 25 July and 24 and 30 August 2000 when samples were collected on a daily basis. Elevated PM10 and PM2.5 levels occur between May and September 1999, during May 2000, and between July and September 2000. A similar pattern of PM10 and PM2.5 variation was observed at Gombak.

3.3. Aerosol chemistry

Figure 5 displays plots of the relationships between various chemical species measured in the PM2.5 aerosol samples. The evident structural relationships between these species illustrate characteristic “chemical fingerprints” of different sources.

Figure 5a displays the relationship between Na^+ and Mg^{2+} and Fig. 5b the relationship between Si and Al along with the known ratios of these species in seawater (Millero, 1974) and crustal rocks (Mason and More, 1982). The similarity between the ratios of these species measured in the aerosol samples, and the ratios measured in seawater and crustal rocks, suggests that Na^+ and Mg^{2+} are appropriate tracers for sea-salt and Si and Al are tracers for soil-dust.

Figure 5c displays the relationship between NH_4^+ and nssSO_4^{2-} . nssSO_4^{2-} represents non-sea-salt SO_4^{2-} (i.e. all SO_4^{2-} that is derived from particles other than sea-

Haze in the Klang Valley of Malaysia

M. D. Keywood et al.

© EGU 2003

salt). NssSO_4^{2-} was calculated by assuming that all Na^+ present was of sea-salt origin, enabling sea-salt SO_4^{2-} to be calculated from the known ratio of Na^+ to SO_4^{2-} in seawater. The strong relationship between these species arises from the neutralisation of SO_4^{2-} (produced by oxidation of SO_2) by NH_4^+ , and reflects the stoichiometry of this relationship. This suggests a secondary production source for the aerosol via photochemical oxidation of SO_2 to SO_4^{2-} in the atmosphere followed by uptake of NH_3 , which is ubiquitous in the atmosphere.

Figure 5d displays the relationship between nssK^+ and EOM. NssK^+ is non sea-salt K^+ and is calculated in analogous fashion to the calculation of nssSO_4^{2-} , in this case using the ratio of Na^+ to K^+ in seawater. NssK^+ is a significant component of two major particle sources, soil dust and vegetation. EOM is an estimate of organic mass and is calculated from the difference between gravimetric mass (GM), and the sum of elemental carbon (EC) and inorganic mass (IM), where IM is calculated as described in Brook et al. (1997), see Sect. 4.4 for details. The evident structural relationship between nssK^+ and EOM in Fig. 5d suggests a significant biomass-burning source for $\text{PM}_{2.5}$ aerosol material at both Petaling Jaya and Gombak, since there is minimal organic matter in soil dust.

Time series for some of these chemical marker species are shown in Fig. 6. The time series for Na^+ at Gombak and Si at Petaling Jaya are displayed in Fig. 6a. Note that the time series of Na^+ at Petaling Jaya is similar to that seen at Gombak in Fig. 6a and the time series of Si at Gombak is similar to that displayed at Petaling Jaya in Fig. 6a. A peak in Na^+ concentrations during January and February 2000 suggests an influx of sea-salt aerosol during this time. A possible influx of soil-dust occurring during May 1999 is shown in the Si time series, with a peak in Si concentration at Petaling Jaya in August 2000 most likely representing localised building activity, particularly the construction of a building adjacent to the Petaling Jaya sampling site.

Figure 6b shows the time series plot of nssK^+ at Gombak and EOM at Petaling Jaya. Again note that the time series of nssK^+ displayed at Petaling Jaya is similar to that shown by Gombak in Fig. 6b and the time series for EOM at Gombak is similar to that

displayed by Petaling Jaya shown in Fig. 6b. EOM and nssK^+ display elevations during May 1999 and August 1999 and June to August 2000. This pattern suggests an influx of biomass burning aerosol, or smoke, during these times, which are coincident with periods of excessive haze, defined in Sect. 4.2.

