# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

#### **Abstract**

Observations of peroxynitric acid (HO<sub>2</sub>NO<sub>2</sub>) obtained simultaneously with those of NO and NO<sub>2</sub> provide a sensitive measure of the ozone photochemical production rate. We illustrate this technique for constraining the ozone production rate with observations obtained from the NCAR C-130 aircraft platform during the Megacity Initiative: Local and Global Research Observations (MILAGRO) intensive in Mexico during the spring of 2006. Sensitive and selective measurements of HO<sub>2</sub>NO<sub>2</sub> were made in situ using chemical ionization mass spectrometry (CIMS). Observations were compared to modeled HO<sub>2</sub>NO<sub>2</sub> concentrations obtained from the NASA Langley highly-constrained photochemical time-dependent box model. The median observed-to-calculated ratio of HO<sub>2</sub>NO<sub>2</sub> is 1.18. At NO<sub>x</sub> levels greater than 15 ppbv, the photochemical box model underpredicts observations with an observed-to-calculated ratio of HO<sub>2</sub>NO<sub>2</sub> of 1.57. As a result, we find that at high NO<sub>x</sub>, the ozone production rate calculated using measured HO<sub>2</sub>NO<sub>2</sub> is faster than predicted using accepted photochemistry. Inclusion of an additional HO<sub>2</sub> source from the reaction of excited state NO<sub>2</sub> with H<sub>2</sub>O or reduction in the rate constant of the reaction of OH with NO<sub>2</sub> improves the agreement.

#### Introduction

Peroxynitric acid, HO<sub>2</sub>NO<sub>2</sub>, is an important reservoir of both HO<sub>x</sub> (HO<sub>x</sub>=OH+HO<sub>2</sub>) and NO<sub>x</sub> (NO<sub>x</sub>=NO+NO<sub>2</sub>) radicals. These radicals are of primary atmospheric importance as they influence the production and degradation of tropospheric ozone and numerous volatile organic compounds (Murphy et al., 2004). Ozone production in urban environments is initiated by OH radicals and requires sunlight, NO<sub>v</sub>, and hydrocarbons. The relative amounts of these species control the rate of ozone production (Seinfeld and Pandis, 2006).

The only known pathway for the formation of HO<sub>2</sub>NO<sub>2</sub> in the atmosphere is the association reaction of HO<sub>2</sub> and NO<sub>2</sub>, R1 (Niki et al., 1977). HO<sub>2</sub>NO<sub>2</sub> is lost via thermal

decomposition, R-1 (Graham et al., 1977, 1978; Zabel et al., 1995; Gierczak et al., 2005); UV and visible/near-IR photolysis, R2 (Macleod et al., 1988; Roehl et al., 2002; Knight et al., 2002); and reaction with the OH radical, R3 (Trevor et al., 1982; Smith et al., 1984; Barnes et al., 1986; Jimenez et al., 2004).

$$_{5} HO_{2} + NO_{2} + M \rightleftharpoons HO_{2}NO_{2} + M \tag{R1}$$

$$HO_2NO_2 + h\nu \rightarrow \text{products}$$
 (R2)

$$HO_2NO_2 + OH \rightarrow H_2O + NO_2 + O_2$$
 (R3)

The relative importance of the HO<sub>2</sub>NO<sub>2</sub> sinks depends on temperature, pressure, OH radical concentration, and the UV/IR radiation field. The lifetime of HO<sub>2</sub>NO<sub>2</sub> with respect to thermal decomposition varies due to the strong temperature dependence of this process (Kim et al., 2007). As temperature decreases, loss due to photolysis and reaction with OH radical become increasingly important. At altitudes greater than 7 km, photolysis and reaction with OH become the dominant loss mechanisms (Roehl et al., 2002). The formation of HO<sub>2</sub>NO<sub>2</sub> followed by its loss via reaction with OH forms a NO<sub>x</sub>-catalyzed sink of HO<sub>x</sub> radicals (Roehl et al., 2002).

The role of HO<sub>2</sub>NO<sub>2</sub> in photochemistry of the lower troposphere has been less explored, in part because of a paucity of observations of this compound. In situ measurements of HO<sub>2</sub>NO<sub>2</sub> have been obtained previously in the free troposphere during the 2004 INTEX-NA campaign (Kim et al., 2007) and in Antarctica (Slusher et al., 2001). An indirect estimate of the HO<sub>2</sub>NO<sub>2</sub> abundance was obtained from the sum of peroxynitrate observations during the 2000 TOPSE campaign (Murphy et al., 2004).

