

Response to review #1 on acp-2015-1054

Co-benefits of global and regional greenhouse gas mitigation on U.S. air quality in 2050

Yuqiang Zhang, Jared H. Bowden, Zachariah Adelman, Vaishali Naik, Larry W. Horowitz, Steven J. Smith, and J. Jason West

We thank Referee #1 for providing thoughtful comments. We have responded to each comment below and have noted the page and line number for each revision to the manuscript. (blue colors are for referee's comments).

This study used dynamical downscaling to investigate the climate impact on air quality. Based on their previous work West et al. (2013), they applied relatively high resolution (36 km) to further explore some regional features of climate impact on O₃ and PM_{2.5}. The scenarios designed are interesting and I recommend its publication after addressing the concerns below:

The added values in regional models: In the world of dynamical downscaling, researchers try to improve model predictions using regional climate models despite intensive computational resources. It would be very useful if the authors show some comparisons between regional downscaled results and the driven GCM either in meteorology or air quality or both. For meteorology, the authors show changes in Figure S1 to S3, but we are not sure which one performs better. Similar question applies to air quality.

Response: We agree that the comparisons between the global models and downscaled regional models are very important to justify the downscaling work. We have added new analysis to the paper to provide more complete comparisons of both the global and regional models with observations. In Fig. S1, we add comparisons of 2-m temperature (T₂) and precipitation for both the GCM and WRF results with observational data. We compare the T₂ modeled by GFDL AM3 and WRF with 21 years of observations (1979 to 2000) from the North America Regional Reanalysis data (Mesinger et al., 2006). We also compare the precipitation from GFDL AM3 and WRF with 41 years of observations (1948 to 1998) from the Unified US Precipitation data products from NOAA Climate Prediction Center (Higgins et al. 2000). We see that the WRF downscaling helps to resolve important features that influence the average regional climate that are not resolved by GFDL AM3.

We rephrase the sentences in Pg 5 line 18-24 to show these changes:

“We compare the downscaled WRF and the global GFDL AM3 simulations (for three-year averages instead of four to be consistent with CMAQ outputs below), for 2-m temperature (T₂) with 21 years (1979 to 2000) of observation data from the 32-km North America Regional Reanalysis (NARR; Mesinger et al. 2006), and for precipitation with 41 years (1948 to 1998) of observation data from the 0.25° × 0.25° Unified US precipitation data product from NOAA Climate Prediction Center (Higgins et al. 2000). The large-scale spatial patterns for both T₂ and precipitation between WRF and GFDL AM3 are similar (Fig. S1). However, the downscaled simulations help resolve important features that influence the average regional climate, such as those related to topography.”

For air quality, we added new comparisons between MOZART-4 and CMAQ for the simulated 2000 PM_{2.5} and O₃ (see the new Fig S11 in the supporting info). We see that the CMAQ is better in capturing the urban scale air quality than MOZART-4. We add the following text in Pg 9 line 7:

“By comparing the simulated annual PM_{2.5} and O₃ in 2000 (both are three-year averages) between MZ-4 and CMAQ, we see that CMAQ captures urban scale air quality better than MZ-4 (Fig. S11).”

We also show in Fig 2 that the future PM_{2.5} changes for RCP4.5 in 2050 relative to 2000 (also see Fig S16 for comparison between REF in 2050 relative to 2000), are within the ACCMIP ensemble model means for both the MOZART-4 results and CMAQ results. For future O₃ changes for RCP4.5 in 2050 relative to 2000, the results between MOZART-4 and CMAQ are similar. Spatially, we compare the total co-benefits for both PM_{2.5} and O₃ between MOZART-4 and CMAQ in Fig S20-S25. As for the 2000 comparison, we see that CMAQ better simulates air quality changes in urban environments at finer scale. So we add one sentence in Pg 9 Line 27 “CMAQ better simulates air quality changes in urban environments at a finer scale compared with MZ-4.”

Figure S2 and Figure S3: the change in precipitation The values seem to be huge. The Figure S1 in the supporting information in Gao et al, 2014 (Gao et al., 2014, Robust spring drying in the southwestern U.S. and seasonal migration of wet/dry patterns in a warmer climate, *Geophys. Res. Lett.*, 41, 1745–1751) shows the average annual precipitation of US is smaller than 5 mm/day (see the top left panel from that figure). Mean summer precipitation change was shown in Figure 20 in the following paper (Eric D. Maloney, et al., 2014: North American Climate in CMIP5 Experiments: Part III: Assessment of Twenty-First-Century Projections. *J. Climate*, 27, 2230–2270), and mean winter precipitation was shown in Figure 1 in the following paper (Neelin et al., 2013: California Winter Precipitation Change under Global Warming in the Coupled Model Intercomparison Project Phase 5 Ensemble. *J. Climate*, 26, 6238–6256). Both of these two papers show increase of precipitation at about 1-2 mm/day from CMIP5 multi-ensemble mean results. The statement on Page 5, Line 25, “US average increase of precipitation 8.16 and 7.63 mm/day” is a rather large value. Please double check the WRF simulations. In addition, please look at historical precipitation, and see if it is comparable to PRISM (top left panel of the figure below; PRISM is an observational dataset). This comment also applies to Fig. 1 in the main paper showing large differences in precipitation between RCP 4.5 and RCP 8.5. Thus, to have a reasonable historical 3-year precipitation spatial distribution is essential before these comparisons make sense. Page 5, Line 29-30: “However, the only region where the regional climate is warmer and drier in RCP 4.5 is in the Northwest US”. This statement does not make too much sense. Because RCP 4.5 mostly show smaller warming than RCP 8.5, which is expected, thus, the statement regarding “drier” should not combine with the warming statement. In particular, I am afraid this feature from a single model WRF may not be robust.

Response: We thank the reviewer for calling our attention to this error and for providing detailed references. We became aware of this error soon after this paper was submitted, and found that it was due to our miscalculation of rainfall changes. We corrected this error in the new manuscript by replacing the plots in Fig 1 (b), Fig. S2(b) and Fig. S3(b). Please see Pg 5 Lines 25-26:

“Additionally, precipitation is projected to decrease over most of the U.S. in both scenarios, with U.S. average decreases of 0.20 and 0.15 mm day⁻¹ in RCP8.5 and RCP4.5.” Also, as mentioned

in our first response, we compared WRF and GFDL AM3 annual average precipitation against CPC Unified Precipitation. We used the CPC precipitation instead of PRISM because of the horizontal resolution of CPC is of closer to WRF.

We deleted this text as suggested by the reviewer (Pg 5, Line 29-30):

“However, the only region where the regional climate is warmer and drier in RCP 4.5 is in the Northwest US”.

Section 3.5: Co-benefit from domestic and foreign GHG mitigation. For domestic effect: S_Dom vs. S_REF (in Table 1). This is fine since the only differences between these two scenarios are emissions in US For foreign GHG mitigation: the authors compared S_RCP45 vs. S_Dom. I don't think these two scenarios can be interpreted as foreign GHG mitigation effect. Although the authors pointed out the limitations on Page 13 (Lines 11-15), I think the effect from US could be quite large. Since the authors did not conduct an experiment by reducing GHG over other countries only, the discussions related to foreign GHG mitigation should be revised (Figs. 7,8)

Response: We have constructed the scenarios to separate the total co-benefits (S_RCP45—S_REF) into components due to domestic emissions reductions (S_Dom—S_REF) and foreign emission reductions (S_RCP45—S_Dom). In comparing S_Dom and S_REF, the only difference is domestic air pollutant emissions. This provides a clean comparison to give an understanding of the importance of domestic emission changes, although it neglects the effect of US emissions on air quality through changes in global climate (via GHGs), regional climate (via short-lived climate pollutants), and methane. We consider that global climate and methane are mainly due to foreign emissions (as US emissions are much smaller than the rest of the world) and we neglect possible changes in regional climate from reductions in US short-lived climate pollutants.

We mainly focus on the effect of domestic reductions and compare that with the total. But we also find the effects of foreign reductions by simple subtraction (S_RCP45—S_REF) – (S_Dom—S_REF) = S_RCP45—S_Dom. In doing so, we attribute the effects of all climate changes and methane changes to foreign reductions (as most GHGs and methane are from foreign sources). Doing more work to better understand changes in regional climate due to emission mitigation, and to attribute those changes to US emissions, would require extra simulations with WRF, SMOKE, and CMAQ; as these are computationally intensive, they are beyond what we can perform for this study.

We have improved the text in the Methods sections to better clarify the logic of our simulation design, and to better communicate its limitations (Pg 8 line 3):

“By comparing S_Dom (applying GHG mitigation from RCP4.5 scenario in the U.S. only) with S_REF, and S_RCP45 with S_Dom, we quantify the co-benefits from domestic and foreign GHG mitigation. The co-benefits from foreign reductions are found by simple subtraction (S_RCP45 – S_REF) – (S_Dom – S_REF) = S_RCP45 – S_Dom. In estimating the co-benefits of domestic reductions, we account for the influences of methane and of global climate change as foreign influences (as most methane and GHG emissions are outside of the U.S.), and assume that U.S. air pollutant emissions have small effects on global or regional climate, such as through aerosol forcing.”

There are quite a few places showing website link and accessed by a certain date. I suggest to move those links as footnotes and remove the words of “accessed date ***”.

Response: According to the ACP website:

http://www.atmospheric-chemistry-and-physics.net/for_authors/manuscript_preparation.html

Footnotes: *These should be avoided, as they tend to disrupt the flow of the text. If absolutely necessary, they should be numbered consecutively. Footnotes to tables should be marked by lowercase letters.)*

We have chosen to keep these as they are. If the paper is accepted for publication, we will consult with the editor on whether our format is proper.

Page 8, Line 24-25 The authors claimed that US EPA (2007) recommended use median instead of mean for evaluation. In fact, I did not find this statement. US EPA (2007) does recommend NMB, MNB, and a few other metrics MFB, MFE. They also showed benchmarks (Page 252-261), although there is a range of the benchmarks. The biases (in %) shown in Table 3 is relatively small. However, I am not quite sure the evaluation of median is a good way. Did the authors look at the mean in other way if the authors do not prefer to show metrics with mean value, i.e., spatial patterns?

Response: The right reference should be from Appel et al. (2008) instead of the EPA (2007) report. We corrected in the main paper. Appel et al. (2008) suggested to use “median” over “mean” when the species evaluated are not normally distributed, which is common for PM species. They also suggested that if the data were normally distributed, the mean and median would be the same (section 4 paragraph 5 in Appel et al., 2008).

Page 8, Line 30 “emissions are derived from global datasets rather than specific emissions for US” The authors mentioned in section 2.2 that they used SMOKE to process emissions. I don’t quite understand why the emissions are not specific for US.

Response: Here we mean that we are not using the NEI 2001 emission dataset, and instead downscale from the global RCP emissions in 2000. We rephrase this sentence to make it more clearly in Pg 8 Line 29-30:

“Model performance is not expected to be perfect as meteorology does not correspond with actual year 2000 meteorology, and emissions are derived from global datasets rather than the specific NEI dataset for the U.S.”

Page 9, Line 15 “NO_x titration” should be “NO titration” Figure S14: S_RCP45 is largely due to NO titration. However, in Figure S13, RCP 8.5 scenario or REF scenario, increase in methane concentration should play a big role in ozone increases. In fact, line 9-18 of Page 9 refers to the figures in the supporting information, which may not be an ideal way to present.

Response: We changed from “NO_x titration” to “NO titration”. See Pg 9, Line 15.