Figure 6c displays the time series plots of nssSO_4^{2-} at both sites. Again, a similar pattern of variation is observed at both sites. The relatively uniform amplitude fluctuation through the year is consistent with a major local source such as secondary production.

3.4. Mass balance

In this work, an attempt was made to measure as many chemical species as was practically possible. The chemical composition of aerosol can be divided into major and trace species, and there should be a balance between the mass of aerosol determined and the sum of all chemical constituents. Besides gravimetric mass (GM), the major species determined in this work were inorganic mass (IM), determined from the sum of all soluble and insoluble inorganic species according to Brook et al. (1997), elemental carbon (EC) and organic mass (OM), where

$$\text{GM} = \text{IM} + \text{EC} + \text{OM}. \quad (2)$$

OM was determined by two methods: firstly, it was directly measured as total carbon on the QF filters and the EC subtracted according to

$$\text{TC} = \text{OM} + \text{EC}. \quad (3)$$

Secondly, EOM was estimated using the difference between the total mass and chemical constituents according to

$$\text{EOM} = \text{GM} - \text{EC} - \text{IM}. \quad (4)$$

A comparison of the EOM and measured OM for 24 samples is shown in Fig. 7. The figure displays scatter consistent with the expected measurement uncertainties (reproducibility $\pm 15\%$ and blank measurements $\pm 5\%$). This diagram confirms that the EOM is a good surrogate for OM and is used in the following discussion to represent OM.

© EGU 2003

The average composition of the major chemical components of the aerosol is shown in Fig. 8. At Petaling Jaya, EOM is the major constituent, with EC and IM being approximately equal. Of the IM, sulfate, ammonium, K and oxalate are the most significant species (Fig. 8a). A similar picture is seen for Gombak (Fig. 8b).

Note that nssSO_4^{2-} makes up 98% of sulfate and nssK^+ makes up 98% of K. This is because the aerosol samples collected were the PM_{2.5} size fraction, therefore excluding particles greater than 2.5 μm in aerodynamic diameter, the size range in which most sea-salt sulfate, sea-salt K and soil-dust K predominately occur. Thus in the following discussion, sulfate and K are used instead of nssSO_4^{2-} and nssK^+ . Also, note that oxalate is an organic acid associated with biomass burning. Oxalic acid is present in the cellulose material of vegetation.

4. Discussion

The observations of the temporal and diurnal patterns of Bsp, PM₁₀ and PM_{2.5} chemical composition, along with the chemical relationships described above, allow us to make qualitative suggestions about the sources of aerosol to Petaling Jaya and Gombak. Smoke from biomass burning is clearly a very important and at times the dominant source of aerosol at each site, as displayed by the predominance of EOM (Fig. 8) and its association with K. Sulfate makes up 50% of IM, indicating the potential importance of secondary production at both Petaling Jaya and Gombak. Na^+ and Si are both minor components of IM, indicating that sea-salt and soil-dust are insignificant sources of PM_{2.5} aerosol.

An early study of aerosol in KL by JICA (1993) gives a comprehensive assessment of air quality issues and consequences in the Klang Valley region. One small component of that study was a source apportionment analysis applied to a limited number of SPM samples. This source apportionment differentiated various sources contributing to the atmospheric haze, including soil-dust, sea-salt, industry, woodsmoke, secondary particle production and diesel and petrol combustion. Interestingly, a later study by NERI

(1998) could not identify a vehicle source of particles at Petaling Jaya using source apportionment analysis, despite noting that the diurnal pattern in PM10 variation showed evidence of a contribution by traffic throughout the day.

We have not identified a vehicle emissions source in our qualitative description of the variations in aerosol chemistry, because of the lack of a suitable tracer for vehicle emissions in our chemical analysis of the PM2.5 aerosol samples. Previously, variations in Pb and Br have been useful tracers for vehicle emissions; however, Pb has been removed from petrol in Malaysia since January 1999. Nevertheless, we believe that a detailed source apportionment analysis utilising other tracers for vehicle emissions such as NO and CO will result in identification of this source in the Klang Valley. A detailed source apportionment study will be reported elsewhere.

