## Abstract

IASI measurements of spectral radiances made between the 1 April 2008 and the 15 April 2008 are compared with simulations performed using the RTTOV fast radiative transfer model utilizing regression coefficients based on different line-by-line models. The comparisons are performed within the framework of the European Centre for Medium-Range Weather Forecasts Integrated Forecasting System using fields of temperature, water vapour and ozone obtained from short-range forecasts. Simulations are performed to assess the accuracy of the RTTOV computations and investigate relative differences between the line-by-line models and the quality of the spectroscopic databases on which the RTTOV coefficients are based.

## 1 Introduction

The exploitation of satellite radiance data for Numerical Weather Prediction (NWP) requires the use of an accurate and fast radiative transfer (RT) model to simulate radiances from an input atmospheric profile. The high spectral resolution of radiances measured by the Atmospheric Infrared Sounder (AIRS) (Aumann et al., 2003) on the Earth Observing System (EOS) Aqua platform and the Infrared Atmospheric Sounding Interferometer (IASI) (Chalon et al., 2001) on the MetOp-A platform provides temperature and constituent profiles at a higher accuracy and with more vertical resolution than the conventional filter wheel radiometers. The assimilation of AIRS and IASI long-wave temperature sounding channels at ECMWF has produced a significant positive impact on forecast quality (McNally et al., 2006; Collard and McNally, 2008) and in the near future the use of IASI data could be extended to other spectral bands. The variational approach to the assimilation of these datasets into the ECMWF four-dimensional variational analysis scheme, 4D-Var (Rabier et al., 1998), involves the definition of the observation-error covariance matrix that is used to specify errors associated with radiance data. The observation-error covariance matrix is the sum of the instrumental-error

covariance matrix and the forward-model-error covariance matrix which is based on the estimation of errors associated with fast RT models. The low noise level of IASI and AIRS makes RT errors an important contribution to the definition of the observation-error covariance matrix and consequently they must be properly evaluated and their origin fully understood.

Fast RT model errors are dominated by two main components: the parameterization used for the atmospheric transmittances and the errors associated with the spectroscopic parameters and the computational procedures adopted in the line-by-line (LBL) models on which fast RT models are generally based. The fast RT model used operationally at the European Centre for Medium-Range Weather Forecasts (ECMWF) is the Radiative Transfer Model for TOVS (RTTOV) (Saunders et al., 1999). In RTTOV the transmittances of the atmospheric gases are expressed as a function of profile-dependent predictors. This parameterization of the transmittances makes the model computationally efficient and thus fulfils the NWP requirement of near real-time monitoring and assimilation of satellite radiance data. In fact, LBL models are too computationally expensive to be used in an NWP operational environment. In this paper we give a brief review of the current status of the RTTOV model and discuss the main features of the LBL models that have been used to derive the RTTOV coefficients for IASI focusing on the aspects that distinguish one model from another.

Errors associated to the RTTOV transmittance parameterization for the IASI channels are discussed in detail in Matricardi (2008) whereas LBL model errors have been investigated in several studies (e.g., Rizzi et al. 2002; Tjemkes et al., 2003) using high-spectral resolution aircraft data. In this paper we try to assess the absolute accuracy of the RTTOV model as a whole. The availability of RTTOV regression coefficients based on different LBL models has also offered the opportunity to investigate relative differences between LBL-models and the quality of the spectroscopic databases used in the LBL-model computations. The assessment of the RTTOV accuracy has been carried out by running a number of Integrated Forecast System (IFS) monitoring experiments where IASI spectra simulated by RTTOV have been compared to IASI spectra

measured during the period 1–15 April 2008 using short range operational forecasts of temperature, water vapour and ozone fields to specify the RTTOV input state vector.

## 2 The RTTOV model

The RTTOV model was originally developed at ECMWF (Eyre and Woolf, 1988) to retrieve temperature and humidity profiles from the Television InfraRed Observation Satellite (TIROS-N) Operational Vertical Sounder (TOVS) (Smith et al., 1979). Subsequently the code has gone through several developments (e.g., Matricardi et al., 2004), more recently within the EUMETSAT NWP Satellite Application Facility (SAF), of which RTTOV-9 is the latest version (Saunders et al., 2008). RTTOV covers the spectral range 3–20 microns in the infrared and the frequency range 10–200 GHz in the microwave and supports a large number of platforms and sensors with updates as new sensors are launched. An important feature of the RTTOV model that is essential for use in a NWP environment is that it not only performs the fast computation of the forward (or direct) radiances but also the fast computation of the gradient of the radiances with respect to the state vector variables for the input state vector values (i.e. temperature, variable gas concentrations, cloud and surface properties).

The model uses the polychromatic form of the radiative transfer equation (i.e. the use of channel averaged transmittances in the radiative transfer equation is based on the assumption that this is equivalent to the convolution of the monochromatic radiances) (see Matricardi et al., 2004, for details). The polychromatic approximation is adequate when channels are narrow enough that the convolution of the Planck function can be replaced with its value at the central wave number of the channel. For IASI and AIRS channels the polychromatic approximation results in errors typically below 0.05 K whereas for broad channels the accuracy is generally poor and can result in biases of  $\sim 1\text{--}2$  K (Brunel and Turner, 2003). The RTTOV fast transmittance scheme uses regression coefficients derived from accurate LBL computations to express the optical depths as a linear combination of profile dependent predictors that

Interactive Discussion

are functions of temperature, absorber amount, pressure and viewing angle (Matricardi and Saunders, 1999). The regression coefficients are computed using a training set of diverse atmospheric profiles chosen to represent the range of variations in temperature and absorber amount found in the atmosphere. Regression coefficients for RTTOV are available based on the 43 profile training set described in Matricardi and Saunders (1999), the 52 profile training set described in Chevallier (2000) and, more recently, on the 83 profile training set described in Matricardi (2008) (henceforth we will refer to these training sets as ECMWF\_43\_P, ECMWF\_52\_P and ECMWF\_83\_P, respectively). The latter dataset includes variable profiles of carbon dioxide (CO<sub>2</sub>), nitrous oxide (N<sub>2</sub>O), methane (CH<sub>4</sub>) and carbon monoxide (CO) in addition to water vapour (H<sub>2</sub>O) and ozone (O<sub>3</sub>). The LBL computations for the minor gases that are not allowed to vary in RTTOV are carried out assuming a climatological mean profile (see next section for details).