We agree that methane increases in RCP8.5 plays an important role in winter O₃ increases in the U.S., as suggested by the sensitivity simulation of Gao et al., (2013). We added new sentences in Pg 9, line 15-16:

“O₃ increases over the Northeast and West U.S. in winter in both S_REF and S_RCP45, caused by the weakened NO titration as a result of the large NO decrease in the two scenarios (Table 2), as also reported by other studies (Gao et al., 2013; Fiore et al., 2015), and as well as the large methane increases in RCP8.5 (Gao et al., 2013).”

With respect to the fact that Figures S12-S15 are in the supporting information, we have chosen to emphasize the co-benefits (Section 3.3) in this paper and so have included figures addressing the co-benefits in the main paper (Figs. 3-5). The changes relative to the year 2000 (Section 3.2) are included in the paper mainly as backdrop for understanding the future simulations, and for comparison against other studies that simulated 2050 relative to 2000 for these same scenarios. We appreciate the reviewer's suggestion to put one or more of these figures in the main paper, but have chosen to keep them in the supporting information so that the main paper will not be excessively long.

Page 10, line 25-26 and Table 1 for S_Emis and S_REF. These two scenarios (S_Emis and S_REF) were used to evaluate the impact from emissions. Since in standard RCP 8.5, methane concentrations show dramatic increase which is closely related to ozone concentrations. My question is whether CH₄ should keep the same as S_REF in S_Emis so as to be considered as RCP 8.5.

Response: By comparing between S_REF and S_Emis, we want to see the effect of global emission reductions from the RCP4.5 scenario, separate from changes in climate. These are the two mechanisms of co-benefits identified and quantified by West et al. (2013). We use methane concentrations from RCP4.5 in S_Emis to simulate the effect of all emission reductions, including both methane and short-lived air pollutants. The reviewer asks about RCP8.5, but we use the REF scenario for emissions throughout the paper and not RCP8.5. This design of scenarios (Table 1) is consistent with the global simulations of West et al., (2013). We have added text to the discussion of Table 1 to clarify that methane decreases in S_Emis (Page 8, Line 1-3): "The emission benefit from the first mechanism is calculated as the difference between S_Emis and S_REF, for which the change in methane concentration is included as an emission benefit, and the meteorology benefit is calculated as S_RCP45 minus S_Emis."

Fig. 6 (Page 29) should have titles for readers easy to recognize. The note of S_Emis-S_REF (described on Page 10, Line 26) is also useful to be added in the titles.

Response: We added the notes of "S_Emis-S_REF" and "S_RCP45-S_Emis" into Fig 6. We also added the notes in Fig 7.

Page 13, Line 8 "only one model is used at each step during downscaling". This sentence needs to be rephrased. For example, simply removing "at each step" may work better.

Response: We have revised text in Pg 13 line 8 as:

"Moreover, only one model is used during downscaling for regional climate (WRF) and air quality (CMAQ) modeling, and the mean of a model ensemble can be used to reduce model error."

Response to review #2 on acp-2015-1054

Co-benefits of global and regional greenhouse gas mitigation on U.S. air quality in 2050

Yuqiang Zhang, Jared H. Bowden, Zachariah Adelman, Vaishali Naik, Larry W. Horowitz, Steven J. Smith, and J. Jason West

We thank referee #2 for the positive and constructive suggestions and comments, which have helped us improve the manuscript. All comments have been carefully addressed here (blue colors are for referee's comments), and we have tracked all changes in the revised manuscript.

The authors expand a previous study using dynamical downscaling and global emissions inventories in order to evaluate the impacts of global climate policy and climate change on regional air quality in the US, and compare these impacts to those modeled (in a consistent manner) at a coarser resolution. This study provides many valuable contributions including comparisons of: (1) regional vs global scale air quality co-benefits of consistent GHG emissions scenarios both with and without a climate policy (2) domestic vs foreign contributions of GHG emissions/policy to US air quality co-benefits (3) the effects of GHG policy on co-emitted pollutants vs changing climate on co-benefits. The study is ready for publication after a few minor revisions, assuming the units reported for the average change in rainfall amounts were a mistake.

Response: The reviewer is correct that the rainfall changes were wrong by miscalculation, and we have corrected this error in the new manuscript, Fig 1 (b), Fig. S2(b) and Fig. S3(b). Please see Pg 5 Lines 25-26: "Additionally, precipitation is projected to decrease over most of the U.S. in both scenarios with U.S. average decrease of 0.20 and 0.15 mm day⁻¹ in RCP8.5 and RCP4.5."

Given the importance of foreign GHG policies on US ozone, it would be helpful to see more information about the source of those rather large decreases in domestic ozone. There were two places where the paper suggested that global (but non-US) methane was the largest contributor to changes in domestic ozone, but it would be extremely helpful if that could be quantified, or discussed in more detail especially in light of the issue areas of the western US seems to be having with the idea of meeting more stringent ozone targets given these large contributions from "background" or "uncontrollable" sources. And if the reduction in methane concentration (as reported in Table 1) is indeed the largest source of the reduction of domestic ozone, what does that look like with respect to emissions? This finding was a big take-away from the paper and so more information about it from the policy perspective would be valuable.

Response: We agree that it would be useful to quantify the influence of global methane changes under RCP4.5 on U.S. ozone with extra sensitivity simulations. However doing so will require more simulations of both global and regional models. Considering the intense computational requirement, we are unable to perform these extra model simulations here. We suspect that methane emissions are very important because there is a large difference in methane between REF and RCP4.5. For the global co-benefits study (West et al., 2013), we tried to estimate the methane contribution by multiplying the change in methane by the present-day sensitivity of ozone to methane, which yielded a very large ozone change that was greater than the total change. The problem is that 2050 precursor emissions are lower than at present, and so the sensitivity to methane would also be lower. Without extra simulations, we cannot quantify this effect.

Methane is included in both the global and regional model as a fixed global concentration, but at the Referee's request, we have reported the global anthropogenic emissions that these correspond to (Pg 11 Line 11): "This large influence of foreign reductions for O₃ highlights the importance of global methane reductions in RCP4.5 (anthropogenic emissions of 330 Tg yr⁻¹ in 2050 in RCP4.5, compared to 432 Tg yr⁻¹ in REF), and air pollutant emission reductions particularly in Asia and intercontinental transport.

Can you also clarify why US methane is not included? Even if inventory suggests it is small.

Response: The US methane emissions are only a small fraction of the global CH₄ emissions (32 Tg yr⁻¹ in REF in 2050, 7.4% of the anthropogenic total). We didn't model the effects of methane emissions directly, but instead use fixed concentrations of methane in 2050 that correspond with the emissions in the different scenarios. It would be possible to calculate the change in global methane concentration associated with US methane emissions alone (or foreign emissions alone), but that calculation would be uncertain. Doing so would also require additional simulations with the global model MOZART-4 in addition to CMAQ. Instead we chose to treat methane emissions as entirely from foreign sources and acknowledge the small error involved.

To address the reviewer's concern, we rephrase the sentence in Pg 8 line 7-9:

"In each scenario, we fix global methane at concentrations given by the RCPs (Table 1), and account for methane changes as a foreign influence, neglecting the fraction of global anthropogenic methane emissions that are from the U.S. (7.4% in 2050 REF scenario and 7.0% in 2050 RCP4.5)."

There seems to be some inconsistency between the original spatial distribution of emissions from the global inventories and the spatial allocation that was used for regional modeling of both emissions and meteorology. You mention that a benefit to using the global emission inventories (versus projecting the NEI) is that they take into account changing land use. But wouldn't both WRF and SMOKE use land use data that is both constant between 2000 and 2050, and inconsistent with the global representation?

Also, it is not clear to me how the emissions downscaling methods you used would provide any additional spatial detail (greater than that provided at a 0.5 x 0.5 degree level)? It seems that for VOCs and PM, there is detail added by scaling un-specified totals by the speciation profile of the predominant source in each grid cell? But if I'm understanding your methods correctly, for any species other than VOC or primary PM there actually isn't any improvement in spatial allocation? If that is true, this is a downside you should mention as it would essentially smear your emissions out to the global scale resolution. But perhaps I'm missing something, in which case, your paper would benefit from more clarity in this regard.

Response: We address these related comments together. The reviewer is right that we use constant (year 2000) land use and land cover in both the WRF and CMAQ simulations. This would lead to inconsistencies in the land use and land cover distributions and the spatial distribution of emissions. For CMAQ this would be important, for example, for biogenic VOC emissions. We are not aware of any downscaling study that simulates spatial distributions land use changes and anthropogenic emissions in a way that is completely consistent, and we are planning to do work that increases this consistency in the future.

For anthropogenic emissions, however, we account for future land use changes and their effects on the spatial distribution of emissions in the two scenarios. In the paper, we contrast our emission downscaling method with the traditional NEI scaling method, which multiplies the spatial emissions from the current NEI by a national mass ratio between the future emissions and the current NEI. By doing this, the traditional method assumes that the air pollutant spatial distributions in the future stay the same as the current NEI. In contrast, we use the projected RCP emissions datasets that include projected changes in the spatial distribution of emissions at 0.5×0.5 degree resolution, and regrid those to the CMAQ grid (36 km). Because we simply regrid the RCP emissions, our methods do not provide additional spatial detail beyond what is provided by the RCPs at 0.5 degree resolution. Our results show that the spatial distribution of emissions do change in the future (rightmost plots in Figs. S4-S10).

We have added text in Pg 6 line 10 to the paper to acknowledge the inconsistency in land use assumptions:

“We use constant (year 2000) land use and land cover for all simulations in WRF and CMAQ, whereas the spatial distributions of anthropogenic emissions change in the RCP scenarios.”

To clarify, we add text in section 2.2 Pg 6 line 4:

“By doing this, the traditional method assumes that future spatial distributions of emissions stay the same as the current NEI.”

We rephrase text in Pg 6 line 9-10:

“By regridding the REF and RCP4.5 data, we account better for changes in the spatial distribution of future emissions projected in the RCPs (Figs. S4-S10), but do not provide additional spatial detail beyond what is provided by the RCPs at 0.5 degree resolution,”

I was glad to see more details on the relative changes to different PM species as a result of the GHG policies and climate impacts, however, it was not clear why OM is the largest change? That would seem related to the changing climate, less so changing emissions, but changing emissions dominate so that doesn't explain what is going on with OM.

Response: The OM decreases are dominated by the decrease of primary organic carbon (POC, $0.074 \mu\text{g m}^{-3}$ decreases). By adding new figures showing the OM component changes from emission reductions and climate (Fig S19 in the supporting info), we see that the POC decreases are mainly caused by emission reductions, and the SOA decreases by changing climate. To clarify, we add the following text in Pg 10 Line 30 “In Fig. S18, the OM decrease is caused mainly by primary organic carbon (POC, $0.074 \mu\text{g m}^{-3}$ decreases), followed by biogenic SOA (ORGB, $0.057 \mu\text{g m}^{-3}$) and non-carbon organic matter (NCOM, $0.048 \mu\text{g m}^{-3}$). The POC and NCOM decreases are caused mainly by emission reductions, while the SOA decrease is caused mainly by changing climate (Fig. S19).”

Page 5, line 25: That unit can't be correct. ??

Response: We corrected magnitude change for precipitation in the manuscript, as well as Fig. 1(b), Fig. S2(b) and Fig. S3(b).

Page 6, line 18-19: This sentence is not clear. Why not use the spatial allocation data available through SMOKE, or is that what you mean here?

