Abstract

The evolution of the global aerosol system from 1860 to 2100 is investigated through a transient atmosphere-ocean General Circulation Model climate simulation with interactively coupled atmospheric aerosol and oceanic biogeochemistry modules. The microphysical aerosol module HAM incorporates the major global aerosol cycles with prognostic treatment of their composition, size-distribution, and mixing state. Based on an SRES A1B emission scenario, the global mean sulfate burden is projected to peak in 2020 while black carbon and particulate organic matter show a lagged peak around 2070. From present day to future conditions the anthropogenic aerosol burden shifts generally from the northern high-latitudes to the developing low-latitude source regions with impacts on regional climate. Atmospheric residence- and aging-times show significant alterations under varying climatic and pollution conditions. Concurrently, the aerosol mixing-state changes with an increasing aerosol mass fraction residing in the internally mixed accumulation mode. The associated increase in black carbon causes a more than threefold increase of its co-single scattering albedo from 1860 to 2100. Mid-visible aerosol optical depth increases from pre-industrial times, predominantly from the aerosol fine fraction, peaks at 0.26 around the sulfate peak in 2020 and maintains a high level thereafter, due to the continuing increase in carbonaceous aerosols. The global mean anthropogenic top of the atmosphere clear-sky short-wave direct aerosol radiative perturbation intensifies to -1.1 W m^{-2} around 2020 and weakens after 2050 to -0.6 W m^{-2} , owing to an increase in atmospheric absorption. The demonstrated modifications in the aerosol residence- and aging-times, the microphysical state, and radiative properties challenge simplistic approaches to estimate the aerosol radiative effects from emission projections.

Interactive Discussion

1. Introduction

The importance of atmospheric aerosols for the earth system has become well established. Aerosol particles influence the global radiation budget directly, by scattering and absorption (Ångström, 1962; McCormic and Ludwig, 1967) as well as indirectly by the modification of cloud properties (Twomey, 1974; Graßl, 1975; Twomey, 1977; Albrecht, 1989; Hansen et al., 1997; Lohmann, 2002), with feedbacks to the hydrological cycle (Roeckner et al., 1999; Liepert et al., 2004). In addition, aerosols link the biogeochemical cycles of the atmosphere, the ocean, and the land surfaces acting as micro-nutrients for the marine (Martin and Fitzwater, 1988; Johnson et al., 1997) and terrestrial (Swap et al., 1992; Okin et al., 2004) biosphere. However, aerosol deposition can also have detrimental environmental effects, such as acidification with impacts on aquatic and terrestrial ecosystems (e.g. Likens and Bohrmann, 1974).

Assessments of the role of aerosols in the earth system and in particular of their climatic impact require the knowledge of the state of the global aerosol system for past and present conditions as well as for future scenarios.

However, while observations provide a wide range of information about the present day global aerosol system, they are not sufficient for an assessment of the aerosol climatic effects. Direct observations of the global aerosol system provide detailed insights into the aerosol system, but are representative of limited spatial and temporal scales. Remote sensing data from ground-based lidar and sun-photometers provides valuable information but suffers from similar sampling issues. Up to now, operational remote sensing data from space only provides integral aerosol properties and the retrievals rely on a-priori information about the aerosol system and internal aerosol models. While present-day satellite observations allow estimates of the total aerosol radiative effects over the oceans (e.g. Zhang et al., 2005), fundamental assumptions have to be made to estimate the anthropogenic contribution to the radiative effects. As natural aerosols are dominated by primary particles in the larger size fraction, the fine fraction is typically used as proxy for the anthropogenic contribution to the aerosol radiative perturbation

Interactive Discussion

(Christopher and Zhang, 2004).

Global aerosol models can contribute to increase the understanding about the complex global aerosol system for past, present, and future conditions. Furthermore, they permit to identify the effects of specific aerosol components and aerosol sources, natural or anthropogenic, on the global climate system.

In early transient coupled atmosphere-ocean global circulation model (AOGCM) climate simulations, the radiative impact of aerosols has been neglected. Later, some aerosol components or their radiative properties have been prescribed from aerosol climatologies (Tanre et al., 1984; Koepke et al., 1997) in century scale AOGCM simulations (e.g. Roeckner et al., 1992). Prognostic sulfur cycle schemes have been added to some more recent simulations, mainly with atmospheric GCMs coupled to mixed layer oceans (e.g. Kiehl et al., 2000). The consideration of prognostic sulfur cycle schemes in coupled AOGCM climate simulations remains the exception (Roeckner et al., 1999; Johns et al., 2003). However, the importance of other anthropogenic aerosol components, in particular of carbonaceous aerosols, has received considerable attention (e.g. Penner et al., 2001; Menon et al., 2002; Jacobson, 2002) and their relative importance is projected to increase according to recent emission scenarios (e.g. SRES: Nakicenovic et al., 2000). While, according to the widely used SRES A1B scenario, anthropogenic SO₂ emissions, as the main sulfate precursor, are projected to peak in the year 2020, the emissions of the carbonaceous aerosols are expected to increase up to the year 2100. Therefore, the limitation to sulfate aerosols in most previous transient AOGCM climate simulations is likely to draw an incomplete picture, in particular with respect to future climate projections.