The RTTOV-9 fast transmittance algorithm supports a range of predictor sets, namely RTTOV-7 predictors, RTTOV-8 predictors and RTTOV-9 predictors. The selection of the predictors is made according to the coefficients file supplied to the program. The RTTOV-8 predictors (Matricardi et al., 2004) allow to vary the amounts of H<sub>2</sub>O, O<sub>3</sub> and optionally CO<sub>2</sub> whereas the RTTOV-9 predictors (Matricardi, 2003) allow to vary the amounts of H<sub>2</sub>O, O<sub>3</sub>, CO<sub>2</sub>, N<sub>2</sub>O, CH<sub>4</sub> and CO. Coefficients based on RTTOV-9 predictors can only be used for AIRS and IASI and input profiles for CO<sub>2</sub>, N<sub>2</sub>O, CH<sub>4</sub> and CO are mandatory. In addition, RTTOV-9 predictors can be used to compute optical depths for the long atmospheric paths involved in the computation of top of the atmosphere (TOA) radiances if solar radiation is required to be included in the short-wave infrared channels.

Regression coefficients are computed separately for all gases with fixed amounts and for each species that is allowed to vary. Since the convolution of the transmittance of all the gases differs from the product of the transmittance of the single gases convolved individually, effective transmittances are derived that allow Beer's law to be obeyed to a very good approximation (Matricardi and Saunders, 1999). The accuracy

of the fast model transmittance parameterization can be assessed by comparing the transmittances and radiances computed by the fast model with the corresponding values from LBL models in different ways. Firstly, the fast model transmittance profiles and TOA radiances computed for the regression training data set can be compared with LBL model equivalents to determine the accuracy of the fast model itself. Secondly, a set of profiles independent of the regression coefficients can be used to allow uncertainties from different type of profiles to be included. The accuracy of the RTTOV-9 predictors is discussed in detail in Matricardi (2008). Results for an independent profile set show that the root mean square (rms) of the difference between fast model and LBL radiances is below 0.15 K for the vast majority of the channels. Larger errors are observed in spectral regions that see the presence of medium strength water vapour lines, in the ozone band at 9.8 microns and in regions where H<sub>2</sub>O lines interfere with absorption lines of other gas species. Results for RTTOV-8 predictors are similar (Matricardi et al., 2004). If we use this error figure as representative of errors associated with the RTTOV fast transmittance parameterization then we can reasonably assume that the RTTOV accuracy is largely determined by the accuracy of the LBL algorithm. For instance the inaccurate knowledge of molecular line strengths alone can result in TOA radiance errors as large as 0.3–0.4 K (Rizzi et al., 2002).

The computation of TOA radiances in RTTOV-9 is performed using a parameterization of the Planck function based on the linear-in- $\tau$  assumption that the source function throughout an atmospheric layer is linear with the optical depth,  $\tau$ , of the layer. An altitude dependent correction to the local path is also applied that takes into account the curvature of the Earth and its surrounding atmosphere. Finally, to compute the infrared emissivity over water a fast surface emissivity routine, ISEM, (Sherlock, 1999) is used.

### 3 The line-by-line models

As discussed in the previous section, the RTTOV fast transmittance algorithm uses regression coefficients obtained from LBL transmittance calculations. As noted in Rizzi et al. (2002), LBL model errors tend to be dominated by insufficient knowledge of basic spectroscopy rather than by the computational procedures used in the codes. Spectroscopic errors are of paramount importance for high-resolution sounders like AIRS and IASI that allow the use of channels placed between spectral lines. These channels have weighting functions that are sharper than the weighting functions that characterize the channels placed on top of the spectral lines and consequently particular attention must be paid to the spectral line shape of species like H<sub>2</sub>O and CO<sub>2</sub> for which optical depths in the atmosphere can reach very large values. The effect of line mixing, i.e. the change in line shape due to the redistribution of radiation in overlapping spectral lines (Strow and Reuter, 1988), in the CO<sub>2</sub> Q-branches is now routinely incorporated in LBL algorithms and in the recent past progress has been made in the development of improved CO<sub>2</sub> line shapes by taking into account the effect of line mixing in CO<sub>2</sub> P/R-branches (e.g. Niro et al., 2005). Progress in the development of improved H<sub>2</sub>O line shapes is still hindered by the difficulty of achieving good measurements of H<sub>2</sub>O amounts in the atmosphere and in the laboratory and the nature of water vapour continuum absorption and its effect on atmospheric radiance is an outstanding and unresolved issue (e.g. Ma et al., 2008). In LBL models water vapour continuum is usually parameterized using the semi-empirical CKD model by Clough et al. (1989). This model has been recently revised (Tobin et al., 1999) based on the assumption that the continuum absorption in water vapour bands is dominated by the collision-induced absorption resulting from the generation of a short-lived complex of water vapour and colliding molecules (MT\_CKD model). Finally, the accuracy of the line parameters used in the LBL calculations can introduce significant errors in the simulated radiances (Tjemkes et al., 2003).

RTTOV regression coefficients for IASI are available based on various LBL models.

Interactive Discussion

Regression coefficients based on version 4 of the GENLN2 LBL model (GENLN2\_v4) and version 11.1 of the LBLRTM LBL model (LBLRTM.v11.1) have been generated at ECMWF using RTTOV-9 predictors whereas coefficients based on version 1.11 of the kCARTA LBL model (kCARTA.v1.11) have been generated at Meteo France using RTTOV\_8 predictors. A description of the LBL models is given in the following sections.