Here, we present in situ measurements of HO<sub>2</sub>NO<sub>2</sub> in and around Mexico City. These measurements were made in March of 2006 from the NCAR C-130 aircraft platform during the MILAGRO field experiment. One goal of the MILAGRO mission, and the focus of the C-130 flights, was to investigate the processing and outflow of pollution from Mexico City. Most flights occurred during the daytime hours at altitudes below 7 km and temperatures between 250 and 300 K. This study is limited to six of the

MILAGRO flights (8, 22, 23, 26, 28, and 29 March) during which all necessary species were measured. A photochemical steady-state approximation of HO<sub>2</sub>NO<sub>2</sub> under MILA-GRO conditions is discussed, and measured HO<sub>2</sub>NO<sub>2</sub> concentrations are compared to those predicted by the NASA Langley Research Center LaRC highly-constrained photochemical time-dependent box model (NASA LaRC box model). A simplified method of estimating the rate of ozone production using HO<sub>2</sub>NO<sub>2</sub> is compared to full NASA LaRC box model calculations of the rate of ozone production.

#### Method

#### Instrumentation 2.1

NO and NO<sub>2</sub> mixing ratios were measured by photofragmentation/chemiluminescence. The overall uncertainty for these measurements is 10-20% (Campos et al., 1998; Weinheimer et al., 1998). HO<sub>2</sub> mixing ratios were determined by chemicalconversion/chemical ionization mass spectroscopy with an uncertainty of 35% (Cantrell et al., 2003). H<sub>2</sub>O mixing ratios were measured using a dew/frost point water hygrometer.

HO<sub>2</sub>NO<sub>2</sub> measurements were made using the Caltech chemical ionization mass spectrometry (CIMS) instrument. The instrument has been described in detail previously by Crounse et al. (2006). Briefly, the Caltech CIMS consists of a flow tube controlled at 35 mbar total pressure where a reagent ion, CF<sub>3</sub>O<sup>-</sup>, interacts with ambient air diluted 1:4 with dry nitrogen. Ions are sampled from the flow tube into a quadrupole mass filter and detected with a channel electron multipler. Each mass-to-charge ratio is observed for ~0.5 s. HO<sub>2</sub>NO<sub>2</sub> masses were monitored every ~15 s.

Negative ion chemistry of CF<sub>2</sub>O<sup>-</sup> has been shown to provide sensitive and selective detection of many inorganic and organic acids (Huey et al., 1996; Amelynck et al., 2000a,b; Crounse et al., 2006) and was exploited in this work to detect HO<sub>2</sub>NO<sub>2</sub>. The reaction of CF<sub>3</sub>O<sup>-</sup> with acids follows several pathways. Reaction with strong acids

proceeds via fluoride ion transfer (Huey et al., 1996) while reaction with weaker acids yields clusters of reagent ion and analyte (Amelynck et al., 2000a). HO<sub>2</sub>NO<sub>2</sub> reacts with CF<sub>3</sub>O<sup>-</sup> via fluoride ion transfer (R4), clustering (R5) (Crounse et al., 2006), and a HF elimination Reaction (R6), providing three distinct ion signals. Reactions (4–6) are complicated by competing reactions with CF<sub>3</sub>O<sup>-</sup> water cluster (CF<sub>3</sub>O<sup>-</sup> · H<sub>2</sub>O).

$$CF_3O^- + HO_2NO_2 \rightarrow HF \cdot OONO_2^- (m/z 98) + CF_2O$$
 (R4)

$$CF_3O^- + HO_2NO_2 \rightarrow CF_3O^- \cdot HO_2NO_2(m/z \ 164)$$
 (R5)

$$CF_3O^- + HO_2NO_2 \rightarrow CF_2O \cdot OONO_2^- (m/z 144) + HF$$
 (R6)

### 2.1.1 Sensitivity and calibration

Due to differences in reactivity of  $CF_3O^-$  and its water cluster, the sensitivity of the CIMS instrument to the ion products of the three channels (R4, R5, R6) is dependent on the mixing ratio of water vapor in the flow tube (Crounse et al., 2006). This dependence is quantified via laboratory measurements. A small quantity of  $HO_2NO_2$  was introduced into the flow tube. The flow tube humidity was controlled using mass flow controllers to adjust the ratio of air saturated with water vapor to dry zero air. Humidity was quantified by Fourier Transform Infrared (FTIR) spectroscopy using HITRAN line lists (Rothman et al., 2005) and the commercial spectral manipulation software package GRAMS (Galactic Industries Inc.). The sensitivity of the instrument to the fluoride ion transfer and cluster channels of  $HO_2NO_2$  as a function of  $H_2O$  mixing ratio in the flow tube was determined and is presented in Fig. 1. Sensitivity is expressed in ion counts, normalized by the ion counts of the +1 isotopes of the reagent ions,  $^{13}CF_3O^-$  and  $^{13}CF_3O^- \cdot H_2O$ , per pptv of  $HO_2NO_2$ . The yield of R6 is typically one-third that of R5. Due to the low reaction yield, R6 is not used to quantify the ambient observations of  $HO_2NO_2$ .