Here we present results from a transient climate simulation from 1860 to 2100 with an evolving earth system model consisting of interactively coupled atmosphere and ocean GCMs with embedded atmospheric aerosol cycles and ocean biogeochemistry. In addition to the traditional physical coupling of the atmosphere and ocean models, also the atmospheric and oceanic biogeochemical cycles are coupled interactively. The microphysical aerosol module HAM (Stier et al., 2005a) has a prognostic representation

of the major global aerosol components with prognostic treatment of their microphysi-
cal state and interactions. The aerosol components considered are sulfate (SU), black
carbon (BC), particulate organic matter (POM), sea salt (SS), and mineral dust (DU).
Aerosol composition, size-distribution, and mixing-state are prognostic. Natural emis-
sions of mineral dust, sea salt, and dimethyl-sulfide (DMS) are calculated interactively.
Anthropogenic aerosol and aerosol-precursor emissions are prescribed based on the
SRES A1B scenario.

The focus of this study is to analyse the transient evolution of the simulated global
aerosol system from 1860 to 2100. Other aspects of the results, such as the regional
climate impact of carbonaceous aerosols (Roeckner et al., 2005¹; henceforth: R2005)
or the interactive DMS cycle (Kloster et al., 2005²; henceforth: K2005), are addressed
in accompanying publications.

Section 2 describes the setup of the earth system model. The analysis of the simu-
lated aerosol evolution from 1860 to 2100 is presented in Sect. 3. Section 4 concludes
the discussion.

2. Model description

In this study, we use a sub-model of the emerging Max Planck Institute – Earth Sys-
tem Model (MPI-ESM), consisting of the following interactively coupled models: the
atmospheric general circulation model ECHAM5 (Roeckner et al., 2003), the ocean
general circulation model MPI-OM (Marsland et al., 2003), the atmospheric aerosol
module HAM (Stier et al., 2005a), and the ocean biogeochemistry module HAMOCC5

¹Roeckner, E., Stier, P., Feichter, J., Kloster, S., and Esch, M.: Impact of carbonaceous
aerosol forcing on regional climate change, Max Planck Institute for Meteorology, Hamburg,
Germany, submitted, 2005.

²Kloster, S., Feichter, J., Maier-Raimer, E., Roeckner, E., Wetzell, P., Stier, P., Six, K. D.,
and Esch, M.: Response of DMS in the ocean and atmosphere to global warming – a model
estimate, Max Planck Institute for Meteorology, Hamburg, Germany, submitted, 2005.

(Maier-Reimer et al., 2005). The atmospheric and oceanic biogeochemical cycles are coupled by accounting for deposition of mineral dust and subsequent iron dissolution as micro-nutrient for the ocean biogeochemistry and by emitting DMS produced by phytoplankton from the ocean surface to the atmosphere. A detailed description and evaluation of the coupled ECHAM5 – HAM system is given in Stier et al. (2005a) and the coupled ECHAM5 – HAM – MPI-OM – HAMOCC5 system is evaluated in Kloster et al. (2005).

2.1. The atmosphere GCM ECHAM5

The atmospheric GCM ECHAM5 (Roeckner et al., 2003) is the fifth-generation climate model developed at the Max Planck Institute for Meteorology. ECHAM5 solves prognostic equations for vorticity, divergence, surface pressure and temperature expressed in terms of spherical harmonics with a triangular truncation. Non-linear processes and the physical parameterisations are solved on a corresponding Gaussian grid. Water vapour, cloud liquid water, cloud ice and trace components are transported in grid-point space with a flux form semi-Lagrangian transport scheme (Lin and Rood, 1996). ECHAM5 contains a microphysical cloud scheme (Lohmann and Roeckner, 1996) with prognostic equations for cloud liquid water and ice. Cloud cover is predicted with a prognostic-statistical scheme solving equations for the distribution moments of total water (Tompkins, 2002). Convective clouds and convective transport are based on the mass-flux scheme of Tiedtke (1989) with modifications by Nordeng (1994). The solar radiation scheme (Fouquart and Bonnel, 1980) has 4 spectral bands, 1 for the visible and ultra-violet, and 3 for the near-infrared. The long-wave radiation scheme (Mlawer et al., 1997; Morcrette et al., 1998) has 16 spectral bands. A resolution of horizontally T63 (corresponding to 1.8°) with 19 vertical levels has been applied in the coupled model setup.

2.2. The aerosol module HAM

The microphysical aerosol module HAM (Stier et al., 2005a) predicts the evolution of an ensemble of seven interacting internally- and externally-mixed log-normal aerosol modes. In the current setup, the components sulfate, black carbon, particulate organic matter, sea salt, and mineral dust are included. The aerosol mixing state is prognosed within the possible mixing-state configurations illustrated in Table 1. The modes are composed either of compounds with no or low solubility, henceforth denoted as insoluble mode, or by an internal mixture of insoluble and soluble compounds, henceforth denoted as soluble mode. The main components of HAM are the microphysical core M7 (Vignati et al., 2004), an emission module, a sulfur chemistry scheme (Feichter et al., 1996), a deposition module, and a module to calculate the aerosol radiative properties.

The microphysical core M7 calculates the coagulation among the modes, the condensation of gas-phase sulfuric acid on the aerosol surface, the binary nucleation of sulfate, and the water uptake. Sulfate is assumed to occur semi-neutralised in form of ammonium bisulfate (Adams et al., 1999). The aerosol radiative properties as well as the sink processes dry deposition, sedimentation, and wet deposition are parameterised in dependence of mode size and composition. The aerosol radiative properties are passed to the ECHAM5 radiation scheme.