Response: This sentence refers to our method of back-calculating total PM emissions from BC and OC, and does not refer to the spatial allocation of emissions. When we downscale the RCP emissions for CMAQ, there are more than one sub-categories inside one sector, e.g., the sector “Industries” includes emissions from “1A2_2A_B_C_D_E” as listed in Table S1. SMOKE provides more detailed sub-category information for the emission sectors. So when we match the emission sectors between the global RCPs and SMOKE, there usually are more than one category, and the speciation cross-reference files are slightly different between each sub-category. When that happens, we use the speciation cross-reference file from the sub-category with largest mass fraction in this sector, following the methods of Reff et al. (2009) and Xing et al. (2013).

To make it more clearly, we revise the sentence in Pg 6 line 18-19:

“In back-calculating total PM emissions from BC and OC, there are usually more than one sub-category within one sector, e.g., the sector “Industries” includes emissions from the sub-category of “1A2_2A_B_C_D_E” (Table S1). When that happens, we use the speciation cross-reference file from the sub-category with largest mass fraction in this sector, following the methods of Reff et al. (2009) and Xing et al. (2013).”

[Page 8, line 24-26: it seems you used median for both ozone and PM2.5? Can you justify?](#)

Response: From a recent CMAQ evaluation paper (Appel et al., 2008), they suggested using “median” over “mean” when the species evaluated are not normally distributed, which is commonly the case for PM species. They also suggested if the data were normally distributed, the mean and median would be the same. We provided the right reference for this sentence in the new manuscript.

[Page 9, line 6: These are switched, are they not? Over-prediction is higher for MDA8?](#)

Response: Yes, and it should be “The overprediction is slightly lower for 1hr-O₃ than for MDA8-O₃”. We fixed in the new manuscript (Pg 7, line 6).

[Page 13, line 5-7: Seems there is an error in this sentence.](#)

Response: We used spectral nudging in our WRF downscaling studies, and meant to compare here with “analysis nudging”. We updated in the new manuscript Pg 13 Line 5-7:

“Spectral nudging is adopted in this study to restrain WRF from drifting from the GCM, which has been shown to be better for some meteorological variables, but analysis nudging better for others (Bowden et al., 2012, 2013; Liu et al., 2012; Otte et al., 2012).”

Co-benefits of global and regional greenhouse gas mitigation on U.S. air quality in 2050

Abstract. Policies to mitigate greenhouse gas (GHG) emissions will not only slow climate change, but can also have ancillary benefits of improved air quality. Here we examine the co-benefits of both global and regional GHG mitigation on U.S. air quality in 2050 at fine resolution, using dynamical downscaling methods, building on a previous global co-benefits study (West et al., 2013). The co-benefits for U.S. air quality are quantified via two mechanisms: through reductions in co-emitted air pollutants from the same sources, and by slowing climate change and its influence on air quality, following West et al. (2013). Additionally, we separate the total co-benefits into contributions from domestic GHG mitigation versus mitigation in foreign countries. We use the WRF model to dynamically downscale future global climate to the regional scale, the SMOKE program to directly process global anthropogenic emissions into the regional domain, and we provide dynamical boundary conditions from global simulations to the regional CMAQ model. The total co-benefits of global GHG mitigation from the RCP4.5 scenario compared with its reference are estimated to be higher in the eastern U.S. (ranging from 0.6-1.0 $\mu\text{g m}^{-3}$) than the west (0-0.4 $\mu\text{g m}^{-3}$) for $\text{PM}_{2.5}$, with an average of 0.47 $\mu\text{g m}^{-3}$ over U.S.; for O_3 , the total co-benefits are more uniform at 2-5 ppb with U.S. average of 3.55 ppb. Comparing the two mechanisms of co-benefits, we find that reductions of co-emitted air pollutants have a much greater influence on both $\text{PM}_{2.5}$ (96% of the total co-benefits) and O_3 (89% of the total) than the second co-benefits mechanism via slowing climate change, consistent with West et al. (2013). GHG mitigation from foreign countries contributes more to the U.S. O_3 reduction (76% of the total) than that from domestic GHG mitigation only (24%), highlighting the importance of global methane reductions and the intercontinental transport of air pollutants. For $\text{PM}_{2.5}$, the benefits of domestic GHG control are greater (74% of total). Since foreign contributions to co-benefits can be substantial, with foreign O_3 benefits much larger than those from domestic reductions, previous studies that focus on local or regional co-benefits may greatly underestimate the total co-benefits of global GHG reductions. We conclude that the U.S. can gain significantly greater domestic air quality co-benefits by engaging with other nations to control GHGs.

1 Introduction

Climate change and air quality are interrelated problems. First, climate change can affect the formation, destruction and transport of major air pollutants, through changes in meteorological variables of temperature, precipitation, air stagnation events, etc. (Weaver et al., 2009; Jacob and Winner, 2009; Fiore et al., 2012, 2015). It can also affect natural emissions (biogenic, dust, fire and lightning) that influence air quality. Second, air pollutants such as particulate matter (PM) and ozone (O₃) can change the climate by altering the solar and terrestrial radiation balance through direct and indirect effects (Myhre et al., 2013). Third, the sources of emissions of greenhouse gases (GHGs) and air pollutants are usually shared, particularly through the combustion of fossil fuels, so actions to control one can also influence emissions of the other. Policies to control GHG emissions will therefore not only slow climate change in the future, but will also provide co-benefits of improvements to air quality and consequently to human health (Bell et al., 2008; Nemet et al., 2010).

Recent studies that model future air quality have focused on single or combined changes in future climate and emissions on global and regional air quality, using both global and regional Chemical Transport Models (CTMs) (Weaver et al., 2009; Jacob and Winner, 2009; Fiore et al., 2012). Climate change is likely to decrease background O₃ over remote places due to the elevated humidity, and increase O₃ over urban and polluted areas, in part because of higher temperature. Jacob and Winner (2009) concluded that future climate change could increase summertime O₃ by 1-10 ppb over polluted regions in the U.S. in scenarios from the Special Report on Emission Scenarios (SRES; Nakicenovic and Swart, 2000). In one study, climate change in 2050 under the SRES A1B scenario is projected to increase summertime O₃ by 2-5 ppb over large areas in the U.S., comparable to the effect of reduced anthropogenic emissions of O₃ precursors which reduces O₃ by 2-15 ppb, especially in the east (Wu et al., 2008). The overall effect of climate change on PM is less clear, as different components of PM may respond differently to changes in climate variables (Jacob and Winner, 2009; Tai et al., 2010; Fiore et al., 2012, 2015).

Many studies have also estimated the co-benefits of regional or local GHG mitigation on air quality and human health through reductions in co-emitted air pollutants. Cifuentes et al. (2001) found that GHG mitigation through reduced fossil fuel combustion could bring significant local air pollution-related health benefits to some megacities. These health benefits have been estimated in many studies (Bell et al., 2008), and give co-benefits ranging from \$2–196 /tCO₂ when monetized, comparable to the costs of GHG reductions (Nemet et al., 2010). A few studies also analyze the co-benefits on future air quality and human health from future regional GHG mitigation scenarios (Thompson et al., 2014; Trail et al., 2015). Thompson et al. (2014) studied the co-benefits of different U.S. climate policies on 2030 domestic air quality, and found that when monetized, the human health benefits due to the improved air quality can offset 26–1050% of the cost of the carbon policies, depending on the policy.

These co-benefits studies may underestimate the total co-benefits as they only consider local or regional climate policies, neglecting benefits outside of the region considered, and benefits within those regions from global GHG mitigation. The total co-benefits of global mitigation are relevant as meaningful GHG mitigation requires participation from at least several of the most highly-emitting nations. We examined the co-benefits of global GHG reductions on both global and regional air quality

and human health, using a global atmospheric model (Model for OZone And Related chemical Tracers, version 4, MOZART-4, hereafter referred to as MZ4) and self-consistent future scenarios (West et al., 2013, referenced hereafter as WEST2013). In addition to evaluating co-benefits through reductions in co-emitted air pollutants, WEST2013 was the first study to quantify co-benefits through a second mechanism: slowing climate change and its effects on air quality. There are several other innovations of WEST2013: we account for global air pollution transport and long-term influences of methane using the global CTM; we consider realistic scenarios in which air pollutant emissions, demographics, and economic valuation are modeled consistently; and we evaluate chronic mortality influences of fine PM (PM_{2.5}, PM with diameter smaller than 2.5 μm) as well as O₃. WEST2013 concluded that global GHG mitigation could bring significant air quality improvement for both PM_{2.5} and O₃, and avoid 2.2±0.8 million premature deaths globally by 2100 due to the improved air quality. When monetized, the global average marginal co-benefits of avoided mortality were \$50–380/tCO₂, higher than the previous estimates (Nemet et al., 2010). The co-benefits from the first mechanism of reduced co-emitted air pollutants were shown to be much greater than the co-benefits from the second mechanism via slowing climate change.

The WEST2013 study is limited by the coarse resolution of the CTM used (2°×2.5° horizontally). Here we investigate the co-benefits of global GHG mitigation on U.S. air quality at much finer resolution (36km×36km), building on the scenarios in the global study. WEST2013 simulated co-benefits in 2030, 2050, and 2100, and we choose here to downscale the results in 2050, as climate change influences air quality by 2050 and it is within the timeframe of current decision-making for both climate change and air quality. We use a comprehensive modeling framework in the downscaling process, including a regional climate model to dynamically downscale the global climate to the contiguous United States (CONUS), an emissions processing program to directly process the global anthropogenic emissions to the regional scale, and we create dynamical boundary conditions (BCs) from the global co-benefits outputs for the regional CTM. We quantify the total co-benefits of global GHG mitigation on U.S. air quality for both PM_{2.5} and O₃, and then separate the co-benefits from the two mechanisms analyzed by WEST2013. We also quantify the co-benefits from domestic GHG mitigation versus the co-benefits from those of foreign countries' reductions. We then present the co-benefits from global and domestic GHG mitigation on nine U.S. regions.

With regard to previous studies on the effect of climate change on future air quality (e.g. Jacob and Winner, 2009), our work differs in our reframing of this impact as a co-benefit of slowing climate change from GHG mitigation, and by analyzing that co-benefit through realistic future scenarios, following WEST2013. With regard to previous co-benefits studies that have been conducted on a regional scale (e.g., Thompson et al., 2014), this research differs by embedding the regional co-benefits study in consistent global context, accounting for the effects of changes in global air pollutant emissions and climate change on U.S. air quality.

30

2 Methodology

Future air quality changes under global and regional GHG mitigation scenarios are simulated using a regional CTM. The scenarios modeled here are built on those of WEST2013, who compared the Representative Concentration Pathway 4.5 (RCP4.5) scenario with its associated reference scenario (REF). Air pollutant emissions in REF are state of the art long-term emissions projections created by using the Global Change Assessment Model (GCAM) (Thomson et al., 2011). RCP4.5 was developed based on REF by applying a global carbon price to all world regions and all sectors including carbon in terrestrial systems. As discussed by van Vuuren et al. (2011), the air pollutant emissions for the four RCP scenarios were prepared by different groups using different models and assumptions, so they are inconsistent with one another. But by comparing REF with RCP4.5, we use a self-consistent pair of scenarios, where the difference is uniquely attributed to a climate policy. WEST2013 used both emissions and meteorology from RCP4.5 to simulate future air quality under the RCP4.5 climate policy, and used emissions from REF and meteorology from RCP8.5 to simulate future air quality assuming no climate policy. Since no General Circulation Model (GCM) conducted future climate simulations for the REF scenario, RCP8.5 is used as a proxy for the future climate under REF. The differences between these two scenarios give the total co-benefits for future air quality under climate policy from RCP4.5. Through one extra simulation with emissions from RCP4.5 together with RCP8.5 meteorology (e45m85 in Table 1), and by comparing with REF and RCP4.5, WEST2013 separated the total co-benefits into the two mechanisms: the co-benefits from reductions in co-emitted air pollutants, and co-benefits from slowing climate change and its influence on air quality.