During calibration, the concentration of  $HO_2NO_2$  in the flow tube was determined by thermally decomposing the  $HO_2NO_2$  into  $NO_2$  (R-1) and quantifying the resultant  $NO_2$  2796

using CIMS with SF<sub>6</sub> as the reagent ion (R7) (Huey et al., 1995):

$$SF_6^- + NO_2 \rightarrow SF_6 + NO_2^- \ (m/z \ 46)$$
 (R7)

NO<sub>2</sub> is not detected with high sensitivity using CF<sub>3</sub>O<sup>-</sup>.

Synthesis of HO<sub>2</sub>NO<sub>2</sub> was performed offline using the procedure described in Roehl <sub>5</sub> et al. (2002); gas-phase HO<sub>2</sub>NO<sub>2</sub> was produced by flowing dry N<sub>2</sub> over the solution of HO<sub>2</sub>NO<sub>2</sub>. A small portion of this flow was directed through a critical orifice into a PTFE three-way valve which directed the flow through either a heated or unheated glass inlet tube (6 mm OD). The heated inlet tube was kept at 190°C, a temperature at which 99.8% of the HO<sub>2</sub>NO<sub>2</sub> decomposed, as determined by monitoring the signal with CF<sub>3</sub>O<sup>-</sup> at m/z 98. The unheated inlet was maintained at room temperature. The sensitivity of the CIMS to NO<sub>2</sub> was determined using a dilute mixture of NO<sub>2</sub> in N<sub>2</sub>; the concentration of NO<sub>2</sub> in this mixture was quantified with FTIR using HITRAN line lists (Rothman et al., 2005) and the commercial spectral manipulation software package GRAMS (Galactic Industries Inc.).

The CIMS sensitivity to HO<sub>2</sub>NO<sub>2</sub> was determined by back-to-back measurements of the products of R4, R5, and R7. HO<sub>2</sub>NO<sub>2</sub> was added through the room temperature inlet and measured using  $CF_3O^-$  as the reagent ion. Next,  $HO_2NO_2$  was added through the heated inlet and NO<sub>2</sub> was measured using SF<sub>6</sub> as the reagent ion (R7). Background NO<sub>2</sub> from NO<sub>2</sub> impurity in the HO<sub>2</sub>NO<sub>2</sub> solution was measured using SF<sub>6</sub> by passing the HO<sub>2</sub>NO<sub>2</sub> through the room temperature inlet; this background signal was subtracted from the NO2 signal when the heated inlet was used. The signals from R4 and R5 obtained using the room temperature inlet were also corrected for the small amount of HO<sub>2</sub>NO<sub>2</sub> that did not dissociate in the heated inlet and other backgrounds (see below) by monitoring those masses using CF<sub>3</sub>O<sup>-</sup> as the reagent ion with the heated inlet in use. This procedure was repeated at a number of humidities to obtain water-dependent calibration functions for each ion product. Post-mission laboratory calibrations for HO<sub>2</sub>NO<sub>2</sub> were conducted. During flight, isotopically labeled HNO<sub>3</sub> was periodically added to the flow tube to monitor the stability of the instrument sensitiv-

ity. Sensitivity of the instrument to HNO<sub>3</sub> was consistent and comparable during flight and laboratory calibrations indicating the sensitivity of the instrument to HO<sub>2</sub>NO<sub>2</sub> was consistent.

In the absence of HO<sub>2</sub>NO<sub>2</sub>, ion signals at *m/z* 98 and *m/z* 164 are non-zero, and these background signals must be accounted for in the data analysis. These background signals were measured during flight by periodically passing ambient air through a filter consisting of alumina pellets coated with palladium and nylon wool coated with sodium bicarbonate, quantitatively removing HO<sub>2</sub>NO<sub>2</sub>. This technique is described in Crounse et al. (2006).

### 2.1.2 Ambient HO<sub>2</sub>NO<sub>2</sub> concentration

 $HO_2NO_2$  concentrations are calculated from the signals observed at m/z 98 and m/z 164 after normalization by the amount of reagent ion signal, subtraction of background signals, and application of the appropriate sensitivity factor for  $HO_2NO_2$ .

Acetate in the form  $HF \cdot CH_3C(O)O^- \cdot H_2O$  is a known interference in the m/z 98 signal.  $HF \cdot CH_3C(O)O^- \cdot H_2O$  is seen at m/z 97, with approximately 2.5% of the m/z 97 signal appearing at m/z 98 due to heavy isotopes of the ion. Because the m/z 97 signal was not monitored during these flights, the interference at m/z 98 was estimated from the monitored signal of the acetate-fluoride transfer ion ( $HF \cdot CH_3C(O)O^-$ ) at m/z 79 and ambient water levels, using a function derived through post-mission laboratory measurements. There are no interferences of which we are aware at m/z 164. Background signals were measured (as described above) about every 15 min and are used to model background levels during the flight.

