

## ***Interactive comment on “Halogen Occultation Experiment (HALOE) and balloon-borne in situ measurements of methane in stratosphere and their relation to the quasi-biennial oscillation (QBO)” by P. K. Patra et al.***

**P. K. Patra et al.**

Received and published: 23 May 2003

The general approach in this paper has been to use HALOE observed CH<sub>4</sub> profiles to understand the variabilities in the balloon-borne CH<sub>4</sub> measurements. Since the balloon-borne experiments are expensive, thus not made very frequently at the Indian site (Hyderabad). This makes the interpretation of the widely spaced (one in about 4 years) vertical profiles often difficult. Therefore, our orientation in this paper has been to use the frequently measured CH<sub>4</sub> profiles by the HALOE instrument to extract the dynamical information (e.g. QBO) and use that to understand the variabilities in the in situ observations.

It is probably not fair to say that `the direct comparison of satellite data in 1994 to

balloon data doesn't show any similarity'. In our opinion the changes in mixing ratio with height compares quite well between the two datasets from different measurement techniques. Infact the changes in gradient are the main focus of this work. We are not quite sure why an offset ( $\sim 0.1$  ppm) is present during 1994. Larger than average negative anomaly (comparable to this offset) was also found in the HALOE CH<sub>4</sub> data during 1994 over the tropics (Fig. 7 of Rosenlof, JMSJ, Vol.80, No.4B, p. 831, 2002). However, the match between the two datasets in 1998 is excellent, both in terms of altitude gradient and absolute concentration of CH<sub>4</sub>. To discuss this issue further, our measurements suggest an overall decrease in CH<sub>4</sub> concentration in the stratosphere between 1994 and 1998, which could be explained by the increased loss due to higher abundance of inorganic chlorine (and hydroxyl radicals), while the CH<sub>4</sub> growth rate near the surface was low ( $\sim 7$  ppb per year). As discussed in Patra et al. (in Proc. Non-CO<sub>2</sub> Greenhouse Gases, Eds. Van Ham et al., Millpress, p.295, 2002) the growth rate of CH<sub>4</sub> in lower stratosphere was higher ( $\sim 1\%$ ) in the period of 1992-1997 and close to zero in the period of 1995-2000. One may argue here whether or not the CH<sub>4</sub> growth rate near the surface should be similar to that at the base of the stratosphere as most of the chemical loss of CH<sub>4</sub> occurs in the troposphere, which by its nature is variable. More on interannual variability of the troposphere is given later.

The references in the text to Randel et al. (1998) is directed to this paper. We are sorry for the incorrect bibliography list.

As we have tried to point out in the beginning, we are not really trying to isolate the dynamical signals in our balloon measurements. Instead take the information available from other datasets, such as the HALOE CH<sub>4</sub> observations and NCEP/NCAR reanalysed winds, to understand the gross changes in the balloon measurements.

Yes, it is rather difficult task to explain every features in the CH<sub>4</sub> vertical profiles by using the zonal wind shear. However, one can see that the large scale features to be quite consistent as explained in Section 2, para#3. We will modify this discussion during the revision for more clarity. As an example the 1990 profiles of both CH<sub>4</sub> and

zonal winds are quite different from all others in the stratosphere. It should also be kept in mind that the zonal wind shear do not produce the changes in CH<sub>4</sub> profiles exactly at the same height and the affects can be seen only in the stratosphere. Generally, the effect of wind shear on CH<sub>4</sub> occurs at the layers above as the slopes in CH<sub>4</sub> mixing ratio are lesser at lower heights, e.g., the wind shear at 27 km would influence the CH<sub>4</sub> concentration at 30 km. In the troposphere the story is quite different as we move in to a convective system from stratified system (the stratosphere). We see clear evidences that vertical transport is responsible for producing the observed slopes in CH<sub>4</sub> between the middle troposphere (8-9 km height or ~300 mb pressure level) and tropopause (at ~17 km). The NCEP/NCAR reanalysis generated relative humidity at 300 mb, monthly means for March and/or April averaged over the global tropics (20S-20N), exhibit very strong anti-correlation (coeff.=0.99) with CH<sub>4</sub> slope. This means that slope in CH<sub>4</sub> mixing ratio is smaller when there are stronger upward motion in the tropics, which is also strongly supported by similar analysis of NCEP/NCAR vertical velocities (Omega in Pa/S). We plan to include this discussion in the revised version.

We think, the suggested overplot would be quite similar to that is shown in Figure 4. We shall give a try to make this comparison better.

Since we are not dealing with precise amplitude and phase of the QBO signal and there is also quite a bit of discussion on the analysed HALOE CH<sub>4</sub> distributions, we believe the analysed wind data is more relevant to this study. Only the amplitude of QBO signal is known to be smaller in the reanalysed winds compared to that is actually observed in the observed winds over Singapore (e.g. McCormack and Siskind, JGR, Vol.107, No.D22, 2002).

The figure caption has been changed.