Here we conduct downscaling processes to provide fine-resolution inputs for the regional CTM. We use the Weather Research and Forecasting model version 3.4.1 (WRF, Skamarock and Klemp, 2008) to downscale the future global climate from the GCM to the regional scale at a horizontal resolution of 36×36 km for the CONUS. We directly process global anthropogenic emissions to regional scale using the Sparse Matrix Operator Kernel Emissions (SMOKE, v3.5, <https://www.cmascenter.org/smoke/>) program. The outputs from the global MZ4 simulations of WEST2013 (Table 1) are downscaled to provide initial condition (IC) and dynamic hourly BCs for the regional CTM. The latest version of the Community Multi-scale Air Quality model (CMAQ, v5.0.1, Byun and Schere, 2006) is used as the regional CTM to simulate air quality changes over the CONUS domain. WEST2013 simulated five consecutive years for each scenario, and used the last four years' average for the data analysis with the first year as a spin-up. Due to the limitations of computational resources, we run CMAQ for 40 months consecutively for each scenario, with the first 4 months as spin-up, and analyze the results as three-year averages.

2.1 Regional meteorology

WEST2013 used NOAA Geophysical Fluid Dynamics Laboratory (GFDL) atmospheric model AM3 (Donner et al., 2011; Naik et al., 2013) simulations to provide global meteorology for MZ4. Here we dynamically downscale GFDL AM3, which has a horizontal resolution of 2°×2.5°, to 36×36 km over the CONUS using the WRF model. GFDL AM3 meteorology for the

two RCP scenarios (RCP8.5 and RCP4.5) in 2050 used by WEST2013 is downscaled using a one-way nesting configuration for five consecutive years. WRF is initialized at 0000 Coordinated Universal Time (UTC) 1 January 2048 and run for a 12-month spin-up, then run continuously through 0000 UTC 1 January 2053. A historical period from GFDL AM3 is also downscaled with WRF initialized at 0000UTC 1 January 1999 and run for a 12-month spin-up, then run continuously through 5 0000 UTC 1 January 2004. The WRF physics options include the Rapid Radiative Transfer Model for global climate models (Iacono et al., 2008) for longwave and shortwave radiation, WRF single-moment 6-class microphysics scheme (Hong and Lim, 2006), the Grell ensemble convective parameterization scheme (Grell and Devenyi, 2002), the Yonsei University planetary boundary layer scheme (Hong et al., 2006), and the Noah land surface model (Chen and Dudhia, 2001). The WRF configuration also applies spectral nudging. Otte et al. (2012) and Bowden et al. (2012, 2013) demonstrated that using nudging 10 in WRF improves the overall accuracy of the simulated climate over the CONUS at 36-km and does not squelch extremes in temperature and precipitation. In particular, spectral nudging affects the model solution through a nonphysical term in the prognostic equations based on the difference between the spectral decomposition of the model solution and the reference analysis. Spectral nudging is used to constrain WRF toward synoptic-scale wavelengths resolved by GFDL AM3 exceeding 1200 km. Nudging is applied equally to potential temperature, wind, and geopotential with a nudging coefficient of 1.0×10^{-4} , 15 which is equivalent to a time scale of 2.8 hours. The downscaled meteorology from WRF is used to provide meteorological inputs to CMAQ. Hourly WRF outputs are processed using Meteorology-Chemistry Interface Processor (MCIP v4.1; Otte and Pleim, 2010) to provide meteorological inputs for CMAQ.

We compare the downscaled WRF and the global GFDL AM3 simulations (for three-year averages instead of four to be consistent with CMAQ outputs below), for 2-m temperature (T2) with 21 years (1979 to 2000) of observation data from the 20 32-km North America Regional Reanalysis (NARR, Mesinger et al. 2006), and for precipitation with 41 years (1948 to 1998) of observation data from the $0.25^\circ \times 0.25^\circ$ Unified US precipitation data product from NOAA Climate Prediction Center (Higgins et al. 2000). The large-scale spatial patterns for both T2 and precipitation between WRF and GFDL AM3 are similar (Fig. S1). However, the downscaled simulations help resolve important features that influences the average regional climate, such as those related to topography. Comparing WRF future projected change centered on 2050 with 2000, we see that the 25 three-year average of T2 generally increases over the entire U.S. for both RCP8.5 and RCP4.5 (Fig. S2-S3). Temperature increases are largest for extreme northeastern latitudes, the Southeast and Southwest U.S. in both scenarios, with U.S. average warming of 3.05°C and 2.59°C for RCP8.5 and RCP4.5, respectively. Additionally, precipitation is projected to decrease over most of the U.S. in both scenarios with U.S. average decrease of 0.20 and 0.15 mm day⁻¹ in RCP8.5 and RCP4.5. Comparing the changes between scenarios (RCP8.5 minus RCP4.5), Fig. 1 illustrates that temperature increases are smaller in RCP4.5 30 throughout the CONUS, except in the Northwest. The precipitation difference between scenarios has a larger spatial variability than the T2. Ignoring other influences of climate change, decreases in precipitation would be expected to decrease PM wet scavenging, and increase PM concentration.

2.2 Regional emissions

Similar studies in the past have typically chosen to run SMOKE with the present-day U.S. National Emission Inventory (NEI), and then scale the SMOKE outputs into future years, using the mass ratio of projected future to present-day emissions from global inventories (e.g., Hogrefe et al., 2004; Nolte et al., 2008; Avise et al., 2009; Chen et al., 2009; Gao et al., 2013). By doing this, the traditional method assumes that future spatial distributions of emissions stay the same as the current NEI. Instead, we use SMOKE to directly process the global emissions in 2000 and in 2050 from REF and RCP4.5 to provide temporally- and spatially-resolved CMAQ emission input files. We first regrid the global emissions datasets at $0.5^{\circ} \times 0.5^{\circ}$ into finer resolution ($36\text{km} \times 36\text{km}$), and then apply source-specific temporal and speciation profiles from the NEI to assign temporal variations and re-speciate the PM and VOCs species. By regridding the REF and RCP4.5 data, we account better for changes in the spatial distribution changes of future emissions projected in the RCPs (Figs. S4-S10), but do not provide additional spatial detail beyond what is provided by the RCPs at 0.5 degree resolution, whereas the traditional method only considers changes in the magnitude of air pollutants in the future, assuming a constant spatial and sectoral distribution. We use constant (year 2000) land use and land cover for all simulations in WRF and CMAQ, whereas the spatial distributions of anthropogenic emissions change in the RCP scenarios.

In addition, the RCP datasets report only elemental carbon (EC) and organic carbon (OC), but ignore emissions of other primary PM species. Here we back-calculate the total $\text{PM}_{2.5}$ and PM coarse (PMC) primary emissions for all sectors from the reported EC and OC. We first derive the emission fractions of EC and OC in each sector by cross-comparing the definitions of the sectors in IPCC, the Source Clarification Codes (SCC) in the speciation cross-reference file (http://www.airqualitymodeling.org/cmaqwiki/index.php?title=CMAQv5.0_GSREF_example, accessed 5 September 2013), and the NEI PM speciation profile file (http://www.airqualitymodeling.org/cmaqwiki/index.php?title=CMAQv5.0_GSPRO_Example, accessed 5 September 2013) (Table S1). In back-calculating total PM emissions from BC and OC, there are usually more than one sub-category within one sector, e.g., the sector “Industries” includes emissions from the sub-category of “1A2 2A B C D E” (Table S1). When that happens, we use the speciation cross-reference file from the sub-category with largest mass fraction in this sector, following the methods of Reff et al. (2009) and Xing et al. (2013). Then we calculate the total $\text{PM}_{2.5}$ and PMC in each grid cell by dividing the reported EC and OC by their emission fractions individually, and average these two. By doing this, we increase the total $\text{PM}_{2.5}$ emissions of the RCPs by incorporating the inorganic components of primary PM, such as sulfate and nitrate. We check these results by comparing the total 2000 $\text{PM}_{2.5}$ emissions of 4.14 Tg yr^{-1} in this study (Table 2) with other studies, finding that it is comparable to the total of 4.69 Tg yr^{-1} in 2001 from the U.S. NEI (<http://www.epa.gov/ttnchie1/trends/>, accessed 5 October 2013). Our calculated $\text{PM}_{2.5}$ emission is also lower than the estimated 5.53 Tg yr^{-1} in 2000 by Xing et al. (2013), which used an activity data based approach to develop consistent temporally-resolved emissions from 1999 to 2010. In Table 2, we list the U.S. anthropogenic emissions for major air pollutants in 2000 and 2050 from REF and RCP4.5. Significant decreases are seen for most pollutants from 2000 to 2050 for both REF and RCP4.5, except for NH_3 which is

Deleted: If multiple sources are included in one IPCC sector (e.g., energy and industries in Table S1), we use the mass ratio from the source that contributes the largest fraction by referring to previous studies (Reff et al., 2009; Xing et al., 2013)

projected to increase due to agricultural activity (van Vuuren et al., 2011). Comparing RCP4.5 and REF, emissions of PM_{2.5} and O₃ precursors also decrease, including EC (7.59%) and OC (6.17%), with NO_x and NMVOC decreasing by more than 10%. SO₂ has the largest relative decreases between RCP4.5 and REF in 2050 (28.78%). Large spatial variations in emissions reductions are also seen over the U.S., with the largest reductions seen on the east and west urban areas of U.S. for most air pollutants and smaller reductions in the Great Plains (Figs. S4-S10).

Biogenic emissions are estimated using the Biogenic Emission Inventory System (BEIS v3.14), which responds to the changing climate for different scenarios. It is configured to run on-line in CMAQ, and calculates the emissions of 35 chemical species including 14 monoterpenes and 1 sesquiterpene. We assume that land use and land cover will stay constant in the future for the purpose of estimating biogenic emissions. We also use the BEIS on-line calculation for natural soil NO_x emissions. The on-line option of lightning is also turned on to calculate the NO_x emissions by estimating the number of lightning flashes based on the modeled convective precipitation, which also changes with climate. We prepare the ocean/land mask for the domain to calculate sea salt emissions which can be significant in coastal environments (Kelly et al., 2010).

2.3 Regional air quality model and dynamical chemical BCs

The latest CMAQ model (<https://www.cmascenter.org/cmaq/index.cfm>, accessed 15 June 2012) is used to perform the regional air quality simulations with the CB05 chemical mechanism and updated toluene reactions. The model incorporates the newest aerosol module (AE6), including features of new PM speciation (Reff et al., 2009), oxidative aging of primary organic carbon (Simon and Bhawe, 2012), and an updated treatment and tracking of crustal species (e.g., Ca²⁺, K⁺, Mg²⁺) and trace metals (e.g., Fe, Mn) (Fountoukis and Nenes, 2007). Several other enhancements in v5.0 of CMAQ were discussed by Appel et al. (2013) and Nolte et al. (2015), and there are no significant changes for the aerosol module between v5.0 and v5.0.1 (http://www.airqualitymodeling.org/cmaqwiki/index.php?title=CMAQ_version_5.0.1_%28July_2012_release%29_Technical_Documentation, accessed 15 August 2012). The model is configured with 34 vertical layers, with the lowest level being 34 m high, to the highest level at 50 hPa. The horizontal resolution is 36 km by 36 km for the CONUS domain. PM_{2.5} is calculated from the CMAQ output as the sum of the species EC, OC, secondary organic aerosol (SOA), non-carbon organic matter (NCOM), nitrate (NO₃⁻), sulfate (SO₄²⁻), ammonium (NH₄⁺), sodium (Na⁺), chloride (Cl⁻), eight crustal and trace metal species, and other unspiciated fine PM (OTHER).