A scatter plot of the independent determinations of  $HO_2NO_2$  calculated from the m/z 98 and the m/z 164 signals is shown in Fig. 2. During the flight, there is an ~8 s delay between a m/z 98 measurement and the corresponding m/z 164 measurement. Only observations obtained when the measured  $NO_y$  differs by less than 10% between m/z 98 and m/z 164 sampling times are included in Fig. 2. The slope of the robust fit line (DuMouchel and O'Brien, 1989; Street et al., 1988) is 0.90; intercept is 0.76 pptv;

### **ACPD**

9, 2791-2822, 2009

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

 $R^2$ =0.94. These independent measurements are in good agreement, providing confidence in the use of this ion chemistry to quantify  $HO_2NO_2$ .

The concentration of  $HO_2NO_2$  used in the subsequent analysis is determined by combining the independent measurements from m/z 98 and m/z 164 as follows. When the water mixing ratio in the flow tube is less than or equal to 200 ppmv, the m/z 98 measurement is used because the sensitivity at m/z 164 is low (Fig. 1; recall that the ambient air pulled into the flow tube is diluted 1:4 with dry  $N_2$ ). When the water mixing ratio in the flow tube is between 200 to 500 ppmv, the mean of the m/z 98 and the m/z 164 measurements is used. At water vapor mixing ratios greater than 500 ppmv, the m/z 164 measurement is used exclusively. Although the sensitivity is somewhat lower at m/z 164 than at m/z 98 for water mixing ratios between 500 to 1000 ppmv, higher backgrounds and interference from acetate at m/z 98 make the cluster ion (m/z 164) a more robust measure of  $HO_2NO_2$  than the fluoride transfer product ion (m/z 98) at these higher water mixing ratios.

The uncertainty in the PNA measurements is approximately (30% + 30 pptv). The uncertainty reflects the sum of the precision of the data determined by the counting statistics of the ions, the variability of the background signal, and the uncertainty of the sensitivities shown in Fig. 1.

### 2.2 Photochemical time-dependent box model

Calculated concentrations of  $HO_2$ ,  $NO_2$ , and  $HO_2NO_2$  and rates of ozone production were obtained from a highly-constrained photochemical time-dependent box model (NASA LaRC box model) (Olson et al., 2006). The modeling approach used is based on the assumption of a diurnal equilibrium (Olson et al., 2006, 2004; Frost et al., 2002; Jaegle, 2000). Model inputs include observations of atmospheric parameters such as temperature, pressure, water vapor, and critical long-lived chemical precursor species ( $O_3$ , CO, NO,  $CH_4$ , non-methane hydrocarbons (NMHC), acetone). With the exception of NO and the radiation field, the atmospheric state is held

### **ACPD**

9, 2791-2822, 2009

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

constant throughout the model run. NO varies diurnally; however reactive nitrogen, NO<sub>y</sub>=NO+NO<sub>2</sub>+NO<sub>3</sub>+2N<sub>2</sub>O<sub>5</sub>+HONO+HO<sub>2</sub>NO<sub>2</sub>, is held constant with partitioning as determined by the model. The amount of total reactive nitrogen is determined so that NO matches the observed value at the time of the measurement. Additional constraints are implemented if data are available. These additional constraints include methanol, ethanol, H<sub>2</sub>O<sub>2</sub>, CH<sub>3</sub>OOH, HNO<sub>3</sub>, PAN, acetic acid, and formic acid. Concentrations of these species are computed by the model when data are unavailable.

The model chemistry includes  $HO_x-NO_x-CH_4$  gas phase reactions based on the recommendations of Atkinson et al. (2004) and Sander et al. (2003). In addition, the model uses the rate for  $O(^1D)$  quenching by  $N_2$  suggested by Ravishankara et al. (2002), temperature dependent quantum yields for acetone photolysis from Arnold et al. (2005), and the parameterization for near-IR photolysis of  $HO_2NO_2$  described by Roehl et al. (2002). Nonmethane hydrocarbon chemistry is based on the condensed mechanism of Lurmann et al. (1986) with modifications included to address remote low- $NO_x$  conditions. Explicit chemistry is included for  $C_2H_6$ ,  $C_3H_8$ ,  $C_2H_4$ , isoprene, and benzene.  $C_4$  and higher alkanes are lumped together, as are  $C_3$  and higher alkanes, and aromatics other than benzene. Photolysis rate coefficients are based on spectroradiometer measurements (Shetter and Muller, 1999). The diurnal profiles of the photolysis rates are computed by a DISORT four-stream implementation of the Tropospheric Ultraviolet Visible (TUV) radiative transfer code (Madronich and Flocke, 1998). These calculated profiles are then normalized to match the instantaneous observations at the time of measurement.

Model calculations use the 1-min merged data set available on the INTEX-B public data archive (http://www-air.larc.nasa.gov). In this study, we limit the analysis to those points that include direct measurement of NMHCs.