### 3.1 GENLN2\_v4

GENLN2\_v4 (Edwards, 1992) is a line-by-line atmospheric transmittance and radiance model. Line strengths and half-widths are adjusted to the path pressure and temperature and Doppler broadening of the spectral lines is taken into account. To describe the effects of pressure and Doppler line broadening, GENLN2\_v4 adopts the Voigt line shape. The GENLN2\_v4 CO<sub>2</sub> line shape includes the effect of line mixing and takes into account the sub-Lorentzian behaviour in the far-wing of the line. If data is available, CO<sub>2</sub> Q-branch line mixing in the  $\nu_2$  and  $\nu_3$  band can be included out to an arbitrary 10 cm<sup>-1</sup> from line centre. For greater distances from the centre the line shape is approximated by the empirical model by Cousin et al. (1985). This model explains the sub-Lorentzian nature of the CO<sub>2</sub> far wing line shape in terms of duration of collision effects and uses a temperature dependent  $\chi$ -factor to adjust the standard line shape function based on the impact theory. If no line-mixing data is available then the sub-Lorentzian line shape is used everywhere. The standard release of GENLN2\_v4 includes the water vapor continuum model CKD\_2.1. However, we carried out our computations using the model CKD\_2.4 that became available at the time the regression coefficients were about to be generated. The pressure-broadened band of N<sub>2</sub> at 2350 cm<sup>-1</sup> (Menoux et al., 1993) and that of O<sub>2</sub> at 1550 cm<sup>-1</sup> (Timofeyev and Tonkov, 1978; Rinsland et al., 1989) is included as broadband continuum contribution to the absorption and heavy molecules can be modeled using high-resolution cross-sectional data. In our computations, CO<sub>2</sub> Q-branch line mixing has been fully accounted for using first order line-mixing coefficients from Strow et al. (1994).

## 3.2 kCARTA\_v1.11

The kCARTA\_v11.1 model (De Souza-Machado et al., 2002) is a fast LBL algorithm where transmittances are computed from compressed look-up tables of atmospheric transmittances (Strow et al., 1998). The look-up tables are computed using a LBL model developed at the University of Maryland, Baltimore County (UMBC-LBL) (Strow et al., 2003) and their use in kCARTA results in very fast computation times. The water vapour continuum model (hence after referred to as MTK\_CKD\_UMBC) is based on the MTK\_CKD\_1.0 model. It uses revised values of the spectral density function coefficients based on measurements of AIRS spectra utilizing in-situ data available from the ARM sites (De Souza-Machado, personal communication, 2008). Line mixing coefficients for CO<sub>2</sub> are available for 12 P/R-branch bands and 12 Q-branch bands in the short wave and in the long wave. The kCARTA model for the CO<sub>2</sub> line shape is based on the work by Tobin (1996) and De Souza-Machado et al. (1999). For the P/R-branch it involves an approximation for the combination of line mixing and duration-of-collision effects. Regarding the UMBC-LBL model it should be stressed that it relies on a full treatment of the CO<sub>2</sub> Q- and P/R-branch line mixing and does not use the perturbation theory. Finally, the collision-induced bands of oxygen at 1600 cm<sup>-1</sup> and nitrogen at 2350 cm<sup>-1</sup> are incorporated using the model by Thibault et al. (1997) and Lafferty et al. (1996), respectively.

## 3.3 LBLRTM\_v11.1

The LBLRTM line-by-line model (Clough et al., 1992) has been developed at the Atmospheric and Environmental Research Inc. (AER). To describe the effects of pressure and Doppler line broadening the Voigt line shape is used at all atmospheric levels with an algorithm based on a linear combination of approximating functions. LBLRTM incorporates the self- and foreign-broadened water vapor continuum model MT\_CKD\_2.0 (Tobin et al., 1999) and the collision-induced bands of oxygen at 1600 cm<sup>-1</sup> and nitrogen at 2350 cm<sup>-1</sup> are included as broad-band continuum contributions to the absorp-

Interactive Discussion

tion using the models by Thibault et al. (1997) and Lafferty et al. (1996), respectively. In LBLRTM the CO<sub>2</sub> line shape includes the effects of line mixing for the P-R-branch and Q-branch in the  $\nu_2$  and  $\nu_3$  band using first order line coupling parameters generated using the code by Niro et al., 2005. Since the model by Niro et al. (2005) combines the effects of line mixing and duration of collision effects, the  $\chi$  factor is set equal to 1. In addition, the CO<sub>2</sub> continuum is computed using the Niro et al. (2005) coupling coefficients with a scaling factor of 0.75 applied to the  $\nu_3$ -band to agree with AIRS spectra in the  $\nu_3$  spectral region. LBLRTM uses temperature dependent cross section data to model the absorption of heavy molecules. The pressure dependence of the cross sections is treated by performing a convolution of the cross section spectrum with an appropriate Lorentz function.

The computation of the LBL transmittances is performed on a grid of vertical levels of fixed pressure for a regression dataset of diverse atmospheric profiles and require the use of appropriate parameters from a molecular database. These details are summarized in Table 1. Note how for kCARTA and GENLN2 the same molecular database has been used although it should be noted that for GENLN2 the use of the Strow et al. (1994) line mixing coefficients requires the use of CO<sub>2</sub> molecular line parameters from the HITRAN\_1992 compilation. For the LBLRTM computations we have envisaged a molecular database that blends line parameters obtained from various sources. This is based on the results shown in Matricardi (2007) which suggest that in a number of spectral regions the use of line parameters from different sources can result in a better agreement of simulations with observations. This blended database is largely drawn from HITRAN\_2004 (Rothman et al., 2005) and includes updates up to 1 January 2007. However, in the 9.8 micron ozone band we use ozone line parameters from HITRAN\_2000 (Rothman et al., 2003) whereas in the spectral region between 1700 and 2400 cm<sup>-1</sup> we use water vapour line parameters from GEISA\_2003 (Jaquinet-Husson et al., 2005). Although Matricardi (2007) suggests that the use of CO<sub>2</sub> line parameters from GEISA\_2003 could also be envisaged in the 15 micron CO<sub>2</sub> band, the use of Niro et al. (2005) line mixing coefficients requires that line parameters

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

for CO<sub>2</sub> are obtained from the HITRAN\_2000 compilation. From Table 1 it can also be seen that regression coefficients are based on different profile training sets and that all the computations have been performed on the 101 level vertical grid specified by the AIRS science team (Strow et al., 2003).