Emissions of mineral dust are calculated online in dependence of the ECHAM5 wind speed and hydrological parameters (Tegen et al., 2002, 2004). Preferential source areas and the vegetation cover are assumed constant, taken from Tegen et al. (2002). Freshly emitted dust is assumed insoluble. Sea salt emissions are parameterised following Schulz et al. (2004). Emissions of DMS are calculated interactively from the simulated DMS seawater concentrations of the HAMOCC5 ocean biogeochemistry, applying the air-sea exchange formulation of Wannikhof (1992). The emissions of biogenic terrestrial DMS, POM from secondary biogenic sources, and volcanic SO₂ emissions are based on the AEROCOM aerosol model inter-comparison experiment

(<http://nansen.ipsl.jussieu.fr/AEROCOM/>) emission inventory (Dentener et al., 2005³). The emission size-distributions of BC and POM follow the AEROCOM recommendations (see Stier et al., 2005a) as well as the assumption that 2.5% of all SO₂ emissions are emitted in form of primary sulfate. The applied scenario of anthropogenic emissions is described in Sect. 2.6.

2.3. Aerosol-cloud coupling

The standard ECHAM5 cloud scheme has been extended by a prognostic equation for the cloud droplet number concentration (CDNC) (Lohmann et al., 1999). Nucleation of cloud droplets is parameterised semi-empirically in terms of the aerosol number size distribution and vertical velocity (Lin and Leaitch, 1997). Sub-grid scale vertical velocity is derived from the turbulent kinetic energy (Lohmann and Kärcher, 2002). CDNC sink processes are parameterised in analogy to those formulated in ECHAM5 for the in-cloud liquid water content. The cloud radiative properties depend on the droplet effective radius, which is calculated from the liquid water content and CDNC. These co-determine also the auto-conversion rate following Khairoutdinov and Kogan (2000). Thus, this setup accounts for both the first and second indirect aerosol effects. The semi-direct aerosol effects are implicitly included by the coupling of the aerosols and the ECHAM5 radiation scheme.

2.4. The ocean GCM MPI-OM

The ocean GCM MPI-OM (Marsland et al., 2003) is based on the primitive equations for a hydrostatic Boussinesq fluid with a free surface. The bottom topography is resolved

³Dentener, F., Wilson, J., Marelli, L., Putaud, J.-P., Bond, T., Hoelzemann, J., Kinne, S., Generoso, S., Textor, C., Schulz, M., van der Werf, G., Gong, S., Ginoux, P., Cofala, J., Boucher, O., Ito, A., and Penner, J.: AEROCOM – aerosol emission data-sets recommendations for years 2000 and 1750, Atmos. Chem. Phys. Discuss., submitted, 2005; data available from <ftp://ftp.ei.jrc.it/pub/Aerocom/>.

by means of partial grid cells. The poles of the curvilinear grid are shifted to land areas over Greenland and Antarctica. Parameterised processes include along-isopycnal diffusion, horizontal tracer mixing by advection with unresolved eddies, vertical eddy mixing, near-surface wind stirring, convective overturning, and slope convection. Concentration and thickness of sea ice are calculated by means of a dynamic and thermodynamic sea ice model. In the coupled AOGCM setup (Jungclaus et al., 2005), the ocean passes to the atmosphere the sea surface temperature, sea ice concentration, sea ice thickness, snow depth on ice, and the ocean surface velocities. Using these boundary values, the atmosphere model accumulates the forcing fluxes during the coupling time step of one day. The daily mean fluxes are then passed to the ocean. A horizontal resolution of 1.5° and a vertical discretisation on 40 Z-levels is applied in the coupled model setup. No flux adjustment is employed.

2.5. The ocean biogeochemistry module HAMOCC5

The Hamburg oceanic carbon cycle model (Maier-Reimer et al., 2005) is coupled online to the circulation and diffusion of the MPI-OM. The embedded ecosystem model is based on nutrients, phytoplankton, zooplankton, and detritus (NPZD-type), as described by Six and Maier-Reimer (1996). In addition, new elements such as nitrogen, dissolved iron, and dust are accounted for and new processes like denitrification and nitrogen-fixation, formation of calcium carbonate and opaline shells, DMS production and consumption processes, dissolved iron uptake and release by biogenic particles, as well as dust deposition and sinking are implemented. Iron is released into the ocean surface from the dust deposition flux of the HAM aerosol module, assuming a dust iron content of 3.5%. The DMS production is parameterised in terms of the degradation of phytoplankton by senescence and grazing processes. DMS sink processes are consumption by bacteria, chemical oxidation, and the flux to the atmosphere, passed as emission flux to the aerosol module HAM.

2.6. Simulation setup

The experimental design follows the standard procedure in coupled atmosphere-ocean climate simulations. From a pre-industrial control experiment “20th century” integrations are started and complemented from the year 2000 on by a future scenario simulation based on SRES A1B. Two 20th century ensemble realisations have been performed. Here we present results for 1860 to 2000 from the first realization together with the 2001 to 2100 A1B scenario run that was initialised from the second realisation.

In the control simulation, the concentrations of well-mixed greenhouse gases are fixed at their 1860 values ($\text{CO}_2=286.2$ ppmv, $\text{CH}_4=805.6$ ppbv, $\text{N}_2\text{O}=276.7$ pptv, $\text{CFC-11}^*=12.5$ pptv; $\text{CFC-12}=0.$, where CFC-11^* accounts for the radiative effect of minor species, including a small contribution from natural sources) and ozone is prescribed as in ECHAM5 (Roeckner et al., 2003).