Days of excessive haze have been defined for this work as 24-h average Bsp greater than 150 Mm^{-1} . At Petaling Jaya this occurred on 5% of days (9 days of which PM2.5 samples were collected) and at Gombak on 8% of days (10 days of which PM2.5 samples were collected). Table 2 compares the relative proportions of each of the major species and components of IM for days of excessive haze and for days of non-excessive haze. At both sites, on days of excessive haze EOM is a larger component than on the low-haze days. This is matched by an increase in potassium (K) and oxalate, suggesting that on days of excessive haze, smoke from biomass burning makes a larger contribution to the aerosol at both sites.

The variation displayed by SO_4^{2-} on days of excessive haze (Fig. 6c) is not always consistent between Petaling Jaya and Gombak, suggesting that the secondary source of aerosol for which we use SO_4^{2-} as a surrogate is not dependent on a smoke source. This follows since secondary production is the result of photochemical oxidation of SO_2 to SO_4^{2-} , so that any source of SO_2 will influence the strength of secondary particle production. Such sources may include smoke as well as vehicle and industrial emissions. Na^+ and Si do not vary between days of excessive haze and other days, further indicating that sea-salt and soil-dust are not important in the development of excessive haze in the Klang Valley.

4.1. Smoke – seasonal variations

The chemical composition of PM_{2.5} aerosol suggests that smoke is a major source of particles contributing to haze in the Klang Valley. In this section the variations in haze as a function of season are analysed. The four seasons in Malaysia are the southwest monsoon, northeast monsoon and two shorter inter-monsoon seasons (Table 3), and are determined by changes in wind flow patterns, rather than temperature changes. The climate of Malaysia is characterised by uniform high temperatures, high humidity and high rainfall. Wind speed is a relevant meteorological parameter in terms of haze development as it affects ventilation (dilution) rates in an airshed.

Cumulative frequencies of daily mean Bsp at each site for each season of 1999 are shown in Fig. 9. At each site, during the southwest monsoon, the frequency distributions show a clear trend to larger Bsp and a larger range in Bsp values. During the other three seasons the frequency distributions display steeper slopes and a consistent, smaller range in Bsp. The same pattern was observed at both sites for 2000. During the southwest monsoon there is evidently an increased frequency of high Bsp values compared with the other seasons. At Petaling Jaya, as detailed in Table 4, during the southwest monsoon of each year approximately 86% of the data fall below the 150 Mm⁻¹ excessive haze threshold for 24-h average Bsp. During the other seasons, this value is closer to 100%. Similarly, at Gombak, approximately 80% of the data fall below 150 Mm⁻¹.

Figure 10 displays the number of fires on the islands of Sumatra, Kalimantan and Peninsular Malaysia for the period of December 1998 to December 2000. The data for these plots were compiled using satellite records from the Vietnam, Thailand and Darwin nodes of the World Fire Web. Also shown on the plot are the time periods for each season. There appears to be a coincidence between fires on Sumatra and the southwest monsoon periods for both years.

Figure 11a shows the average Bsp as a function of surface (10 m) wind direction at Petaling Jaya for all of the data. The wind directions were modelled using the meteoro-

Haze in the Klang Valley of MalaysiaM. D. Keywood et al.

logical component of TAPM. This plot indicates that wind direction from the southwest corresponded with elevated scattering. In Fig. 11b, which shows the average number of fires for each wind direction, it is evident that the number of fires is greatest in the southwest direction from Kuala Lumpur, ie. on the island of Sumatra. However the satellite observations do also reveal consistently the occurrence of a smaller number of fires on Peninsular Malaysia.

In order to investigate the effect on Bsp levels in the Klang Valley caused by fires on Sumatra, Kalimantan and Peninsular Malaysia, data were extracted from the daily data set according to the following criteria:

1. Wind direction was from 150 to 300° and the number of fires on Sumatra and Peninsular Malaysia was greater than 0.
2. Wind direction was from between 90 and 130° and the number of fires on the island of Kalimantan was greater than 0.