For the interpretation of the results we find it useful to include two figures where differences between the various water vapour continuum models are illustrated. In particular, in Fig. 1 we show the water vapour broadening coefficients for the self continuum while in Fig. 2 we show the broadening coefficients for the foreign continuum (self broadening due to H<sub>2</sub>O-H<sub>2</sub>O collisions is the dominant source of continuum in the window regions whereas foreign broadening due H<sub>2</sub>O-N<sub>2</sub> collisions dominates in the water vapour band). These figures show that in the 10 micron window region MTK\_CKD\_UMBC self broadening coefficients are smaller than CKD\_2.4 and MTK\_CKD\_v1.4 coefficients. In the centre of the water vapour band around 1600 cm<sup>-1</sup> the CKD\_2.4 foreign broadening coefficients are smaller than MTK\_CKD\_UMBC and MTK\_CKD\_v1.4 coefficients whereas for larger wave numbers MTK\_CKD\_UMBC foreign broadening coefficients are larger than CKD\_2.4 and MTK\_CKD\_v1.4 coefficients.

All LBL datasets include N<sub>2</sub>, O<sub>2</sub>, HNO<sub>3</sub>, OCS, CCl<sub>4</sub>, CF<sub>4</sub>, CCl<sub>3</sub>F and CCl<sub>2</sub>F<sub>2</sub> among the gases with fixed amount. Regression coefficients based on the GENLN2 and LBLRTM models allow the variation of CO<sub>2</sub>, N<sub>2</sub>O, CO, and CH<sub>4</sub> amounts whereas in kCARTA the amount of these gas species is fixed. The LBLRTM dataset includes an additional number of fixed gas species, i.e. NO<sub>2</sub>, SO<sub>2</sub> and NO. In general, atmospheric constituent profiles for all gases are based on AFGL profiles scaled to reflect present-day concentrations. However, in the LBLRTM dataset we have used HNO<sub>3</sub> and NO profiles generated using the MOZART chemical transport model (Hauglustaine et al., 1998) whereas in the kCARTA dataset the concentrations of CO<sub>2</sub>, N<sub>2</sub>O, CO and CH<sub>4</sub> are based on the climatological profiles described in Matricardi (2003).

## 4 The monitoring experiments

Three baseline monitoring experiments have been run using cycle 33R1 of the IFS (which was the operational cycle from June until October 2008) using the T799 horizontal truncation. This truncation corresponds to a horizontal resolution of  $\sim 25$  km. A feature of cycle 33R1 of the IFS is a vertical discretization of the atmosphere into a grid of 91 pressure levels. The model uses a hybrid vertical coordinate with coordinates that follow the orography of the terrain in the lower troposphere and pressure coordinates in the stratosphere above about 60 hPa. The top level is fixed at 0.01 hPa (about 80 km) and of the 91 levels in the vertical, 52 are above 100 hPa. The state vector variables used in the RTTOV simulations are forecast fields of temperature, humidity, ozone and surface parameters. IASI data within a 12-h 4D-VAR window are grouped into 30 min time slots. A T799 high resolution forecast is then run from the previous analysis and observation minus model differences are computed for IASI soundings within a given time slot. This sequence is then repeated for each 12-h 4D-VAR window. In this study we consider IASI data inside 12-h 4D-VAR windows during the period 1–15 April 2008. The statistics of the difference between global radiosonde observations and ECMWF analyses in the troposphere show values of the standard deviation typically between 0.5 K and 1 K for temperature and between 0.5 and 1.5 g/Kg for water vapour. In the stratosphere, standard deviations for temperature can reach 1.5 K. Ancillary data used in the RTTOV computations include sea-surface temperature (SST). SST fields in cycle 33R1 are based on analyses received from the National Centers for Environmental Prediction (NCEP), Washington, DC, on a  $0.5^\circ \times 0.5^\circ$  grid. These analyses are based on ship, buoy and satellite observations. The SST root mean square error (rms) relative to buoy observations is  $\sim 0.36$  K (Kara et al., 2007). However, this figure can be significantly different in shallow waters where rapid changes due to the upwelling radiation can occur close to land.

Since the the RTTOV optical depth computations are defined by the number of levels in the coefficient file, the IFS pressure levels must be interpolated to the same levels as

the coefficient files. To this end we have used the RTTOV-9 new internal interpolation scheme that allows the input profile to be defined by the user. However, it should be noted that although RTTOV computes optical depths on the levels specified in the coefficient files, the integration of the RT equation is performed on the 91 IFS levels.

5 To ensure that the Jacobians are properly mapped back on the user levels, the optical depths must be interpolated to the IFS levels using the same interpolation scheme utilized for the atmospheric variables.