### **ACPD**

9, 2791-2822, 2009

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

#### 2.3 Photochemical steady-state

At photochemical steady state, production and loss of HO<sub>2</sub>NO<sub>2</sub> are equal and R1–R3 yield (Kim et al., 2007):

$$[HO_2NO_2]_{ss} = \frac{k_1[HO_2][NO_2]}{J_2 + k_{-1} + k_3[OH]}$$
(1)

For the conditions experienced during the MILAGRO flights, the lifetime of HO<sub>2</sub>NO<sub>2</sub> with respect to thermal decomposition was less than one hour while the lifetimes with respect to UV/IR photolysis and reaction with OH were on the order of 1 day and 6 days, respectively. Under these conditions, the steady-state concentration of HO<sub>2</sub>NO<sub>2</sub> simplifies to:

$$[HO_2NO_2]_{ss} \approx \frac{k_1[HO_2][NO_2]}{k_{-1}}$$
 (2)

To evaluate whether the simplified assumption for steady state (Eq. 2) is robust for MILAGRO conditions, NASA LaRC box model predictions of HO<sub>2</sub> and NO<sub>2</sub> were used in the right-hand side of Eq. (2) to calculate HO<sub>2</sub>NO<sub>2</sub> using the steady state assumption ([HO<sub>2</sub>NO<sub>2</sub>]<sub>ss</sub>). [HO<sub>2</sub>NO<sub>2</sub>]<sub>ss</sub> was then compared to the full diurnal equilibrium model predictions of HO<sub>2</sub>NO<sub>2</sub> (shown in Fig. 3). The slope of the robust fit line (DuMouchel and O'Brien, 1989; Street et al., 1988) is 1.02 and the intercept is 0.10 pptv.  $R^2$ =0.99.

The  $HO_2$  mixing ratio measurements measured from the C-130 were not sufficiently precise to provide for a direct comparison between the measurements of  $HO_2NO_2$  and the steady state calculation of  $[HO_2NO_2]_{ss}$  using observed  $HO_2$  and  $NO_2$ . However, the mean observed concentration of  $HO_2$  was within 15% of the mean concentration of the NASA LaRC box model estimate for each of the flights used in this analysis.

### **ACPD**

9, 2791-2822, 2009

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

### 3 Comparisons with NASA LaRC photochemical box model

An example time trace for  $HO_2NO_2$  is illustrated in Fig. 4. During this flight (29 March 2006), the C-130 flew in and out of air masses heavily impacted by pollution from Mexico City. Variations in the measured and modeled  $HO_2NO_2$  mixing ratio closely follow variations in  $NO_2$ .

Observed  $HO_2NO_2$  mixing ratios, colored by  $NO_x$  mixing ratios, are compared to the NASA LaRC box model calculation of  $HO_2NO_2$  mixing ratios in Fig. 5. The slope of the robust fit line is 0.81 and the intercept is 6.74 pptv. Although overall agreement is good ( $R^2$ =0.82), there is a tendency for the model to underpredict  $HO_2NO_2$  concentrations at  $NO_x$  levels greater than 15 ppbv (shown by the red and orange colors in Fig. 5). Underprediction of  $HO_2NO_2$  at elevated  $NO_x$  levels is in agreement with previous findings of Murphy et al. (2004) and Kim et al. (2007).

### 4 Ozone production

Photochemical ozone production is the result of oxidation of CO and hydrocarbons in reactions involving  $NO_x$  and  $HO_x$ . This process is regulated by the partitioning of species within these chemical families (Seinfeld and Pandis, 2006). The rate of ozone production can be calculated using Eq. (3) (Jacob, 1999).

$$P_{O_3} = k_{HO_2 + NO}[RO_2][NO] + k_{HO_2 + NO}[HO_2][NO]$$
(3)

The rate constants for the reactions of peroxyradicals (including  $HO_2$ ) with NO are similar, so  $P_{O_3}$  can be approximated as:

$$P_{O_3} \approx k_{HO_2 + NO}[NO]([RO_2] + [HO_2])$$
 (4)

In polluted atmospheres,  $HO_2$  is produced primarily from the reaction of  $RO_2$  with NO and therefore, the sum of all non- $HO_2$  peroxy radicals will be closely and linearly related to the concentration of  $HO_2$  (e.g., Jacob, 1999).

$$P_{O_3} = Zk_{HO_2 + NO}[HO_2][NO]$$
 (5)

### **ACPD**

9, 2791-2822, 2009

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

K. M. Spencer et al.

2802

where Z is a number generally close to 2 in polluted air. With  $K_{eq} = k_1/k_{-1}$ , solving Eq. (2) for [HO<sub>2</sub>] and substituting into Eq. (5) yields:

$$P_{O_3} = \frac{Zk_{HO_2 + NO}[HO_2NO_2][NO]}{K_{eq}[NO_2]}$$
 (6)