The 20th century run is initialised from a balanced state of the control run. Well-mixed greenhouse gases are prescribed annually according to observations (smoothly fitted to ice core data, direct observations, and SRES values for the year 2000). Monthly stratospheric and tropospheric ozone concentrations are prescribed as two-dimensional (latitude, height) distributions (Kiehl et al., 1999). Optical depths of volcanic aerosols above the tropopause level are prescribed annually in four latitude bands based on an updated dataset (<http://www.giss.nasa.gov/data/strataer/>) of Sato et al. (1993). Variations in solar irradiance are specified according to Solanki and Krivova (2003).

We periodically apply monthly mean year 2000 offline oxidant fields (OH , H_2O_2 , NO_2 , O_3) for the sulfur chemistry scheme, as used in Stier et al. (2005a). Pham et al. (2005) investigated the effect of changes in the oxidation fields from 2000 to 2100 on the global sulfate distribution based on the SRES A2 scenario. They showed that the effect on the global mean sulfate burden is less than 1% and on regional surface concentrations about 5%, justifying this simplification.

tion, domestic fuel-wood consumption, agricultural waste burning, and forest fires are prescribed based on the Japanese National Institute for Environmental Studies (NIES) emission inventory for the SRES A1B scenario (T. Nozawa et al., personal communication, 2004). We derived emissions of SO₂ from vegetation fire sources and of POM from the BC emissions by assuming source specific emission ratios: SO₂/BC=1.28, POM/BC of 1.4 (fossil fuel), 5.6 (domestic and agricultural), and 11 (vegetation fires) (F. Dentener, personal communication). The fossil fuel emissions of SO₂ and BC are prescribed annually, whilst BC emissions from vegetation fires, domestic fuel-wood consumption, and agricultural waste burning are prescribed monthly. It has to be pointed out that even for present day emission inventories, based on largely well determined fuel use data, significant uncertainties exist. These uncertainties are particularly large for the carbonaceous compounds so that present day inventories differ by as much as a factor of two for fossil fuel use (e.g. Schaap et al., 2004) and are even more uncertain for biomass burning emissions. These uncertainties propagate into the future emission scenarios and further add to their uncertainties regarding population, technological, and legislative developments.

3. Results

3.1. Emissions

The global annual total aerosol and aerosol precursor emissions from 1860 to 2100 are displayed in Fig. 1. Emissions of SO₂, dominated by fossil fuel use, peak with 120 Tg around year 2020 and decrease to 45 Tg in the year 2100. Contrary, dominated by the contribution from vegetation fires, the POM emissions peak with about 190 Tg in the year 2050 and decrease to values around 160 Tg in the year 2100. As the contribution from fossil fuels is projected to increase up to the year 2080, the BC emissions show a lagged peak reaching values of 30 Tg around year 2070 and only a small decrease to the year 2100.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

The trends of the interactively calculated natural emissions are significantly smaller as distinct trends can only be expected as result of significant alterations of the climatological state. The inter-annual variability is analysed in terms of the normalised standard deviation $\sigma^{\text{norm}} = \sigma(E)/\bar{E}$, where E is the annual emission flux and the overbar denotes the integration-period mean.

Although the global annual mean wind speed increases (*not shown*), the wind-driven emissions of DMS constantly decrease, in total by about 10% from the years 1860 to 2100. This reduction can be attributed an enhanced stratification of the oceanic mixed layer in a warmer climate and will be discussed in an accompanying publication (K2005²). The inter-annual variability lies at $\sigma^{\text{norm}} = 0.04$. The sea salt emissions show no significant trend throughout the simulation period and a small inter-annual variability ($\sigma^{\text{norm}} = 0.01$). Mineral dust emissions, however, show a distinct inter-annual variability ($\sigma^{\text{norm}} = 0.09$) and an increase of about 10% towards the end of the integration period. It has to be pointed out that the dust emissions are calculated assuming fixed preferential source areas and year 2000 vegetation cover. Therefore, the simulated century scale variability is likely to be a lower estimate.

The evolution of the global distribution of the emissions of sulfur, black carbon, and particulate organic matter is illustrated in Fig. 2. Shown are the totals and distribution of the global annual aerosol and precursor emissions averaged over 30-year periods. It is clearly discernible that from the 1861–1890 to the 1961–1990 period the dominant emission increase took place at the east coast of the US, in Central Europe and also in China. Contrary, from 1961–1990 to 2021–2050 the US and European emissions are projected to decrease and significant enhancements are expected in the low latitude regions South America, Central and South Africa, and South Asia.

3.2. Atmospheric aerosol burdens

The changes in the atmospheric emissions are reflected in the atmospheric aerosol column burdens, shown as totals and global distribution for sulfate, black carbon, and particulate organic matter as 30-year averages for the periods 1861–1890, 1961–1990,

**Transient evolution of
the global aerosol
system from 1860 to
2100**P. Stier et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

and 2021–2050 in Fig. 3. Resembling the emission changes, the SU aerosol burden increases particularly in the northern hemispheric source regions from the 1861–1890 to the 1961–1990 period. With increasing emissions also the export from the sources regions increases, particularly from Europe to the Mediterranean and northern Africa.