The IASI spectra used in our experiments are measured over the sea. To reduce the amount of data we have sub-sampled by arbitrarily selecting one out of eleven scan-positions. This also ensures that for two adjacent scan lines we always sample two  
10 different scan positions. Only channels detected as clear by the ECMWF cloud detection algorithm are processed. Since the ECMWF cloud detection algorithm (McNally and Watts, 2003) finds clear channels rather than clear locations, the size of sample varies with the sensitivity of the channel to clouds. Channels characterized by weight-  
15 ing functions that peak at high altitudes are less sensitive to clouds than channels with weighting functions that peak at low altitudes or at the surface. To illustrate this, in Fig. 3 we show the size of the sample for each channel in three latitude bands. It can be clearly seen that the size of the sample varies from several thousands spectra for the channels peaking at middle and high altitudes to a few thousands for channels  
20 peaking at low altitudes or at surface. To avoid reflected solar radiation and non-LTE effects (the latter are not modelled in RTTOV), in the spectral region between 2000 and  $2760\text{ cm}^{-1}$  we have sampled only night-time spectra. This is reflected in Fig. 3 where the size of the sample in this spectral region is significantly smaller than the size of the sample in other spectral regions. Note that to exclude night-time spectra  
25 we have used the criterium that the local solar zenith angle is greater than  $100^\circ$ . This means that a given location can be considered not to be in daylight up to an altitude of  $\sim 100\text{ km}$  (i.e. the altitude above which we consider the atmosphere to be transparent in our calculations).

In our RTTOV computations the state vector includes profiles of temperature, water

vapour and ozone, surface parameters (e.g. skin temperature and surface pressure) and a wave number dependent value of the sea surface emissivity that includes the dependence on the viewing geometry. In addition to the profiles of temperature, water vapour and ozone, the experiments that use RTTOV coefficients based on GENLN2 and LBLRTM also require input profiles of CO<sub>2</sub>, CO, N<sub>2</sub>O and CH<sub>4</sub>. Since profiles for these trace gases are not prognostic variables in the ECMWF model we had to fix the amounts in the GENLN2 and LBLRTM experiments. To this end we have chosen the values assumed in the LBL computation used to train kCARTA. The rationale behind this choice is that at present kCARTA coefficients are used operationally at ECMWF for the assimilation of AIRS and IASI radiances and we want to use the kCARTA spectra as benchmark in our comparisons.

## 5 Discussion of the results

### 5.1 IASI band 1 (645 to 1200 cm<sup>-1</sup>)

Results in IASI band 1 are plotted in Figs. 4, 5, and 6 where we show the mean value of the difference (bias) between observed and simulated radiances in units of equivalent black body brightness temperature for the Northern Hemisphere (30° N–90° N), tropics (30° N–30° S) and Southern Hemisphere (30° S–90° S), respectively. In the top panel the LBLRTM spectrum (solid red line) is superimposed on the kCARTA spectrum (solid black line) whereas in the bottom panel the GENLN2 spectrum (solid red line) is superimposed on the kCARTA spectrum. Results show that for all experiments biases are generally within ±1 K in all geographical regions. The only exception is the ozone band at 9.8 microns where biases can reach 1.5 K in the Northern Hemisphere.

#### 5.1.1 Results in the temperature sounding band

Of particular interest are the result obtained in the 15 microns temperature sounding CO<sub>2</sub>v2 band where the GENLN2 experiment shows significantly larger biases between

700 cm<sup>-1</sup> and 750 cm<sup>-1</sup>. To interpret this result we should bear in mind that, as discussed in Sect. 3, GENLN2 uses the Cousin et al. (1985) empirical model to describe the far-wing shape of the CO<sub>2</sub> line shape. The  $\chi$ -factor used in the  $\nu_2$ -band is based on spectra measured in the  $\nu_3$ -band. However, the symmetry of the 4.3 microns bands is different from the symmetry of the 15 microns bands and consequently the component of the  $\chi$  factor due to line mixing is in error and the effect of line-mixing will be over-estimated in GENLN2. As shown in Figs. 4, 5, and 6, errors in the GENLN2 CO<sub>2</sub> line shape can significantly degrade the accuracy of the spectra.

As discussed above, the performance of GENLN2 between 700 to 750 cm<sup>-1</sup> can be explained in terms of the different treatment of the far-wing CO<sub>2</sub> line shape. In the same spectral region kCARTA and LBLRTM spectra show similar features with differences not larger than 0.2 K. However, the kCARTA spectrum is more irregular than the LBLRTM spectrum. This behaviour can be affected by factors that include the line mixing model, uncertainties in the temperature profile and errors in the strengths and widths of the weak water vapour lines originating from the edge of the water vapour pure rotational band. The errors in the line strengths and widths can either be due to uncertainties in the water vapour profile or due to spectroscopic errors (in addition to this kCARTA and LBLRTM use different water vapour molecular databases).

The very close similarities between the LBLRTM and GENLN2 spectra and the differences between these two models and kCARTA in the 645 to 700 cm<sup>-1</sup> spectral region can only be explained in terms of the line mixing model used in the LBL models. In fact, these differences cannot be attributed to the molecular parameters since, for instance, LBLRTM and kCARTA use the same HITRAN\_2000 compilation. Regarding the absolute value of the biases, it should be noted that in this spectral region a consistent number of channels is sensitive to emission at high altitudes and consequently biases can be affected by systematic temperature errors of the ECMWF model in the upper stratosphere and mesosphere.

A feature in common to the LBLRTM and GENLN2 spectra is the large bias (between 1.8 K and 2 K) seen in correspondence to the CO<sub>2</sub> Q-branch at 667 cm<sup>-1</sup>. Since

GENLN2 and LBLRTM use line mixing coefficients based on a 1st order perturbation theory, it would appear that this is not adequate for the  $667\text{ cm}^{-1}$  Q-branch.

### 5.1.2 Results in the ozone sounding band

Spectra in the ozone band are remarkably close. Biases observed in the ozone band are probably dominated by spectroscopic errors although the larger values (up to  $-1.6\text{ K}$ ) observed in the Northern Hemisphere might reflect a poor performance of the ozone assimilation system.