In Fig. 6, we plot  $P_{O3}$  from the NASA LaRC box model versus  $k_{\text{HO}_2+\text{NO}}[\text{HO}_2\text{NO}_2][\text{NO}]/\text{K}_{\text{eq}}[\text{NO}_2]$  to estimate Z. Using the NASA LaRC box model, we examined the predictions of Eq. (6). We limit this analysis to times when the solar zenith angle is < 80°. The slope of the polyfit fit line, Z, in Fig. 6 is 1.77. The correlation is high ( $R^2$ =0.99) suggesting that the production of ozone under MILAGRO conditions can be estimated directly from Eq. (6) using measured HO<sub>2</sub>NO<sub>2</sub>, NO, and NO<sub>2</sub> with Z=1.77. Figure 7 (top panel) shows the rate of ozone production along the flight track as calculated using observed values of HO<sub>2</sub>NO<sub>2</sub>, NO, and NO<sub>2</sub> in Eq. (6) compared to the rate of ozone production predicted by the NASA LaRC box model (bottom panel).

#### Discussion and conclusions

Because of the high correlation of RO<sub>2</sub> and HO<sub>2</sub> in urban air, HO<sub>2</sub>NO<sub>2</sub> concentrations provide a proxy for the concentration of peroxy radicals and thus for the ozone production rate. In a polluted atmosphere, efficient HO<sub>x</sub> chain propagation occurs during oxidation of hydrocarbons in which a hydrogen atom is attached to the alkoxy carbon. Hydrocarbons are oxidized by OH to form peroxy radicals. The peroxy radicals readily react with NO to produce alkoxy radicals and NO2 and thus ozone. Alkoxy radicals combine with O<sub>2</sub> to form carbonyl compounds and HO<sub>2</sub> radicals, which subsequently react with NO to form OH and NO<sub>2</sub>. When all HO<sub>2</sub> originates from RO<sub>2</sub>, Z in Eq. (6) is 2. Because other sources of HO<sub>2</sub> exist, e.g., photolysis or reaction with OH of tertiary aldehydes and CH<sub>2</sub>O (Jacob, 1999), the value is somewhat smaller, 1.77.

The rate of ozone production is sensitive to the rate of HO, production and the amount of NO<sub>v</sub> present. At a fixed HO<sub>v</sub> production rate, the rate of ozone produc-2803

tion increases with NO<sub>x</sub> until NO<sub>y</sub> reaches a level where the rate of nitric acid formation via R8 reduces HO<sub>x</sub> levels and photochemistry slows.

$$OH + NO_2 + M \rightarrow HNO_3 + M$$
 (R8)

This behavior can be seen in the model chemistry (Fig. 8, right panel). Ozone production rates for these MILAGRO flights calculated by the NASA LaRC box model are plotted versus NO levels and colored by the mixing ratio of CH<sub>2</sub>O. CH<sub>2</sub>O is used here as a proxy for the HO<sub>x</sub> production rate (Seinfeld and Pandis, 2006). At low NO, the ozone production rate increases with NO at a fixed level of CH2O, i.e., NOx-limited behavior. At high NO, the ozone production rate becomes independent of or even decreases with NO at a fixed level of CH<sub>2</sub>O, i.e., NO<sub>x</sub>-saturated behavior.

In contrast to NASA LaRC box model calculations, the rate of ozone production estimated from observed HO<sub>2</sub>NO<sub>2</sub>, NO, and NO<sub>2</sub> does not show a saturation behavior (Fig. 8, left panel). At high NO, observed HO<sub>2</sub>NO<sub>2</sub> levels continue to increase with NO, in contrast to model predictions. This suggests that the NASA LaRC box model underestimates the HO<sub>2</sub> levels and therefore either the HO<sub>x</sub> production/loss rate is under/over estimated at elevated NO levels. This is consistent with observed HO<sub>2</sub>NO<sub>2</sub> mixing ratios greater than NASA LaRC model predictions at NO<sub>x</sub> levels greater than 15 ppbv shown in Fig. 5.

Observed values of HO<sub>2</sub>NO<sub>2</sub>, and hence HO<sub>2</sub>, greater than those predicted by the NASA LaRC box model are consistent with a number of urban measurements of HO<sub>2</sub>. Several recent studies have pointed to possible missing HO<sub>x</sub> sources in urban air. At high NO<sub>x</sub> concentrations, HO<sub>2</sub> levels calculated using highly constrained box models were significantly less than measured HO<sub>2</sub> levels during summertime in Nashville, Birmingham, and New York City (Martinez et al., 2003; Heard et al., 2004; Emmerson et al., 2005; Ren et al., 2003) and in New York City and Tokyo in the winter (Ren et al., 2006; Kanaya et al., 2007). Martinez et al. (2003) reported daytime HO<sub>2</sub> levels 1.56 times modeled values in Nashville in 1999. The difference between measured and modeled HO<sub>2</sub> was positively correlated with high NO<sub>x</sub> mixing ratios. In Birmingham,