The dynamical BCs for this study are provided by the global MZ4 simulations of WEST2013. The hourly boundary values from MZ4 are horizontally interpolated from coarser resolution to the regional finer resolution, and also vertically interpolated as MZ4 and CMAQ have different vertical layers. Chemical species are mapped between MZ4 and CMAQ v5.0.1, due to the different chemical mechanisms used by these two models, following the descriptions of Emmons et al. (2010) and ENVIRON (<http://www.camx.com/download/support-software.aspx>, accessed 19 September 2013). For the chemical species in CMAQ that do not exist in MZ4, values are set to defaults as suggested by the CMAQ website.

2.4 Scenarios

We simulate scenarios in CMAQ comparable to WEST2013, except that we carry out one extra scenario to quantify the co-benefits from domestic versus foreign GHG mitigation (Table 1). S_2000 is conducted to evaluate CMAQ model performance and to compare with future scenarios. For this study, we run four scenarios in 2050. The differences between S_RCP45 and S_REF are the total co-benefits on U.S. air quality from global GHG mitigation. The emission benefit from the first mechanism is calculated as the difference between S_Emis and S_REF, for which the change in methane concentration is included as an emission benefit, and the meteorology benefit is calculated as S_RCP45 minus S_Emis. By comparing S_Dom (applying GHG mitigation from RCP4.5 scenario in the U.S. only) with S_REF, and S_RCP45 with S_Dom, we quantify the co-benefits from domestic and foreign GHG mitigation. The co-benefits from foreign reductions are found by simple subtraction (S_RCP45 – S_REF) – (S_Dom – S_REF) = S_RCP45 – S_Dom. In estimating the co-benefits of domestic reductions, we account for the influences of methane and of global climate change as foreign influences (as most methane and GHG emissions are outside of the U.S.), and assume that U.S. air pollutant emissions have small effects on global or regional climate, such as through aerosol forcing. In each scenario, we fix global methane at concentrations given by the RCPs (Table 1), and account for methane changes as a foreign influence, neglecting the fraction of global anthropogenic methane emissions that are from the U.S. (7.4% in 2050 REF scenario and 7.0% in 2050 RCP4.5). All scenarios are set up as continuous runs, with S_2000 running from September, 2000 to December, 2003, with the first four months in 2000 as spin-up. The future scenarios are run from September, 2049 to December, 2052 with the months in 2049 as spin-up. Results are presented as the average of three years.

3 Results

3.1 CMAQ model evaluation

The CMAQ model has been broadly used to study regional future air quality (Hogrefe et al., 2004; Tagaris et al., 2007; Nolte et al., 2008; Lam et al., 2011; Gao et al., 2013) and has been evaluated in many applications (Appel et al., 2010, 2011, 2013; Nolte et al., 2015). Here we evaluate the CMAQ v5.0.1 performance by comparing the model outputs from S_2000 with observations in 2000 from the Interagency Monitoring of PROtected Visual Environments (IMPROVE; <http://vista.cira.colostate.edu/improve/>, accessed 9 May 2014), the Chemical Speciation Network (CSN; previously known as STN, <http://www.epa.gov/ttn/amtic/speciepg.html>, accessed 9 May 2014), and the Clean Air Status and Trends Network (CASTNET; <http://epa.gov/castnet/javaweb/index.html>, accessed 9 May 2014) for total PM_{2.5} and its components, and the EPA Air Quality System (AQS; <http://www.epa.gov/ttn/airs/airsaqs/detaildata/downloadaqsdta.htm>, accessed 9 May 2014) for O₃. We pair the model outputs with observations in space and time, and calculate four groups of statistics to evaluate model performance: Median Bias (MdnB, μg m⁻³ for PM_{2.5} and ppb for O₃), Normalized Median Bias (NMdnB, %), Median Error (MdnE, μg m⁻³ and ppb) and Normalized Median Error (NMdnE, %) (Supplementary material). Median metrics are used here instead of the mean, as for data with non-normal distributions (i.e., PM species) the median gives a better representation of the

Deleted: a

Deleted: global

Deleted: ing

Deleted:

central tendency of the data (Appel et al., 2008). For O₃ evaluation, we use both the maximum daily 1-hour (1hr-O₃) and Maximum Daily 8-hour Average (MDA8), and also calculate these metrics with a cutoff value of 40 ppb for the observed O₃ to evaluate the model's reliability in predicting ozone values relevant for the NAAQS (USEPA, 2007). Model performance is not expected to be perfect as meteorology does not correspond with actual year 2000 meteorology, and emissions are derived from global datasets rather than the specific NEI year dataset for the U.S.

Deleted: USEPA 2007

For total PM_{2.5}, overall model performance is good and the NMdnE for IMPROVE and CSN are less than 50%, with slight differences in performance (Table 3). CMAQ underestimates PM_{2.5} in these two networks and also its components in all three networks (Table S2), except that it overestimates SO₄²⁻ compared with IMPROVE, and NH₄⁺ with CSN. Compared with other components, OC and EC are not well predicted, with higher NMdnB, -63.55% and -37.00% in IMPROVE (OC and EC are not measured in the other two networks). In simulating PM_{2.5} and its species, model performance is better in winter than in summer (not shown here). The model overestimates surface O₃ as indicated by the positive MdnB (ppb) and NMdnB (%). The NMdnE for the 1hr-O₃ (MDA8-O₃) declines from 27.60% (33.35%) to 17.36% (16.95%) after we apply the cutoff value of 40 ppb. The overprediction is slightly lower for 1hr-O₃ than for MDA8-O₃, however this difference becomes smaller when we consider the cutoff values. By comparing the simulated annual PM_{2.5} and O₃ in 2000 (both are three-year averages) between MZ-4 and CMAQ, we see that CMAQ captures urban scale air quality better than MZ-4 (Fig. S11).

3.2 Air quality changes in 2050

Here we show the seasonal and spatial patterns of future air quality changes centered in 2050 relative to 2000 from REF and RCP4.5 (Figs. S12 to S15). The three-year seasonal average of PM_{2.5} over the entire U.S. decrease in 2050 in both S_REF and S_RCP45 compared with S_2000, especially in the Eastern U.S. and California (CA). The seasonal decreases are largest in winter, with U.S. averages in S_REF (S_RCP45) of 4.42 (4.88) μg m⁻³, and lowest in the summer of 1.55 (2.00) μg m⁻³, with annual average of 2.76 (3.23) μg m⁻³. The three-year seasonal average of O₃ decrease significantly in summer in both the east and west coast, with U.S. average of 6.31 (9.50) ppb in S_REF (S_RCP45). O₃ increases over the Northeast and West U.S. in winter in both S_REF and S_RCP45, caused by the weakened NO_x titration as a result of the large NO_x decrease in the two scenarios (Table 2), as also reported by other studies (Gao et al., 2013; Fiore et al., 2015), and as well as the large methane increases in RCP8.5 scenario (Gao et al., 2013). The magnitude of the decreases between S_REF and S_2000 is lower than that between S_RCP45 and S_2000, as the REF scenario did not apply a GHG mitigation policy, and thus has less emission reductions.

Deleted: in

We then compare these air quality changes in 2050 with the MZ4 simulations of WEST2013 for both S_REF (Fig. S16) and S_RCP45 (Fig. 2), and for S_RCP45 with the ensemble model means from the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP, Lamarque et al., 2013) following Fiore et al. (2012), as no ACCMIP models simulated REF in 2050. For the U.S. annual average PM_{2.5}, the decrease in 2050 for S_RCP45 relative to 2000 in this study (3.23 μg m⁻³) is modestly higher than both the results from MZ4 and the ACCMIP ensemble mean, but within the range of ACCMIP models when PM_{2.5} is calculated as a sum of species. The future O₃ changes in our study (5.20 ppb) are clearly in

Deleted: S15

the range of ACCMIP results, and nearly identical to MZ4 (5.13 ppb). Comparisons of the air quality changes in 2050 for S_REF relative to 2000 between CMAQ and MZ4 are similar, except that the magnitudes of the changes are smaller than those for S_RCP45 (Fig. [S16](#)). [CMAQ better simulates air quality changes in urban environments at a finer scale compared with MZ-4](#).

5 3.3 Total co-benefits for U.S. air quality from global GHG mitigation

Projected three-year average PM_{2.5} concentrations in 2050 in both scenarios (S_REF and S_RCP45) are higher in the Eastern U.S. and the west coast of CA, and lower in the Western U.S. (Fig.3). The total co-benefits for U.S. air quality (S_RCP45 minus S_REF) show notable decreases of major air pollutants in 2050. The total co-benefits for PM_{2.5} over the U.S. show a significant spatial gradient over the U.S. domain, greatest in the eastern U.S., especially urban areas, as well as CA, ranging from 0.4 to 1.0 $\mu\text{g m}^{-3}$, and least in the Rocky Mountains and Northwest with values below 0.4 $\mu\text{g m}^{-3}$. The total co-benefits for PM_{2.5} averaged over the U.S. is 0.47 $\mu\text{g m}^{-3}$, with the largest contribution from organic matter (OM, including primary OC, SOA and NCOM), accounting for the 45% of the total (0.21 $\mu\text{g m}^{-3}$), followed by sulfate (0.11 $\mu\text{g m}^{-3}$) and ammonia (0.05 $\mu\text{g m}^{-3}$) (Fig. [S17](#)). The total co-benefits are highest in fall, with U.S. domain average of 0.55 $\mu\text{g m}^{-3}$, and lowest in spring (0.41 $\mu\text{g m}^{-3}$) (Fig. 4). Notice that the region with greatest co-benefits shifts from Central areas in winter and spring to the East in summer and fall, with the largest component of OM also shifting from primary OC to SOA (Fig. [S18](#)).

Deleted: S17

Future O₃ is presented here as the ozone-season average (from May to October) of MDA8. In general, 2050 O₃ concentrations in S_REF and S_RCP45 are projected to be high in the Southern U.S., especially over the coastal areas, and higher in the West than the East (Fig. 5). The total co-benefits for O₃ are fairly uniformly significant over the entire U.S. domain, slightly higher in the Northeast and Northwest, and range from 2-5 ppb with a domain average of 3.55 ppb, unlike PM_{2.5} which is higher over urban regions. The uniformity of the total O₃ co-benefits suggests that they are strongly influenced by global O₃ reductions.

The total co-benefit for PM_{2.5} from this study (0.47 $\mu\text{g m}^{-3}$ over U.S.) is lower than WEST2013 (area-weighted three-year averages of 0.72 $\mu\text{g m}^{-3}$ over U.S.), especially over the Northwest and Central of U.S. (Fig. [S20](#)). Analyzing the components of PM_{2.5}, we find that this difference is mainly caused by OM, with a U.S. annual average of 0.40 $\mu\text{g m}^{-3}$ in WEST2013 and 0.21 $\mu\text{g m}^{-3}$ in this study (Fig. [S21](#)). For other components (EC, SO₄²⁻, NO₃⁻ as reported in MZ4 of WEST2013), the CMAQ results are slightly lower than WEST2013 but share a similar spatial pattern (Figs. [S22-S25](#)). We expect that the total co-benefits of PM_{2.5} in this study might be higher than WEST2013, as we account for inorganic primary PM emissions in SMOKE.