### 5.1.3 Results in the window regions

The absorption in the window regions between  $800$  and  $1200\text{ cm}^{-1}$  is primarily due to water vapour and consists mainly of the absorption due to water vapour self-continuum although in the high-wavenumber boundary of the window (i.e. between  $1080$  and  $1200\text{ cm}^{-1}$ ) the contribution of weak water vapour lines originating in the  $\nu_2$ -band has also to be taken into account. With the exception of a few channels, the specification of the continuum model and the choice of the molecular parameters do not appear to have a significant impact on the spectra obtained in the Northern and Southern Hemispheres. In fact, within each of these geographical regions, spectra are very similar with biases varying between  $-0.1$  and  $-0.6\text{ K}$  in the Northern Hemisphere and between  $-0.1$  and  $-0.4\text{ K}$  in the Southern Hemisphere.

It is difficult to interpret the differences observed between the biases obtained in the Northern and Southern Hemispheres between  $800$  and  $1000\text{ cm}^{-1}$ . The absorption due to the water vapour self continuum is proportional to the square of the water vapour amount and for a fixed amount of water vapour it decreases with temperature. In general, the colder air masses typically encountered at mid-high latitudes are associated with less water vapour and the competing effect of temperature and water amount is stronger than in the much more humid conditions encountered in the tropical regions. Errors in the temperature profiles and, above all, errors in the water vapour profiles in

Interactive Discussion

the lower troposphere and near the surface can then affect the simulated spectra in various measures and result in the different biases observed at different latitudes.

Biases can also be affected by errors in the SST analysis. In addition, SST errors indirectly affect the values of the sea surface emissivities computed by ISEM since ISEM does not take into account the temperature dependence of the water vapour optical parameters. However, since the SST is used as the skin temperature in the RT computations, the larger biases in the Northern Hemisphere cannot be explained in terms of SST alone since this feature should also be present in the high-wavenumber boundary of the window region. It is also possible that channels identified by the cloud detection scheme as clear channels are in fact channels affected by clouds. The negative sign of the biases (i.e. the RT model overestimates the radiances) is consistent with this hypothesis. However, results obtained using aircraft data in controlled clear-sky conditions (e.g. Rizzi et al., 2002) show biases whose magnitude is similar to that obtained in our study. Consequently, the effect due to errors in the cloud detections scheme must be very small.

Results for the tropical region (Fig. 5) show that in contrast to the cases discussed above, differences now exist between the spectra in the window regions. This is a direct consequence of the fact that the high tropical water vapour column concentrations make the water vapour continuum absorption a much more important factor. We have studied this aspect more in depth by running a further experiment where the kCARTA spectra have been computed using the same water vapour continuum model used in the LBLRTM model. The results are shown Fig. 7 where we have plotted the difference between the standard kCARTA mean spectrum and the LBLRTM mean spectrum (top panel) and the difference between the modified kCARTA mean spectrum and the LBLRTM mean spectrum (bottom panel).

Fig. 7 shows that the use of the same continuum model greatly reduce the differences between the spectra. This is all the more evident between  $800$  and  $980\text{ cm}^{-1}$ . The residuals seen in correspondence of the  $\text{CFCl}_3$  band at  $846\text{ cm}^{-1}$  and the  $\text{CF}_2\text{Cl}_2$  band at  $923\text{ cm}^{-1}$  are attributable to the different amounts used for these molecules

in kCARTA and LBLRTM whereas residuals around  $880\text{ cm}^{-1}$  should be attributed to the spectroscopy. In the window region between  $1080$  and  $1200\text{ cm}^{-1}$  the change in the continuum reduces the peak-to-peak differences and shifts the biases towards positive values. This would suggest that in this spectral region differences between the spectra are attributable primarily to differences between the molecular databases. Results shown in the bottom panel of Fig. 7 corroborate this hypothesis in that GENLN2 and kCARTA biases are in very good agreement (they use the same HITRAN\_2000 molecular database).

Finally, we want to comment on the feature (a kink) in the GENLN2 spectrum around  $1000\text{ cm}^{-1}$  observed in the tropics and in the Southern Hemisphere. This feature is not present in the kCARTA and LBLRTM experiments and its origin is difficult to interpret. In this spectral region, the only obvious difference between GENLN2 and the other LBL models is the much smaller value of the foreign broadening spectral density function but it is difficult to argue in favour of a possible impact of the foreign continuum since foreign broadening should not be important at these wave numbers.

### 5.2 IASI band 2 ( $1200$ to $2000\text{ cm}^{-1}$ )

Spectra in IASI band 2 are plotted in Figs. 8, 9, and 10 for the Northern Hemisphere, tropics and Southern Hemisphere, respectively. The values of the biases vary between  $-2\text{ K}$  and  $1\text{ K}$ . Biases observed in the Northern Hemisphere are in general comparable to biases observed in the Southern Hemisphere. Spectra obtained in the tropics are more articulate and the biases observed in this region are larger than the biases observed in the other geographical regions. In addition, the differences between the spectra obtained in the tropics are larger than the differences between the spectra obtained elsewhere. In all geographical regions, the larger biases are seen in correspondence of channels located in the spectral region characterized by the presence of the strong  $\nu_4$ -band of methane at  $1310\text{ cm}^{-1}$  where negative values are in general observed. The larger biases in this region can be partly explained by the fact that

methane amounts are fixed to climatological values.

LBLRTM and kCARTA spectra exhibit very similar features in the left side and central part of the water vapour  $\nu_2$  band from 1400 up to 1700  $\text{cm}^{-1}$ . In this spectral region the GENLN2 spectrum is more irregular and probably reflects differences in the spectroscopy. This is all the more evident around 1600  $\text{cm}^{-1}$  where GENLN2 shows significantly larger biases. We interpret this result in terms of the GENLN2 water vapour continuum model. In fact, in the spectral region around 1600  $\text{cm}^{-1}$  the GENLN2 continuum model uses significantly smaller values of the spectral density function (see Fig. 2). To the right side of the band, the structure of the spectra is more irregular. The GENLN spectrum follows more closely the LBLRTM spectrum and in the case of kCARTA we can observe a consistent number of spikes that are not present in the spectra obtained using the other LBL models. This is very apparent around 1740 and 1800  $\text{cm}^{-1}$ . In general, it would appear that LBLRTM tends to fit better the observations although it is difficult to give a conclusive answer since the results can be affected by uncertainties in the water vapour profiles above all in presence of the high water vapour loadings characteristic of tropical conditions. However, we should also note that in the tropics and in the Southern Hemisphere the LBLRTM spectra between 1980 and 2000  $\text{cm}^{-1}$  exhibit larger biases than the GENLN2 and kCARTA spectra.