England in the summer of 1999 and winter of 2000, Heard et al. (2004) observed HO<sub>2</sub> levels 1.78 and 2.04 times modeled values, respectively. They found that the observed HO<sub>2</sub> concentrations were particularly insensitive to changes in NO<sub>x</sub> levels. Summertime levels of HO<sub>2</sub> in New York City in 2001 were underestimated, with observed levels 1.24 times modeled values. The difference between measured and calculated HO<sub>2</sub> depended on the time of day. At midday, the observed and modeled values were found to agree very well while the model tended to underestimate the observations when NO, was high, usually during the morning hours (Ren et al., 2003). Similar results where found in Tokyo during the winter of 2004. Daytime HO<sub>2</sub> concentrations were underestimated, with observed HO<sub>2</sub> levels 2.08 times modeled values. These comparisons were sensitive to the assumed hydrocarbon levels. When the concentrations of alkenes and reactive alkanes used in the model were increased by factors of 3 and 5, respectively, the observed-to-modeled HO<sub>2</sub> ratio decreased to 1.13. Continued underestimation of HO<sub>2</sub> concentrations occurred at high NO<sub>x</sub> mixing ratios (Kanaya et al., 2007). The higher than expected levels of HO<sub>2</sub> suggest higher rates of ozone production than can be accounted for using known chemistry.

Not all studies have found excess HO<sub>2</sub>. Indeed, several studies have found overpredictions of HO<sub>2</sub> levels by photochemical box models even at high NO<sub>x</sub> concentrations. HO<sub>2</sub> concentrations were overestimated in the Los Angeles basin, Mexico City, and summertime Tokyo (George et al., 1999; Shirley et al., 2006; Kanaya et al., 2007). George et al. (1999) reported daytime HO<sub>2</sub> levels 0.67 times calculated values downwind of Los Angeles in 1993. The agreement for observed and calculated HO2 was quite good in the early morning hours, but calculated HO<sub>2</sub> concentrations were found to be significantly higher than observations during midday. In Mexico City in 2003, Shirley et al. (2006) determined that observations of HO<sub>2</sub> were 0.79 times calculated values of HO<sub>2</sub> during the midday. However, they also calculated an observed-to-modeled ratio of 1.17 during morning rush hour, coinciding with the morning rush hour peak in NO, concentrations. Unlike wintertime findings, summertime HO<sub>2</sub> concentrations in Tokyo were overestimated. An observed-to-modeled HO<sub>2</sub> ratio of 0.78 was reported. Trends

at high NO<sub>v</sub> levels were not discussed as NO mixing ratios greater than 20 ppbv were not seen during this sampling period (Kanaya et al., 2007).

HO<sub>2</sub>, HO<sub>2</sub>NO<sub>2</sub>, and hence the rate of ozone production may be underpredicted at high NO due to errors in calculated NO<sub>x</sub>-dependent HO<sub>x</sub> sources and sinks. We have 5 investigated several possible sources of error. One possibility is an overestimate of the rate constant of R8, a sink of HO<sub>v</sub>. The accepted rate constant for R8 has been subject to numerous revisions in the last decade (DeMore et al., 1997; Sander et al., 2000, 2003, 2006). Recent laboratory work at Jet Propulsion Laboratory and California Institute of Technology suggests that the 2000 JPL critical evaluation (Sander et al., 2000) may be closer than current recommendations (Sander et al., 2006) to the true rate (Okumura and Sander, 2005). The 2000 JPL critical evaluation recommended rate constant for R8 is approximately 30% lower for MILAGRO conditions than the most current evaluation. To test the importance of this on HO<sub>2</sub>NO<sub>2</sub> levels, the recommended rate constant for R8 from the 2000 evaluation was substituted into the model. Figure 9 (top panel) illustrates the sensitivity of the modeled HO<sub>2</sub>NO<sub>2</sub> mixing ratio to a change in the rate constant for R8. At high NO levels, use of the 2000 JPL recommended rate increases the mixing ratio of calculated HO<sub>2</sub>NO<sub>2</sub>, leading to better agreement between measured and calculated HO<sub>2</sub>NO<sub>2</sub>.