Deleted: S22

A possible explanation may be that different chemical mechanisms and deposition processes are adopted for organic aerosols in MZ4 and CMAQ, which may make a shorter atmospheric lifetime for PM in CMAQ than that in MZ4. The differences of the meteorology (e.g., the precipitation and temperature) between the downscaled WRF and the GFDL could also contribute to this difference. Total co-benefit of O₃ from this study (3.55 ppb over U.S.) is comparable to WEST2013 (3.71 ppb) in both the magnitude and spatial distribution (Fig. [S25](#)).

Deleted: S23

3.4 Co-benefits from the two mechanisms

We quantify the co-benefits of global GHG mitigation on PM_{2.5} and O₃ through the two mechanisms: reduced co-emitted air pollutants (S_Emis—S_REF) and slowing climate change and its effect on air quality (S_RCP45—S_Emis). The reduction of co-emitted air pollutants has a much greater effect than slowing climate change for PM_{2.5}, accounting for 96% of the U.S. average PM_{2.5} decrease. The emission benefit for PM_{2.5} over the U.S. domain is 0.45 μg m⁻³, greatest near urban areas where emissions are reduced (Fig. 6), with the largest contribution from OM (0.172 μg m⁻³ over the U.S.), followed by sulfate (0.107 μg m⁻³) and ammonia (0.048 μg m⁻³). In Fig. S18, the OM decrease is caused mainly by primary organic carbon (POC, 0.074 μg m⁻³ decreases), followed by biogenic SOA (ORGB, 0.057 μg m⁻³) and non-carbon organic matter (NCOM, 0.048 μg m⁻³). The POC and NCOM decreases are caused mainly by emission reductions, while the SOA decrease is caused mainly by changing climate (Fig. S19). Slowing climate change only accounts for 4% of the U.S. average total PM_{2.5} decreases (0.02 μg m⁻³). It also has different signs of effect over the U.S., reducing PM_{2.5} in the Southern U.S. but increasing in the North.

For O₃, the emission benefit is also larger than the climate benefit, accounting for 89% of the total O₃ decreases averaged over the U.S. The emission benefit for O₃ over the U.S. domain is 3.16 ppb, and much more uniform over the U.S., slightly higher over Northeast and Northwest. Slowing climate change accounts for 0.39 ppb O₃ decreases, 11% of the total and mainly in the Great Plains and the East, where temperatures are cooler under RCP4.5 compared with RCP8.5 (Fig. 1). The dominance of the emission co-benefit over the climate co-benefit for both PM_{2.5} and O₃ is consistent with WEST2013.

3.5 Co-benefits from domestic and foreign GHG mitigation

We also investigate the co-benefits from domestic GHG mitigation by comparing S_Dom with S_REF, versus foreign GHG reductions by comparing S_RCP45 with S_Dom (Fig. 7). For PM_{2.5}, domestic GHG mitigation accounts for 74% (0.35 μg m⁻³) of the total PM_{2.5} decrease over the whole U.S., with the greatest effect over the East and CA, where emissions of PM_{2.5} and its precursors are greatly reduced (Figs. S3-S9). The benefits from foreign GHG reductions on the U.S. PM_{2.5} change are only obvious in the Southern U.S., influenced by emission reductions in Mexico and global climate change. We conclude that domestic GHG mitigation has a greater influence on U.S. PM_{2.5} than reductions in foreign countries, but that foreign reductions also make a noticeable contribution, accounting for 26% of total PM_{2.5} decreases over the U.S., and a greater fraction, 40% in the South, South West, and East N Central regions. Note that the uncertainty in the foreign co-benefits is much larger than for the domestic reductions (Table S3). Longer simulations would be needed to reduce this uncertainty.

For O₃, foreign countries' GHG mitigation has a much larger influence on the U.S., accounting for 76% (2.69 ppb) of the total O₃ decrease, compared with 24% from domestic GHG mitigation (Fig. 7). The U.S. experiences greater O₃ decreases in the North than the South, which is likely influenced in part by the air quality improvement in Western Canada as a result of slowing deforestation due to the climate policy in RCP4.5 (West et al., 2013). This large influence of foreign reductions for O₃ highlights the importance of global methane reductions in RCP4.5 (anthropogenic emissions of 330 Tg yr⁻¹ in 2050 in RCP4.5, compared to 432 Tg yr⁻¹ in REF), particularly in Asia and intercontinental transport.

Deleted: in the Southern U.S

3.6 Regional co-benefits and variability

We then quantify the co-benefits over nine U.S. climate regions defined by the National Oceanic and Atmospheric Administration (Fig. S26), and their domestic and foreign components. The Central, Southeast, Northeast and South regions have the largest total co-benefits for PM_{2.5} (regional annual means of 0.78, 0.75, 0.62 and 0.62 μg m⁻³), and the Northwest has the lowest total co-benefits (0.16 μg m⁻³) (Fig. 8). Domestic GHG mitigation has the largest effect over these same regions and lowest effects over Northwest and West North Central, with means of 0.13 μg m⁻³. Foreign co-benefits are greatest over the South, Southwest, Central and Southeast, and lowest over Northwest (Table S3). As a fraction of the total co-benefits, the domestic co-benefit is highest in the Northeast, East North Central and Central accounting for more than 80% of the total, while foreign co-benefits are highest over Southwest, South and West North Central, accounting for about 40% of the total.

For O₃, the Northeast, East North Central, and Northwest have the highest total co-benefits, (regional means of 4.61, 4.25, 4.15 ppb; Fig. 9 and Table S3), although the total co-benefits for O₃ are fairly uniform over the U.S (Fig. 5). The Southeast has the lowest total co-benefits, with 2.67 ppb for the regional mean. Domestic co-benefits are higher over the Central, Northeast and Southeast, with regional means of 1.25, 1.16 and 1.14 ppb, and lowest over Northwest (0.4 ppb). In general, foreign mitigation contributes more in the west than the east, most likely influenced by intercontinental transport from Asia. It is highest in the Northwest, West North Central and Northeast, with regional means of 3.75, 3.45 and 3.45 ppb. The fraction of co-benefits from foreign mitigation is larger than 60% in most regions, highest over the Northwest (90%), and lowest over the Southeast (57%).

We also evaluate the variability in co-benefits for the three years simulated (Table S3). Over the U.S., the coefficient of variation (CV) for the total co-benefits for PM_{2.5} (7%) is much lower than that of the total co-benefits for O₃ (37%), which is controlled by the intercontinental transport and global CH₄. The Southeast has the highest CV (29%) for the total co-benefits of PM_{2.5}, while other regions are lower than 15%, lowest in the East North Central and Northeast (3%). Southwest and South have the highest CV (70%, 69%) for the total co-benefits of O₃, and lowest in Northwest (21%). For regions with higher variability, longer simulations would be desirable to better quantify the annual average co-benefits.

4 Discussion

The co-benefits we present here are specific to the reference (REF) and mitigation (RCP4.5) scenarios we choose, and results would differ for other baseline and mitigation scenarios. The estimated co-benefits also depend on participation of many nations in the mitigation policies, and delaying participation will likely change the co-benefits.

The total co-benefits for O₃ when downscaled are comparable to the global study in both magnitude and spatial pattern, but the downscaled simulations capture some local features better than the global model, such the effects of topography and urban areas. For PM_{2.5}, significant differences are seen from the downscaling due to the fine resolution and different chemical mechanisms between the global and the regional model. The resolution we are using for this study (36km by 36 km) is fine

Deleted: S24

enough for us to analyze the co-benefits at a state level, but insufficient to fully resolve urban areas. Finer resolution simulations (such as 12 km by 12 km) with CMAQ or other CTMs can be carried out to better quantify the co-benefits over urban areas. For this study, uncertainties and errors may exist under the assumptions and choices we make for each model. For example, Uncertainties in the input meteorology and emissions data inventory have a significant influence on the CMAQ results. Also we see that the co-benefits of PM_{2.5} have large contributions from OC and SOA over the Central and East U.S. (Fig. 4, Fig. S18). However, our model evaluations show that CMAQ greatly underestimates the total OC (primary OC and SOA) concentration compared with surface observations. New gas-phase and aqueous-phase oxidation pathways for SOA formation are found to play significant roles in producing organic aerosols (Lin et al., 2014; Pye and Pouliot, 2012; Pye et al., 2013), which are missing in the CMAQ version used in this study. We use BEIS model to estimate the biogenic VOC (BVOC) emissions, but studies have shown that the BVOCs from the Model of Emissions of Gases and Aerosols from Nature (MEGAN) are higher than those from BEIS by a factor 2 (Pouliot, 2008; Pouliot and Pierce, 2009), which highlights the uncertainty in representing these emissions and simulating both PM_{2.5} and O₃ (Hogrefe et al., 2011).

We assume constant land use in the GCM, WRF and CMAQ when simulating the global and regional climate and estimating the biogenic emissions, which could introduce errors in our results (Unger, 2014; Heald and Spracklen, 2015). When we process the global anthropogenic emissions with SMOKE, we back-calculate the total PM_{2.5} and PMC from OC and BC, which introduces inorganic PM emissions and may make our results for co-benefits of PM_{2.5} higher. By doing this, we account for missing emissions but also increase the total uncertainties in the emission inventory. Spectral nudging is adopted in this study to restrain WRF from drifting from the GCM, which has been shown to be better for some meteorological variables, but analysis nudging better for others (Bowden et al., 2012, 2013; Liu et al., 2012; Otte et al., 2012). Moreover, only one model is used during downscaling for regional climate (WRF) and air quality (CMAQ) modelling, and the mean of a model ensemble can be used to reduce model error. Simulations are based on three-year averages, due to computational limitations, but these three years may reflect meteorological variability and not only climate change. This uncertainty may be greater for the total co-benefits of O₃, for which we see greater year-to-year variations than for PM_{2.5}. CMAQ simulations could be performed over more years to reduce the influence of the interannual climate variability. In separating domestic and foreign co-benefits, we assume that global and regional climate will be controlled by foreign GHGs emissions, and not influenced by GHG mitigation in the U.S., which introduces a small error into our results. We similarly attribute the global methane change as a foreign influence, as U.S. methane emissions are a small fraction (6-10%) of global emissions.

5 Conclusions

Climate policies to control GHG emissions will not only have the benefit of slowing climate change, but can also have co-benefits of improved air quality. Previous co-benefits studies focus mostly on local or regional GHG reductions. As a result, these studies omit air quality benefits outside of the domain considered, and neglect benefits from global GHG mitigation. In this study we adopt a systematic approach to quantify the co-benefits from both the global and regional GHG mitigation on

regional air quality over U.S. at fine resolution in 2050, building on the global co-benefits study from West et al. (2013). The co-benefits of global GHG mitigation on U.S. air quality are discussed through two mechanisms: reduced co-emitted air pollutants and slowing climate change and its influence on air quality. We also quantify the co-benefits from domestic GHG mitigation versus foreign countries' reduction.

- 5 We find that there are significant benefits for both PM_{2.5} and O₃ over U.S. by 2050 from the global GHG mitigation in RCP4.5. The total co-benefits for PM_{2.5} are higher in the east than the west, with an average of 0.47 µg m⁻³ over U.S. For O₃, the total co-benefits are fairly uniform across the U.S. at 2-5 ppb, with U.S. average of 3.55 ppb. The co-benefits from reductions of co-emitted air pollutants have a greater influence on both PM_{2.5} (accounting for 96% of total decreases) and O₃ (89% of the total decreases) than the second mechanism via slowing climate change, consistent with West et al. (2013).
- 10 Foreign countries' GHG reductions have a much greater influence on the U.S. O₃ reduction (76% of the total), compared with that from domestic GHG mitigation only (24%), highlighting the importance of global methane reductions and the intercontinental transport of air pollutants. For PM_{2.5}, the benefits of foreign GHG control are less than domestic, but still a considerable portion of the total (26%). We conclude that the U.S. can gain significantly greater domestic air quality co-benefits by engaging with other nations for GHG control to combat climate change, especially for O₃. This also applies to
- 15 other nations which can be expected to have ancillary air quality benefits from foreign countries' GHG mitigation. We also conclude that previous studies that estimate co-benefits for one nation or region (e.g., Thomson et al., 2014), may significantly underestimate the full co-benefits when many countries reduce GHGs together, particularly for O₃.