Since GENLN2 and kCARTA use the same molecular database it is difficult to explain the origin of the large spikes in the kCARTA spectra since these cannot be attributed to the continuum model as shown in the upper panel of Fig. 11. In this panel, we have plotted the difference between the standard kCARTA spectrum and the kCARTA spectrum computed in the tropical region using the LBLRTM continuum (kCARTA.LBL). The spectrum in the upper panel of Fig. 11 shows that in IASI band 2, differences between the kCARTA and LBLRTM continuum can only have a significant impact in the regions at the edges of the band. Hence, the vast majority of the spikes seen in kCARTA cannot be attributed to the continuum model. The same conclusion also applies to the spectra obtained in the other geographical regions although the results are not shown here. It could be argued that the kCARTA spikes could be a feature

of the fast transmittance model used in RTTOV. However, in IASI band 1 and IASI band 2 the predictors used to compute the kCARTA coefficients are the same as those used for the LBLRTM and GENLN2 coefficients. Although the computation of the water vapour coefficients involve the weighting of the input data prior to the regression, to our knowledge the details of the procedure used to perform this operation for the kCARTA coefficients does not differ from the procedure adopted for the GENLN2 and LBLRTM coefficients.

Finally, in the lower panel of Fig. 11 we have superimposed the tropical spectra that show the difference between the kCARTA mean spectrum and the LBLRTM mean spectrum and the difference between the kCARTA\_LBL mean spectrum and the LBLRTM mean spectrum. The spectra in the lower panel of Fig. 11 show that differences between kCARTA and LBLRTM in the region between 1970 and 1990  $\text{cm}^{-1}$  and between 1200 and 1280  $\text{cm}^{-1}$  are almost entirely attributable to the continuum model. The same can be said for the spectra in the Southern Hemisphere although the results are not shown here.

### 5.3 IASI band 3 (2000 to 2760 $\text{cm}^{-1}$ )

Results for IASI band 3 are shown in Figs. 12, 13, and 14 for the Northern Hemisphere, tropics and Southern Hemisphere, respectively. The larger biases between 2080 and 2200  $\text{cm}^{-1}$  in the Southern Hemisphere and in the tropics reflect latitudinal gradients of CO amounts not accounted for in the RT computations. In the same spectral region biases in the Northern Hemisphere vary between  $-0.4$  K and  $0.4$  K reflecting smaller CO latitudinal gradients in this geographical region. Very noticeable are the large spikes in the kCARTA spectra between 2000 and 2150  $\text{cm}^{-1}$ .

#### 5.3.1 Results in the temperature sounding band

The biases observed in the  $\nu_3$ -CO<sub>2</sub> band are larger than the biases observed in the  $\nu_2$ -band. Among the factors that can contribute to this result we can include the ac-

curacy of the spectroscopic parameters and biases in the ECMWF stratospheric and mesospheric temperature profiles. In particular, temperature biases could play an important role in a spectral region that sees the presence of a large number of channels characterized by very high-peaking weighting functions with tails that can extend well into 0.2 hPa. It should also be noted that because of the symmetry of the states involved in the molecular transitions, P/R-branch line mixing is expected to be twice as strong than in the  $\nu_2$ -band.

Between 2200 and 2380  $\text{cm}^{-1}$ , biases in the Northern and Southern Hemisphere assume negative values that vary between  $-1.8\text{ K}$  and  $-0.4\text{ K}$ . LBLRTM and GENLN2 exhibit larger biases around 2260  $\text{cm}^{-1}$  whereas kCARTA exhibits larger biases around 2280  $\text{cm}^{-1}$ . Biases between 2320 and 2380  $\text{cm}^{-1}$  are very similar for all models. In the tropical region we observe the same general pattern. However, when compared to results obtained in the other geographical regions, biases between 2320 and 2380  $\text{cm}^{-1}$  are now smaller whereas biases around 2280  $\text{cm}^{-1}$  are now much larger with GENLN2 attaining values as large as  $-3\text{ K}$ . The similarity between the GENLN2 and LBLRTM spectra is noticeable and we tend to attribute this feature to the line mixing model used in the LBL codes.

As shown in our plots, GENLN2 spectra in the region between 2380 and 2400  $\text{cm}^{-1}$  (i.e. the far wing of the R-branch of the  $\nu_3$  band) exhibit biases that are typically larger than the biases observed in the equivalent kCARTA and LBLRTM spectra. Given the importance of P/R-branch line mixing in this region, we tend to interpret this result as a consequence of errors in the GENLN2 Cousin  $\text{CO}_2$  line shape. If the behaviour of GENLN2 is justified on the grounds of inaccurate line shape, the LBLRTM spectra show that there are still issues with the modelling of  $\text{CO}_2$  line shape in the  $\text{CO}_2$   $\nu_3$ -bandhead. This is also true, albeit to a much lesser extent, for kCARTA. In particular, between 2380 and 2400  $\text{cm}^{-1}$  the LBLRTM spectra show large oscillations whose amplitude can reach almost 3 K in the Northern Hemisphere. It is possible that this result could be associated to biases in the ECMWF temperature profiles but we would like to bring forward the hypothesis that this behaviour might in fact be related to the treatment of the

CO<sub>2</sub> continuum in LBLRTM. Our spectra could indicate that the scaling factor of 0.75 applied to the CO<sub>2</sub> continuum might not be universally valid. This hypothesis seems to be corroborated by the results obtained by Masiello et al. (2009) using aircraft data. They show that changing the scaling factor to the value used in a previous release of LBLRTM can improve the accuracy of the spectra.