To the 2021–2050 period, the high latitude emissions are projected to decrease and high values of the burden are largely confined to low latitude regions. For BC and POM the contribution of the low-latitude emissions increases throughout the integration period. With decreasing high-latitude BC and POM emissions from 1961–1990 to 2021–2050, the low-latitude atmospheric aerosol burden is projected to dominate for the future conditions.

The temporal evolution of the atmospheric aerosol burden is shown as total and separated for four equal area latitude bands in Fig. 4. As the aerosol residence-time is short, aerosols do not accumulate and the trends in the global annual mean aerosol burdens to a first order resemble the trends in the aerosol emissions with a peak of the SU aerosol burden centred around the year 2020, maximum values of POM burden around 2050, and a maximum of BC around 2070. Most prominently for BC and POM, but to a minor degree also for SU, the dominant aerosol increase occurs at low latitudes. This can be attributed to the fact that a significant part of the projected emission increase is from tropical vegetation fires and from increased fossil fuel usage in developing countries. For sea salt the total aerosol burden and meridional distribution shows only minor variations. The increase in the dust burden, discernible from the year 2000 onwards, is most pronounced in the 0° to 30° N band. A more detailed analysis (*not shown*) reveals that the dominant changes in the dust emissions occur in the northern African source regions with a decrease in the central-north African source regions, including the Bodele Depression, and an increase in the Saharan north-western African source regions. The decrease in dust emissions in central-north Africa can be attributed to an increase in soil moisture and reduced surface windspeeds. Contrary, the increased emission in the north-western Saharan source regions are a consequence of increased surface wind speeds. These changes of the regional climatological con-

ditions can partly be attributed to an alteration of the monsoon regimes owing to an increase in atmospheric absorption due to increased carbonaceous emissions from vegetation fires (see R2005).

3.3. Atmospheric residence-times

5 As many greenhouse gases have long and approximately constant atmospheric residence-times, the discussion about pollutant mitigation is generally expressed in terms of emission scenarios, implicitly assuming that the atmospheric burden is directly linked to the global total amount of emissions. For the short lived aerosols, however, the atmospheric residence-time (τ) is not necessarily constant and depends on
10 the time and point of emission, chemical, thermodynamical and microphysical transformations (“aging”), and on the meteorological conditions along the aerosol trajectories (Graf et al., 1997; Barth and Church, 1999; Stier et al., 2005b). Figure 5 shows the evolution of the component residence-times throughout the integration period. It is clearly discernible that the residence-time shows non-negligible variations for all components. The interpretation of this complex evolution of the atmospheric residence-times involves a number of competing processes and interactions.

For SU, τ decreases from about 4.5 days at pre-industrial times to about 4 days around 1950. Thereafter, in particular with the distinct shift to low-latitude source regions after 2025 and high burdens in the arid subtropical regions (Figs. 2, 3, 4), τ
20 increases, reaching about 5.5 days around 2050, and remains relatively stable afterwards.

For BC, τ decreases from 6.5 days in 1860 to around 5 days in 1960 and increases thereafter to to 8 days in 2100. The initial decrease in the residence-time is contradictory to the increasing importance of low latitude emissions (c.f. Figs. 2, 4). However,
25 for the initially emitted insoluble BC microphysical aging processes play an important role. From Fig. 6, depicting the evolution of the microphysical aging-time, i.e. the timescale of transformation from the insoluble to the soluble modes (see Stier et al., 2005a), it becomes evident that the BC aging-time is approximately halved from 1860

system from 1860 to
2100**

P. Stier et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

to 1950. As a consequence, the mass fraction of BC residing in the efficiently scavenged internally-mixed accumulation mode soluble increases (Fig. 7), explaining the initial decrease in the BC residence-time. From about 1960 onwards, the increase in the residence-time indicates that the further enhanced aging to the peak of the sulfate burden in 2020 is outweighed by the shift to low latitude emissions, with a large contribution of dry-season vegetation fire emissions.

For POM, after a slow increase from about 4.5 days in 1860 to 5.5 days around 1960, τ increases more rapidly to 8.5 days in the year 2100, closely tracking the evolution for BC. This is a result of the increasing relative importance of the low-latitude dry-season vegetation fire emissions, from which BC and POM are co-emitted.

Interestingly, the residence-time of SS also increases by about 6% from 1860 to 2100. Changes in the surface winds, with a poleward shift of the mid-latitude tropospheric westerlies (see R2005) cause a poleward shift of the SS emissions. This shift is particularly pronounced in the southern latitudes. Associated is a small but continuous shift of the sinks from wet deposition to turbulent dry deposition and sedimentation (*not shown*). As the high latitude regions are dominated by ice clouds with a slightly reduced scavenging efficiency (c.f. Stier et al., 2005a) this could explain the increase in the SS residence-time.

For DU, τ increases from 2000 to 2100 continuously from about 5 to 6 days. This is caused by the north-western shift of the dominant African sources into more arid regions and supported by an associated shift of the sinks from wet deposition to sedimentation. The enhanced microphysical aging under more polluted conditions, indicated by decreased aging-times (Fig. 6) and the associated enhanced mass fraction in the soluble coarse mode (Fig. 7), that potentially reduces τ appears to be a second order effect. Nonetheless, it could explain the relative stable residence-times from 1860 to 2000 and the enhanced increase after the peak of the sulfate burden in 2020.