The extracted data set (days more likely to be affected by fires) is shown in Fig. 11c; the remaining data (days less likely to be affected by fires) are shown in Fig. 11d. On days most likely to be affected by fires, the highest average 24-h Bsp concentrations predominantly occur when the wind is from the southwest direction (Fig. 11c). However, on days less likely to be affected by fires the average 24-h Bsp concentrations are lower and appear to be associated with all wind directions (Fig. 11d).

Having removed the data for days when fires on the surrounding islands are likely to have affected Bsp in the Klang Valley, it is possible to reassess the seasonal variation in Bsp at Petaling Jaya and Gombak. Table 5 shows that during the southwest monsoon season of 1999, some elevation in aerosol scattering was observed at both sites; however, elevation in scattering was not evident during the southwest monsoon period of 2000. Indeed, the overall seasonal pattern is considerably more uniform in absolute Bsp levels and reduced variability (lower stdev) when effects of fires outside Malaysia are filtered out (Table 5), compared with the full dataset (Table 4). The greatest seasonal influence on excessive haze therefore appears to be related to the frequency of

Haze in the Klang Valley of MalaysiaM. D. Keywood et al.

occurrence of fires throughout the Southeast Asian region, at times when atmospheric transport from source regions to the Klang Valley is favoured by seasonal wind patterns. In particular, transport of smoke from Sumatra during the southwest monsoon appears to be an important seasonal contributor to haze in the Klang Valley.

5 Atmospheric transport modelling using the CSIRO model TAPM, supports this conclusion. The model was run in a case study mode to seek confirmation of a cross-border influx of aerosol particles (modelled as PM10) into the Klang Valley region during a period of four days. The period for the model study was chosen to be representative of periods in the southwest monsoon in which fires had been documented
10 in Sumatra by satellite observations. For this particular case study simulation the period 10–13 July 2000 was chosen, a period midway through the southwest monsoon period for which fires were evident in Sumatra.

For the simulation, all particle emission sources other than fires in Sumatra and peninsular Malaysia were set to zero. “Hotspot” information was provided by the
15 Malaysian Department of Environment and derived from the AVHRR infrared Channel 3 of the NOAA12/14 satellite. The majority of regional hotspots in the chosen period (over 90%) were on Sumatra, although it is noteworthy that there were a few persistent hotspots in Malaysia as well.

The hotspots for 10–13 July 2000 were specified on the outer TAPM grid and an
20 arbitrary emission of PM10 was assigned to each fire. Because the source strengths of the fires were unknown, absolute PM10 levels were not modelled. Instead, the transport and dilution patterns of smoke from the fires were simulated. The emission at each TAPM grid square was designated to be proportional to the number of fires mapped into that particular grid point. The duration of the fires was unknown, so each
25 fire was assumed to last for the full 24 h of the day on which the fire was observed.

The flow of PM10 for the specified fires over KL during the four modelled days is shown in Fig. 12. The time index in the upper left hand corner indicates day, hour, minute: thus 01:01:00 means day one, first hour after midnight local time, in this case
10 July 2000, 01:00. Note that the concentration contours are enhanced to show the

© EGU 2003

plume movements more clearly; however, the predicted concentrations have no absolute significance because neither the emission strength, nor duration of fires was accurately known. The first panel shows the location of the fires at the start of the model run.

5 As time progresses on the first two days, a plume drifts towards Peninsula Malaysia with the prevailing southerly air flow, demonstrating that fires on Sumatra do affect KL. On the last two days, the northern part of Malaysia rather than the Klang Valley was affected by smoke from the Sumatran fires. At the same time a few persistent hotspots in Malaysia affected the Klang Valley, and the wind direction shifted from the southwest
10 to the southeast, so that the central peninsular region was affected by the hotspots in southern Malaysia. This demonstrates that Malaysia itself will act as a source of smoke-enhanced haze if fires remain active on the peninsular.