### 5.3.2 Results in the window region

Biases in the 2500 cm<sup>-1</sup> window region tend to be influenced by the same factors discussed in Sect. 5.1.3. It should be noted that the water vapour continuum in band 3 is known to a lesser accuracy than in band 1. As in band 1, spectra in the Northern and Southern Hemispheres are closer than spectra in the tropics. However, opposite to what observed in band 1, biases in the Southern Hemisphere tend to be larger than biases in the Northern Hemisphere. Biases are generally negative but a small number of positive values are also observed. In terms of absolute values, biases vary between -0.4 and 0.8 K.

Differences between the spectra largely reflect differences between the continua models. The top panel in Fig. 15 shows the difference between kCARTA and kCARTA\_LBL in the tropical region and illustrates how the change of the continuum model has an impact between 2380 and 2660 cm<sup>-1</sup>. The bottom panel shows that the use of the same continuum model has reduced to naught differences between kCARTA and LBLRTM in the 2440 to 2624 cm<sup>-1</sup> spectral region. Hence, in this spectral region differences between kCARTA and LBLRTM can be attributed solely to the continuum; it would also appear that the kCARTA spectra are in better agreement with observation suggesting that the modifications made to the continuum model have improved the accuracy of RT computations. It should also be noted that, as shown in Fig. 15, between 2400 and 2440 cm<sup>-1</sup> most of the differences between the LBLRTM and kCARTA spectra cannot be attributed to the continuum. In this spectral interval, the broad features of the LBLRTM spectra are more similar to the features of the GENLN2 spectra than to the features of the kCARTA spectra. A possible explanation of this behaviour could

lie in the implementation of the CO<sub>2</sub> continuum. The implementation of the Nitrogen continuum absorption might also play a role although it is an unlikely factor given the fact that kCARTA and LBLRTM use the same model.

Beyond 2624 cm<sup>-1</sup>, differences between the spectra are attributable to the water vapour spectroscopy. This is clearly demonstrated by the fact the kCARTA spectra are in better agreement with the GENLN2 spectra (the two models use the same molecular database). In this region dominated by line absorption, results tend to suggest that the spectroscopic parameters used in LBLRTM fit marginally better the observations.

## 6 Conclusions

Four monitoring experiments have been carried out to compare IASI observed radiances to radiances simulated by the RTTOV fast radiative transfer model using regression coefficients based on the GENLN2, kCARTA and LBLRTM LBL models using different molecular databases. Results obtained from IASI data between the 1 April 2008 and the 15 April 2008 using clear channels (i.e. channels not affected by clouds) over the sea show that in the northern and Southern Hemisphere biases in IASI band 1 and 2 are typically within  $\pm 1$  K. In the tropics, biases in the water vapour  $\nu_2$ -band do increase but for most of the channels the peak-to-peak value is still within  $\pm 1$  K. The larger biases observed in the water vapour band tend to reflect errors in line parameters generated by spectroscopic errors and by the inaccurate specification of the water vapour profiles. The use of the MT\_CKD continuum model results in a reduction up to 1 K of the biases in the region around 1600 cm<sup>-1</sup>. The large biases observed in the ozone band in the Northern Hemisphere probably reflect a poorer performance of the ozone assimilation system in this geographical region. A more accurate description of the CO<sub>2</sub> line shape has a significant impact on the simulated radiances in the CO<sub>2</sub>  $\nu_2$ -band resulting in a reduction of the biases up to 1 K. In the same band, line mixing coefficients based on a first order perturbation theory appear not to be adequate to model the absorption in the Q-branch at 667 cm<sup>-1</sup>. In the important temperature

Interactive Discussion

sounding CO<sub>2</sub> ν<sub>3</sub>-band we obtained biases significantly larger than biases observed in the ν<sub>2</sub>-band and we tend to attribute this result to spectroscopic errors and to biases in the ECMWF temperature profiles. Since the ν<sub>3</sub>-band contains a consistent number of very good temperature sounding channels placed in spectral regions where the interference of different absorbing species is minimal, it is important that updated CO<sub>2</sub> ν<sub>3</sub>-band line parameters be made available to help reducing errors in this band. The kCARTA and LBLRTM improvements in the CO<sub>2</sub> line shape result in smaller biases in the CO<sub>2</sub> ν<sub>3</sub>-band head. However, the LBLRTM spectra display large oscillations not seen in the kCARTA spectra. We have tentatively suggested that this behaviour might be due to the value used for the scaling factor utilized in the LBLRTM CO<sub>2</sub> continuum model. Finally, we want to conclude by noting that we are aware of the limitations inherent in the study of RT and spectroscopic errors using an NWP environment. We have stressed, for instance, that systematic profile errors can affect the results. However, an NWP system offers the unique possibility of using a very robust statistical sample made of a large number of data obtained in very diverse conditions. In many instances, results obtained in this study are consistent with results obtained by using aircraft data in very controlled atmospheric situations albeit their interpretation may differ. This encourages us in continuing pursuing this effort above all in the light of the continuous improvements made in NWP.

*Acknowledgements.* IASI has been developed and built under the responsibility of the Centre National d'Etudes Spatiales (CNES, France). It is flown onboard the Metop satellites as part of the EUMETSAT Polar System. The IASI L1 data are received through the EUMETCast near real time data distribution service. We want to thank P. Brunel (Météo France) for having made available the kCARTA coefficients, C. Clerbaux (Service d'Aéronomie) for having made available concentrations for minor gas species, T. McNally (ECMWF) for the very helpful collaboration received during the set up of the monitoring experiments and A. Collard (ECMWF) and N. Bormann (ECMWF) for the implementation of IASI and RTTOV-9 in the ECMWF data assimilation system.