A number of aerosol parameters, such as the mixing-state, are fixedly imposed in the mass based bulk modelling approach applied in traditional global aerosol models. However, the observed large internally-mixed aerosol population is a clear indicator

that the mixing state is not constant for different levels of emissions and therefore not under different climatic regimes. The application of the microphysical aerosol module in a transient climate simulation allows to investigate the evolution of previously imposed parameters from prognostic variables.

5 The evolution of the global mean aerosol component mass partitioning among the seven aerosol modes of HAM (Table 1) from 1860–2100 is shown in Fig. 7. For the anthropogenically relevant species SU, BC, and POM it is evident that under the higher polluted conditions their mass shifts from the Aitken modes to the radiatively important accumulation mode. For DU, a larger mass fraction is aged to the soluble modes under
10 more polluted conditions, consistent with the evolution of the microphysical aging-time shown in Fig. 6. The soluble mass fraction of DU decreases with the decay of the SU and POM burdens.

The disproportionate emission changes of the different aerosol components and precursors (Sect. 3.1) imply alterations of the composition of internally mixed modes. The
15 simulated evolution of the composition of the internally mixed modes of HAM is displayed in Fig. 8. Sulfate is, with a relatively constant mass-fraction of 90%, the dominant component of the soluble Aitken mode from 1860 to around 2020. Thereafter, the sulfate fraction decreases to 80% in 2100 as the carbonaceous contribution increases. For the Aitken mode insoluble, the mass fraction of POM gradually decreases from
20 90% in 1860 to 70% in 2100, balanced by an increase in BC. This is largely a consequence of the increasing emission ratio of BC to POM. For the coarse mode soluble the mass fraction of DU increases from about 35% to 45% balanced by a decrease in sea salt, attributable to enhanced microphysical aging of dust and a relative increase in the total DU burden.

25 The evolution of the radiatively important internally-mixed accumulation mode soluble is more complex. With the increase in the anthropogenic emissions, the contributions of the natural components DU and SS are reduced from about 35% in 1860 to 10% in the year 2020. The increase in the sulfate mass is outweighed by the increase in carbonaceous aerosols, particularly POM, so that the mass fraction of sulfate de-

Transient evolution of the global aerosol system from 1860 to 2100

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

creases constantly. This decrease is enhanced after the sulfate peak in the year 2020 so that POM becomes the dominant component in the accumulation mode soluble after 2050. The mass fraction of BC increases constantly from 0% in 1860 to around 7% in 2100.

5 These changes in the composition of the internally mixed modes, with a relative increase in the carbonaceous aerosols, have distinct effects on their interactively calculated radiative properties. Here we focus on the internally-mixed accumulation mode soluble as it dominates the anthropogenic contribution to the aerosol radiative effects. The effect of the increasing importance of the carbonaceous aerosols is nicely demonstrated by the evolution of the global mean optical depth weighted co-single scattering
10 albedo (CO-SSA) at a wavelength of 550 nm depicted in Fig. 9. The CO-SSA, as a measure of the absorption efficiency, increases constantly from 0.02 in 1860 to 0.04 in 2020. This is a consequence of the increase in the carbonaceous mass fraction, particularly of BC, with higher imaginary parts of the refractive indices (see Stier et al.,
15 2005a). With the decline of the projected sulfate emissions in 2020 the increase in the CO-SSA is further enhanced, reaching a plateau of more than 0.07 in the year 2070.

In summary, the projected changes in the aerosol emissions distinctively affect the aerosol mixing-state and the composition of the internally mixed modes on the global scale. Consequently, their radiative properties are altered with a significant enhance-
20 ment of the absorption efficiency, owing to the increased contribution of carbonaceous aerosols throughout the integration period.

Changes in the atmospheric aerosol burden and composition affect the aerosol optical depth (AOD), i.e. the column integrated aerosol extinction. The evolution of the global mean total tropospheric aerosol optical depth, fine mode optical depth (Aitken and accumulation modes), coarse mode optical depth, and the absorption optical depth
25 at 550 nm is shown in Fig. 10. Total AOD increases from a pre-industrial level of 0.15 to 0.26 in year 2020. The relatively high pre-industrial levels of AOD are largely attributable to higher dust emissions in the free climate mode applied in the coupled model setup compared to the nudging mode applied in Stier et al. (2005a). See Timm-

reck and Schulz (2004) for more details. However, the impact on the anthropogenic aerosol effects can be assumed small, as indicated by the small anthropogenic component mass fractions in the coarse modes, dominating the dust contribution. The decrease in the SU contribution after 2020 is partly compensated by the increase in POM so that AOD decreases only weakly and levels off to 0.23 in the year 2100. It is interesting to note that the dominant increase in total AOD can be attributed to an increase in the fine mode AOD confirming the assumption that anthropogenic aerosols predominantly affect the fine mode aerosol optical depth. However, these results do not support the reverse, i.e. that the fine mode optical depth is a direct measure of the anthropogenic aerosol radiative effects. In fact, more than a third of the simulated fine mode optical depth for the year 2000 is of natural origin, indicated by the values at the beginning of the integration period.

The evolution of the absorption aerosol optical depth (AAOD), i.e. the column integrated aerosol extinction owing to absorption (Fig. 10), shows a distinct increase from pre-industrial levels of around 0.001 and levels off around 0.01 in the year 2070. This increase is dominated by the increase in the fine mode AAOD attributable to the increase in the total BC burden (linear Pearson's correlation coefficient $r=0.999$). The small increase in coarse mode AAOD can be attributed to the increase in the DU burden ($r=0.995$).