HO<sub>2</sub>NO<sub>2</sub> mixing ratios and hence rate of ozone production may also be underpredicted at high NO<sub>x</sub> due to missing calculated HO<sub>x</sub> sources at high NO<sub>x</sub>. Li et al. (2008) recently reported significant HO<sub>x</sub> production from the reaction of excited-state NO<sub>2</sub>  $(NO_2^*)$  with  $H_2O$ :

$$NO_2^* + H_2O \rightarrow OH + HONO$$
 (R9)

NO<sub>2</sub> is formed through the excitation of NO<sub>2</sub> at wavelengths longer than 420 nm. These direct and indirect (via HONO photolysis) OH sources lead to increased concentrations of HO<sub>x</sub> at elevated NO<sub>x</sub> levels. Including this process in the box model, using the rate of R9 determined by Li et al. (2008), improves agreement with observed HO<sub>2</sub>NO<sub>2</sub>. As seen in Fig. 9 (middle panel), the inclusion of R9 increases the mixing ratio of calcu-

lated  $HO_2NO_2$ , again leading to better agreement between measured and calculated  $HO_2NO_2$ . Including both the reduced rate of R8 and the Li et al. (2008) process leads to increased levels of calculated  $HO_2NO_2$  (Fig. 9, bottom panel). The transition to  $NO_x$  saturation appears to occur at higher  $NO_x$  levels than estimated by the NASA LaRC box model for Mexico City. This may have implications for engineering of improvements in air quality in the basin. If generally true, it suggests that further  $NO_x$  controls will yield reductions in smog levels. Significant uncertainties remain, however. It is unclear why the  $HO_x$  levels are generally underestimated. Although we identify several possible deficiencies in the photochemical mechanism that may contribute to an underprediction of  $HO_x$ , these are not sufficient to account for the discrepancy and each is uncertain and requires additional laboratory work to test these mechanisms (e.g., Wennberg and Dabdub, 2008). In addition,  $NO_x$  levels are generally much higher at the surface and so it is unclear if  $NO_x$ -limited conditions also apply.

Acknowledgements. The authors wish to thank C. M. Roehl for synthesizing the peroxynitric acid for calibration. P. Weibring and A. Fried, D. R. Blake, and R. E. Shetter provided formaldehyde, whole air sample, and solar actinic flux measurements, respectively, which provided constrains for the photochemical box model. The authors also wish to thank the C-130 crew and support team. The  $\rm HO_2NO_2$  measurements and their interpretation was made possible with the financial support of NASA (NAG: NNG06GB32B). J. D. C. acknowledges support from the EPA-STAR Fellowship Program (FP916334012). This work has not been formally reviewed by the EPA. **Fig. 2.**  $HO_2NO_2$  is measured with two ions: products of fluoride transfer (m/z=98) and clustering (m/z=164). The data are colored by flight date. The data shown are observations obtained when the measured  $NO_y$  differs by less than 10% between m/z 98 and m/z 164 sampling times. The slope of the robust fit line is 0.90; the intercept is 0.76 pptv;  $R^2$ =0.94. Independent measurements of  $HO_2NO_2$  from these two ions agree very well, indicating that these masses are selective to  $HO_2NO_2$ .

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

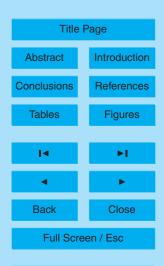

**Fig. 3.**  $[HO_2NO_2]_{ss}$ , calculated from Eq. (2), using modeled values of  $HO_2$  and  $NO_2$  versus  $HO_2NO_2$  predicted by the NASA LaRC box model. The slope of the robust fit line is 1.02; intercept is 0.10 pptv;  $R^2$ =0.99, demonstrating that Eq. (2) is a valid simplification under MILAGRO conditions.

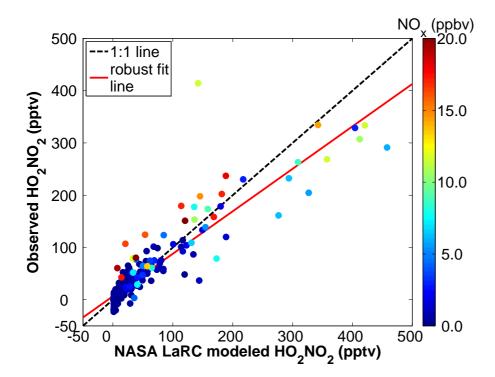

**Fig. 4.** Mixing ratios of  $HO_2NO_2$  and  $NO_2$  during Flight 29 March 2006 in an air mass heavily impacted by pollution. Dots are CIMS measurements of  $HO_2NO_2$ . Triangles are NASA LaRC box model values of  $HO_2NO_2$ . The solid line is observed  $NO_2$  mixing ratio. Variations in the observed and modeled  $HO_2NO_2$  mixing ratios closely follow variations in  $NO_2$ .

# Inferring ozone production using HO<sub>2</sub>NO<sub>2</sub>

K. M. Spencer et al.

**Printer-friendly Version** 

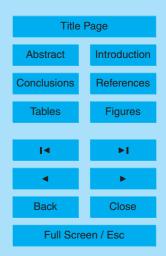

**Fig. 9.** Three different variations of the base model were investigated. Model variations are divided by the base model and plotted versus NO. Use of the 2000 JPL recommendation for the rate constant for  $OH+NO_2$  and inclusion of the  $NO_2^*+H_2O$  reaction result in higher  $HO_2NO_2$  mixing ratios than estimated by the base model. This leads to better agreement between measured and calculated  $HO_2NO_2$ .