Table 1. List of CMAQv5.0.1 simulations in this study. Hourly BCs are from the MOZART-4 (MZ4) simulations of WEST2013. We fix the methane (CH₄) background concentrations in CMAQ consistent with the RCP scenarios and WEST2013.

Years	Scenario	Emissions	Meteorology	BCs	CH₄
2000	S_2000	2000	2000	MZ4 2000	1766 ppbv
	S_REF	REF	RCP8.5	MZ4 REF	2267 ppbv
	S_RCP45	RCP4.5	RCP4.5	MZ4 RCP4.5	1833 ppbv
2050	S_Emis	RCP4.5	RCP8.5	MZ4 e45m85 ^b	1833 ppbv
	S_Dom	RCP4.5 for U.S., REF for Can, Mex ^a	RCP8.5	MZ4 REF	2267 ppbv

^athe part of Canada and Mexico in the domain.

^bglobal simulation using RCP4.5 emissions together with RCP8.5 meteorology in 2050.

Table 2. Anthropogenic emissions in the U.S. for major air pollutants in 2000 and 2050 from REF and RCP4.5 (Tg yr⁻¹), and the relative differences (Relative Diff) between RCP4.5 and REF in 2050 ((RCP4.5 - REF)/REF×100).

	2000	2050 REF	2050 RCP4.5	Relative Diff (%)
SO ₂	14.84	2.46	1.75	-28.78
NH ₃	3.34	4.56	4.30	-5.56
NO _x	19.57	4.40	3.92	-10.93
CO	92.74	11.42	11.25	-1.48
NMVOG	15.23	8.07	7.16	-11.21
EC	0.42	0.22	0.21	-7.59
OC	0.71	0.35	0.33	-6.17
PM _{2.5} ¹	4.14	1.87	1.57	-15.80
PMC ²	11.02	5.50	4.63	-15.80

^{1,2}PM_{2.5} & PMC are the total emissions back-calculated based on the EC & OC.

Table 3. Evaluation of the S_2000 simulation (average of three years modeled) with surface observations in 2000 for PM_{2.5} (µg m⁻³) and O₃ (ppb).

	Pollutants	MdnB	NMdnB (%)	MdnE	NMdnE(%)
IMPROVE	PM _{2.5}	-0.89	-23.31	1.88	49.46
CSN	PM _{2.5}	-2.85	-27.44	4.29	41.30
AQS	1hr_O ₃	8.97	18.40	13.25	27.60
AQS	1hr_O ₃ _40 ^a	2.79	4.76	9.89	17.36
AQS	MDA8_O ₃	11.87	28.01	14.13	33.35
AQS	MDA8_O ₃ _40 ^a	3.95	7.37	9.09	16.95

^a1hr_O₃_40 and MDA8_O₃_40: Observations below 40 ppb are excluded from the comparison.

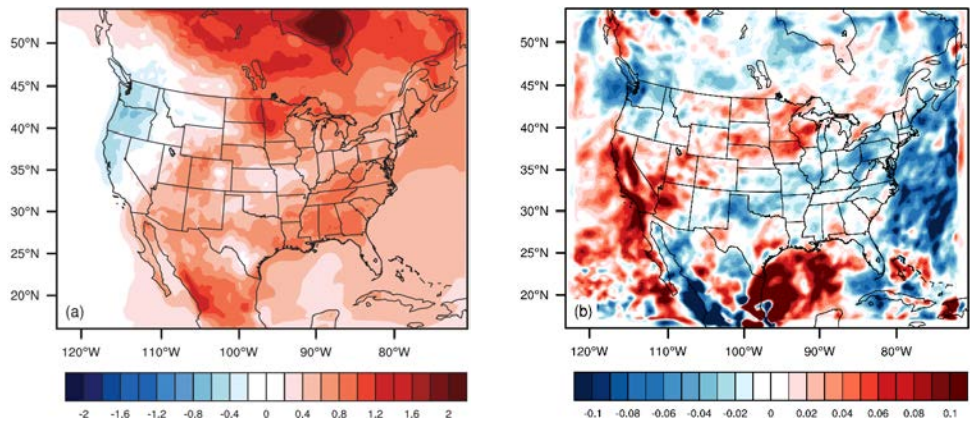

Fig. 1. Changes in (a) 2-m temperature ($^{\circ}\text{C}$) and (b) precipitation (mm day^{-1}) centered on 2050 between RCP8.5 and RCP4.5 (RCP8.5—RCP4.5).

Fig. 2. Comparison of annual U.S. average concentration changes for RCP4.5 in 2050 relative to 2000, for this study (black triangle), MZ4 from WEST2013 (red circle), and the ensemble mean (blue diamond) and multi-model range from ACCMIP (blue lines), for (a) PM_{2.5}, and (b) O₃. In panel a, the total PM_{2.5} reported by the ACCMIP models is shown on the left, and the PM_{2.5} estimated as a sum of species BC+OA+SOA+SO₄+NO₃+NH₄+0.25*SeaSalt+0.1*Dust following Fiore et al. (2012) and Silva et al. (2013) shown on the right. Values shown are the average of three years for CMAQ and MZ4, and 5 to 10 years for ACCMIP for three models (LMDzORINCA, GFDL-AM3 and GISS-E2-R) that report O₃ and two models (GFDL-AM3 and GISS-E2-R) that report PM_{2.5}.

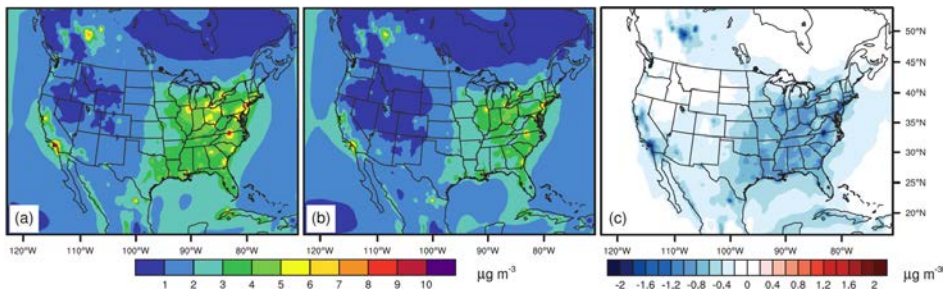

Fig. 3. The three-year average PM_{2.5} ($\mu\text{g m}^{-3}$) distributions in 2050 from (a) S_REF, (b) S_RCP45, and (c) the total co-benefits (shown as the difference between S_RCP45 and S_REF). Blue colors in panel (c) indicate an air quality improvement.

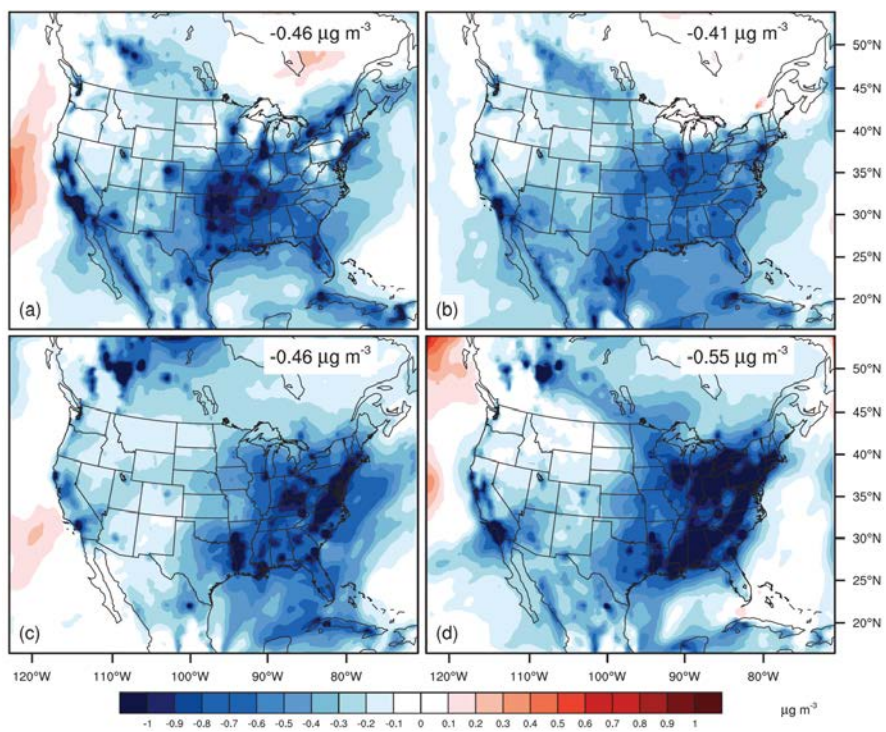

Fig. 4. Seasonal distributions of total co-benefits for PM_{2.5} (µg m⁻³) for (a) winter, (b) spring, (c) summer and (d) fall.

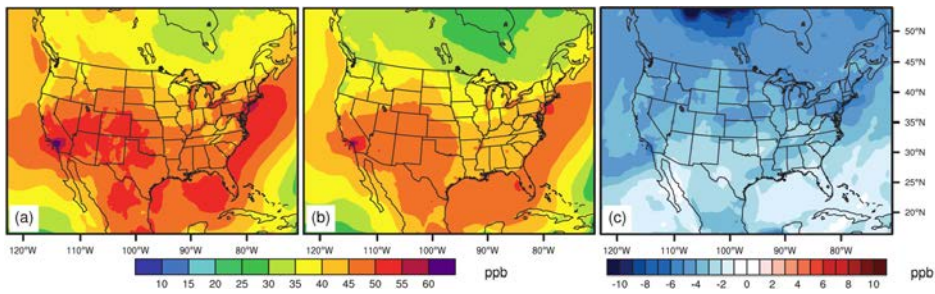

Fig. 5. The three-year ozone-season average (May to October) of MDA8 O₃ (ppb) from (a) S_REF, (b) S_RCP45, and (c) the total co-benefits (shown as the difference between S_RCP45 and S_REF). Blue colors in panel (c) indicate an air quality improvement.