The development of the aerosol distribution and radiative properties determines their direct effects on the global radiation balance. Figure 11 shows the evolution of the simulated global mean total aerosol short-wave clear-sky direct radiative perturbation (DARP), together with the prescribed aerosol optical depth owing to volcanic aerosols in the stratosphere. DARP is defined here as the deviation of the clear-sky net short wave radiation at the top of the atmosphere from the 1860–1870 mean. For technical reasons, areas with a change in surface albedo larger than 0.03 as well as sea-ice covered regions are masked out. Superimposed to the anthropogenic trends are distinct DARPs from volcanic eruptions, reaching values of around -4 Wm^{-2} for the major Krakatoa (1883) and Mount Pinatubo (1991) eruptions. With increasing anthro-

pogenic AOD, the negative DARP intensifies, reaches -0.8 Wm^{-2} around 2000, peaks with about -1.1 Wm^{-2} around 2020 and remains relatively stable up to 2050, largely because the continued increase in POM outweighs the decrease in SU after 2020. Although AOD remains at a higher level than in 2000 thereafter, DARP weakens, reaching -0.6 Wm^{-2} in 2100. This can be attributed to an increase in atmospheric absorption owing to the BC increase (Fig. 10). It is interesting to note that the combination of volcanic and anthropogenic aerosol perturbations between about 1950 and 1970 causes a distinct negative DARP of up to -2 Wm^{-2} . This negative radiative perturbation contributes to mask out the effect of increased greenhouse gas emissions on the global temperature. In combination with the stagnation and even reversal of the increase of the solar irradiance after about 1930–1940 (Solanki and Krivova, 2003; Krivova and Solanki, 2004), this explains the well simulated small trend in global surface temperatures between 1950 and 1970 (see Fig. 1 in R2005) despite the increasing positive greenhouse gas forcing.

4. Conclusions

The evolution of the global aerosol system from 1860 to 2100 is investigated through a transient atmosphere-ocean GCM climate simulation with interactively coupled atmospheric aerosol and oceanic biogeochemistry modules. The microphysical aerosol module HAM incorporates the major global aerosol components sulfate, black carbon, particulate organic matter, sea salt, and mineral dust with prognostic treatment of their composition, size-distribution, and mixing state.

The atmosphere and ocean GCMs are coupled interactively, employing no flux correction. In addition, also the atmospheric and oceanic biogeochemical cycles are coupled interactively by accounting for the deposition of mineral dust acting as micronutrient for a prognostic ocean biogeochemistry scheme and by emitting biogeochemically produced DMS from the ocean surface to the atmosphere. Also the natural emissions of mineral dust and sea salt are calculated interactively. Anthropogenic aerosol

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

and precursor emissions are prescribed based on the Japanese National Institute for Environmental Studies emission inventory from 1860 to 2100. From pre-industrial to present day times greenhouse gases, volcanic stratospheric AOD, and solar variability are prescribed according to observations. For the 2000 to 2100 period, greenhouse gas concentrations as well as aerosol and precursor emissions are based on the SRES A1B scenario.

From pre-industrial times to 2020 the global mean sulfate aerosol burden is projected to increase from 0.4 Tg(S) to 1.3 Tg(S) and thereafter to decrease to 0.8 Tg(S) in 2100. Aerosol burdens of BC and POM are increasing up to around 2070 peaking with burdens of 0.7 Tg and 4 Tg and show a small decrease thereafter. The burdens of natural sea salt and mineral dust also increase, however at a significantly slower rate. It has to be pointed out that the variability and the trend in the emissions of mineral dust and natural secondary organics represents a lower estimate due to the assumption of a fixed vegetation cover and the neglect of climate-vegetation feedbacks.

Regionally, the prognosed emissions and consequently the simulated aerosol burden show inhomogeneous trends. From present day to future conditions the anthropogenic aerosol burden shifts generally from the northern high-latitudes to the developing low-latitude source regions. The resulting spatially inhomogeneous radiative perturbations are a driving force for regional climate change.

The projected increase in low-latitude carbonaceous aerosols and the associated increase in the atmospheric absorption cause an enhancement of local monsoon regimes, particularly pronounced over Central Africa (see R2005). The associated changes in the flow pattern and the increase in precipitation and soil moisture shifts emission regimes and the atmospheric burden of mineral dust northward. Such couplings of the global aerosol cycles, acting in addition to the coupling by microphysical processes (Stier et al., 2005b), will be further enhanced when climate-vegetation feedbacks are taken into account.

An analysis of atmospheric residence-times reveals significant alterations under varying climatic and pollution condition during the integration period. Thus, the at-

**Transient evolution of

mospheric aerosol burden and therefore the aerosol radiative effects cannot be scaled by global annual mean emission data. The evolution of the aerosol burden is rather the result of complex interactions of aerosol microphysics, formation pathways, the point of emission, and the meteorological conditions along the aerosol trajectories. For example, a given sulfate radiative perturbation in the year 2000, scaled to the year 2100 by the change of SO₂ emissions, would be biased low by a factor of $\tau^{2000}/\tau^{2100} = 4.3 \text{ days}/5.6 \text{ days} = 0.8$ solely due to the neglect of the longer residence-time in 2100 (assuming constant sulfate yield from SO₂ emissions and constant aerosol radiative properties).