In summary, should similar fires exist at any other times with similar wind flow patterns, it follows that smoke emitted from fires on Sumatra or on other islands in South-
15 east Asia will augment any background source of PM10 and haze in the Klang Valley.

4.2. Smoke – diurnal patterns

Smoke also contributes to the diurnal pattern of Bsp. Two generic diurnal patterns of haze are evident from the overall Bsp datasets at both sites in the Klang Valley region (Fig. 3). The less common diurnal pattern of haze occurred on days of high haze,
20 and exhibited a persistent peak around midday. It is postulated that the mixing down of smoke present in the lower troposphere after the onset of convective mixing may produce this midday peak. This hypothesis was tested using TAPM, which was run excluding the surface PM10 sources in Malaysia while only including PM10 injected high into the lower troposphere. An arbitrary series of ten point sources was chosen
25 on Sumatra due south of KL emitting particles at 1500 m, thereby simulating particles present in the air well above the surface, lofted there by the buoyancy of the plumes from the fires.

Results are shown in Fig. 13. The particles present in the lower troposphere are

responsible for enhanced modelled PM₁₀ concentrations in KL during the middle of the day. The planetary boundary-layer depth (PBL) reaches values of 1100 m or more during the daytime. The PM₁₀ concentration increase to detectable levels once the PBL depth exceeds 900–1100 m, allowing the mixing down from aloft of the PM₁₀ plume derived from long-range transport.

5. Conclusions

This paper has presented an overview of the methodology and some results from the MHS, with a qualitative assessment of the sources of particles contributing to haze in the Klang Valley.

By investigating the time series of aerosol scattering coefficient and the relationships between marker chemical species determined from PM_{2.5} aerosol samples, we have shown that smoke is a major source of particles to the Klang Valley. Secondary photochemical production of particles appears to be a significant source at the two measurement sites of Petaling Jaya and Grombak at all times. Sea-salt and soil-dust make only a minor contribution to aerosol in the Klang Valley. (Note that these qualitative descriptions of the sources affecting particles in the Klang Valley will be quantified in further work. In particular, source apportionment analysis will be used to identify all sources, including a vehicle emission source, and to determine the relative contribution of each of these sources to the haze in the Klang Valley.)

Periods of excessive haze are defined as 24-h average Bsp concentration of greater than 150 Mm⁻¹. These occurred on a number of occasions, between May and September 1999, during May 2000, and between July and September 2000. These periods coincided with the southwest monsoon seasons and with the presence of forest fires on the island of Sumatra. Transport modelling simulated the transboundary movement of smoke from hotspot sites on the island of Sumatra and Peninsular Malaysia to the Klang Valley for one week during the 2000 southwest monsoon. This modelling suggested that Sumatra is a very strong candidate as a source region for smoke aerosol

that impacts on the Klang Valley region, and more widely across Malaysia. In addition, fires on Peninsular Malaysia were found to impact on haze development in the Klang Valley.

Haze in the Klang Valley of Malaysia

M. D. Keywood et al.

Table 3. Descriptive summary of seasonal wind patterns in Malaysia

| SEASON | DATES (FROM MMS 1999) | CHARACTERISTICS |
|-------------------------|--------------------------|---|
| Inter-monsoon (Int1) | 15 March to 14 May | Light variable winds when an equatorial trough lies over Malaysia. |
| Southwest monsoon (SW) | 15 May to 14 Sept. | Southwesterly winds below 8 m s^{-1} . Sabah and Sarawak may experience winds of 10 m s^{-1} when typhoons develop over the west Pacific and move westwards across the Philippines. |
| Inter-monsoon (Int2) | 15 Sept. to 30 Oct. | Light variable winds when equatorial trough lies over Malaysia. |
| Northeast monsoon (NE) | 1 Nov. to 14 March | Easterly to northeasterly winds 5 to 10 m s^{-1} . East coast states of Peninsular Malaysia may experience winds of 15 m s^{-1} during cold surges from the north. |