In previous climate simulations, the microphysical aging-time of BC, POM, and DU, if considered, has been prescribed as constant. Here we show that it varies by as much as a factor of two during the integration, with enhanced aging under polluted conditions, peaking around the year 2020.

The projected inhomogeneous changes in the aerosol and precursor emissions distinctively affect the aerosol mixing-state and the composition of the internally mixed modes. With increasing levels of anthropogenic pollution, the fraction of SU, BC, and POM residing in the radiatively important internally mixed accumulation mode increases, owing to enhanced microphysical interactions. Under the predicted emission changes, the global mean composition of the internally mixed accumulation mode is altered with a steady increase in the contribution of carbonaceous aerosols. These composition changes are reflected in the aerosol radiative properties. The increasing fraction of carbonaceous aerosols in the internally-mixed accumulation mode causes a more than threefold increase in its co-single scattering albedo, and therefore absorption efficiency, from 1860 to 2100. These findings are in contradiction to the traditional approach of assuming constant radiative properties for each internally mixed mode. They further indicate that the aerosol radiative effects are altered by microphysical interactions of the different aerosol cycles.

The simulated AOD at 550 nm increases from 0.15 at pre-industrial times to 0.26 around the pollution peak in 2020. Despite the significant reduction of sulfate there-

after, AOD shows only a weak decrease as the continuing increase in carbonaceous aerosol is compensating. The anthropogenic enhancement of AOD is attributable to an increase in fine mode AOD. However, more than a third of the simulated global mean fine mode optical depth of the year 2000 is already present under natural conditions, contradicting the assumption that all fine mode AOD is attributable to anthropogenic activities. This introduces a significant uncertainty to remote sensing derived estimates of the anthropogenic contribution to the aerosol radiative effects. An integrated approach is required, combining the strengths of remote sensing and global modelling, to reduce the remaining large uncertainties.

The simulated anthropogenic top of the atmosphere clear-sky short-wave direct aerosol radiative perturbation intensifies from pre-industrial times, reaching about -1.1 Wm^{-2} around 2020. Although AOD remains at a relative high level after 2050, DARP weakens to -0.6 Wm^{-2} , attributable to an increase in atmospheric absorption owing to the continued increase in the BC burden. The onset of the anthropogenic negative DARP in combination with increasing volcanic activity between about 1950 and 1970 contribute to the well simulated observed small trend in global surface temperatures during that period, despite increasing greenhouse gas forcing.

To recapitulate, our results from a transient coupled AOGCM climate simulation from 1860 to 2100 with an embedded microphysical aerosol module show distinct alterations of the aerosol system on global and regional scales over the integration period. Aerosol residence-times, aging-times, size, composition, and mixing-state undergo non-negligible variations. As a consequence, their radiative properties and effects and ultimately their climatic impact cannot be estimated solely based on changes of the global mean emissions.

Large uncertainties, in particular with respect to the future evolution of the aerosol system remain. Aerosol emission inventories even for present day conditions, based on largely well determined fuel use data, are highly uncertain, particularly for the carbonaceous compounds. These uncertainties propagate into the future emission scenarios and add to their large uncertainties regarding population, technological, and legislative

developments. So one key outcome of this study are the demonstrated modifications of aerosol parameters that have previously been assumed constant – under one possible realisation of greenhouse gas, aerosol, and aerosol precursor emissions.

Additional feedbacks of the aerosol cycles with other compartments of the earth system, such as aerosol effects on vegetation via fertilisation and solar dimming, the effect of changing vegetation on the surface emissions of dust and organic matter, as well as feedbacks with the atmospheric chemistry are also likely to affect the evolution of the aerosol system and will be subject of future research activities.

Acknowledgements. This research was supported by the German Ministry for Education and Research (BMBF) under the DEKLIM Project and by the European Community under the ENSEMBLES Project. The simulations were performed on the NEC SX-6 supercomputer of the German High Performance Computing Centre for Climate- and Earth System Research in Hamburg. Review comments by S. Kinne and D. Banse greatly improved this manuscript. We would also like to thank I. Fischer-Bruns for helpful discussions and M. Werner (MPI-Biogeochemistry, Jena) for his support with the dust source. The continuous support of our colleagues L. Kornblueh, U. Schulzweida, U. Schlese, and R. Brokopf was greatly appreciated.

Transient evolution of the global aerosol system from 1860 to 2100

P. Stier et al.

Table 1. The modal structure of HAM. N_i denotes the aerosol number of the mode i and M_i^j denotes the mass of compound $j \in \{SU, BC, POM, SS, DU\}$ in mode i . The ranges for the number median radius \bar{r} give the respective mode boundaries (c.f. [Stier et al., 2005a](#)).

Modes \bar{r} [μm]	Soluble/Mixed	Insoluble
Nucleation $\bar{r} \leq 0.005$	N_1, M_1^{SU}	
Aitken $0.005 < \bar{r} \leq 0.05$	$N_2, M_2^{SU}, M_2^{BC}, M_2^{POM}$	N_5, M_5^{BC}, M_5^{POM}
Accumulation $0.05 < \bar{r} \leq 0.5$	$N_3, M_3^{SU}, M_3^{BC}, M_3^{POM}, M_3^{SS}, M_3^{DU}$	N_6, M_6^{DU}
Coarse $0.5 < \bar{r}$	$N_4, M_4^{SU}, M_4^{BC}, M_4^{POM}, M_4^{SS}, M_4^{DU}$	N_7, M_7^{DU}