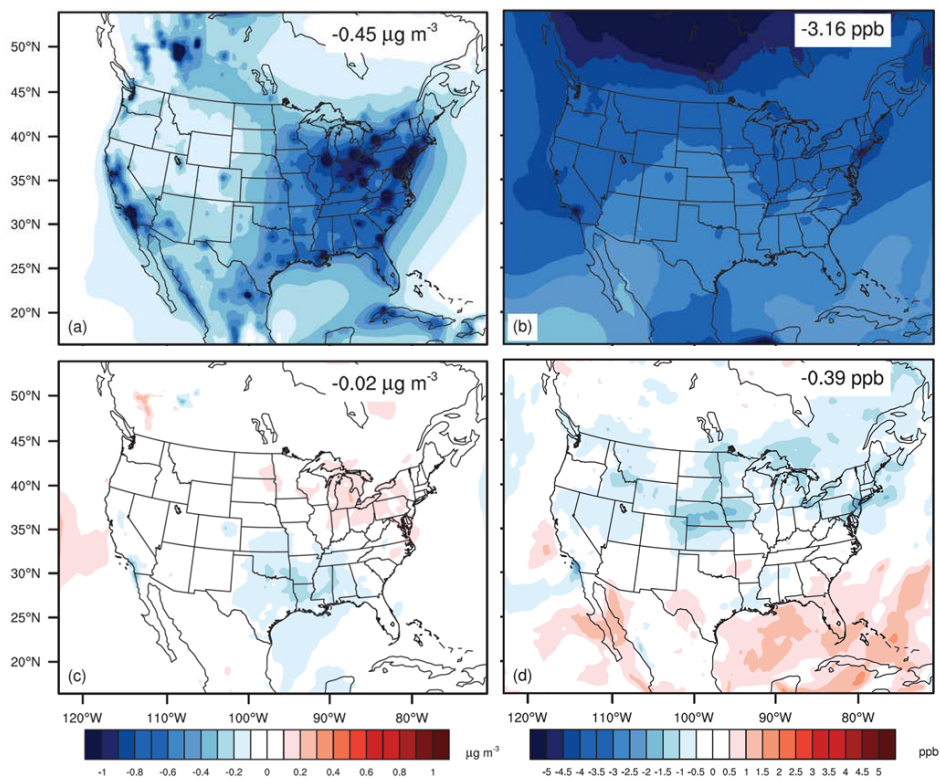

Fig. 6. Benefits of reduced co-emitted air pollutants (a, b; $S_{\text{Emis}} - S_{\text{REF}}$) versus slowing climate change (c, d; $S_{\text{RCP45}} - S_{\text{Emis}}$) for PM_{2.5} (a, c) and ozone season MDA8 surface O₃ (b, d). Blue colors indicate an air quality improvement. The numbers on the plots are the three-year average of air quality changes over the U.S.

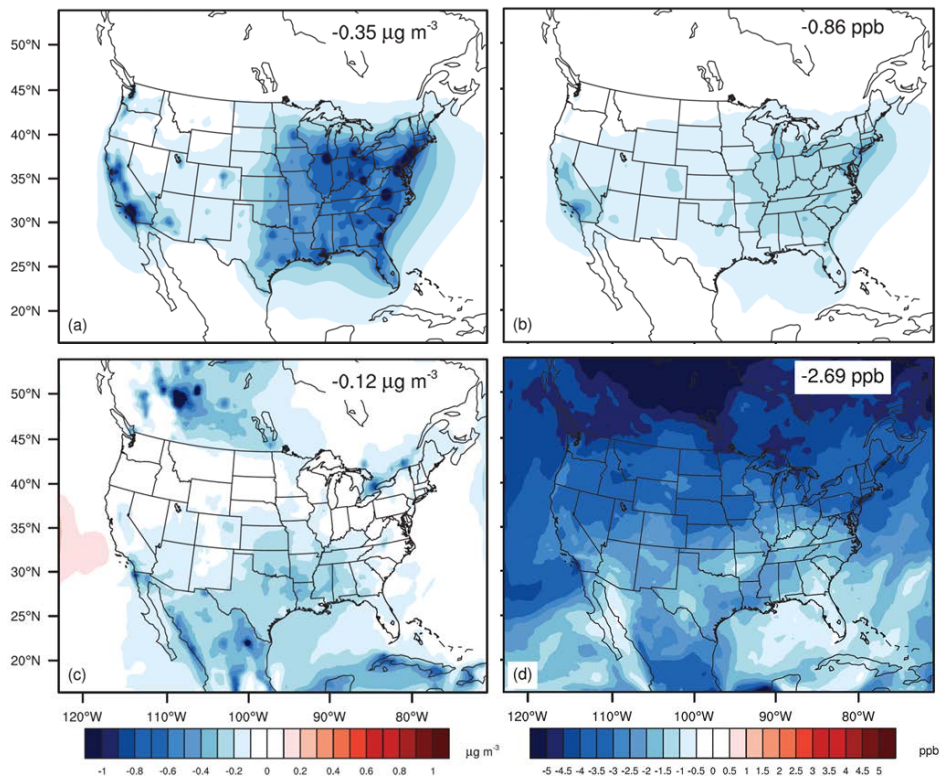

Fig. 7. Benefits of domestic (a, b; $S_{Dom} - S_{REF}$) versus foreign (c, d) GHG reductions for PM_{2.5} (a, c; $S_{RCP45} - S_{Dom}$) and ozone season MDA8 surface O₃ (b, d). Blue colors indicate an air quality improvement. The numbers on the plots are the three-year average of air quality changes over the U.S.

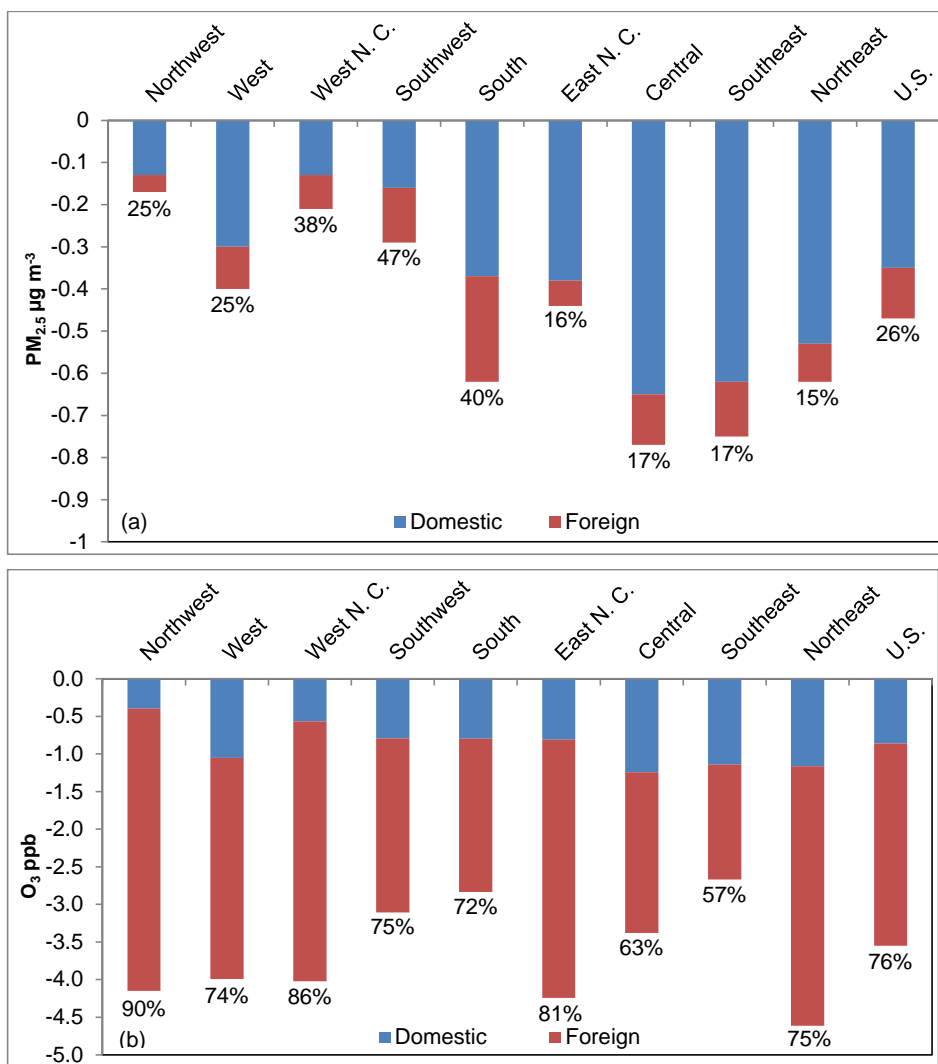

Fig. 8. Mean values of domestic (blue) and foreign co-benefits (red) for U.S. average (a) annual $PM_{2.5}$, and (b) ozone season MDA8 O_3 . The numbers below each bar are the percentage (%) of the foreign co-benefit.

SUPPLEMENTAL MATERIAL

Median Bias: $MdnB = median(C_m - C_o)_N$

Normalized Median Bias: $NMdnB = \frac{median(C_m - C_o)_N}{median(C_o)_N} \times 100\%$

Median Error: $MdnE = median|C_m - C_o|_N$

Normalized Median Error: $NMdnE = \frac{median|C_m - C_o|_N}{median(C_o)_N} \times 100\%$

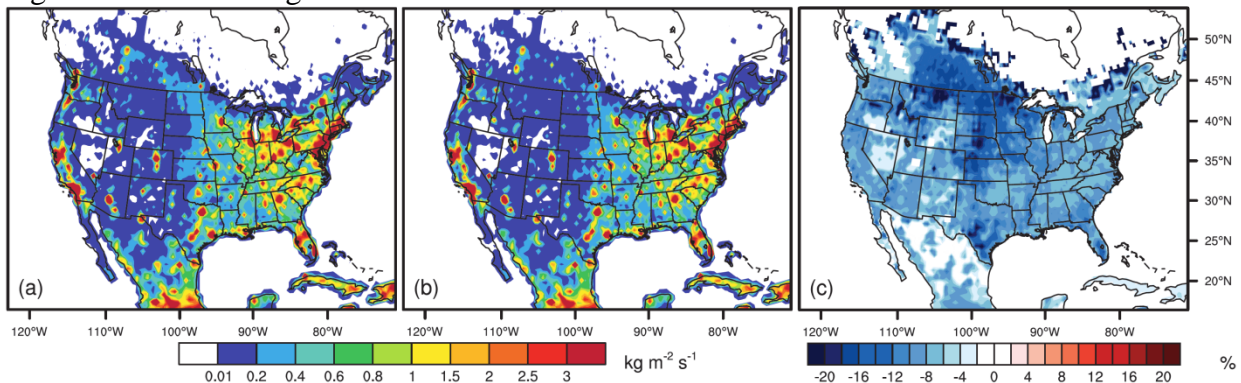

Figure S9. Same as Fig. S4 but for EC.

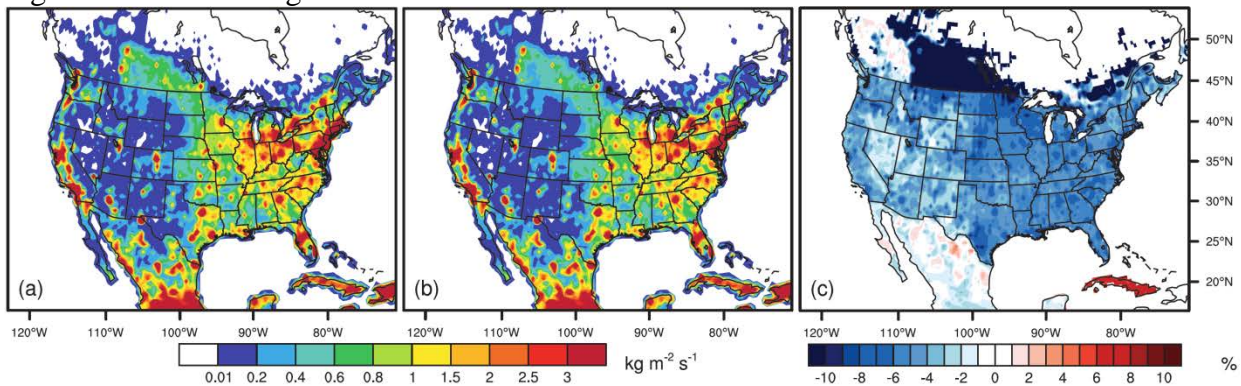

Figure S10. Same as Fig. S4 but for OC.

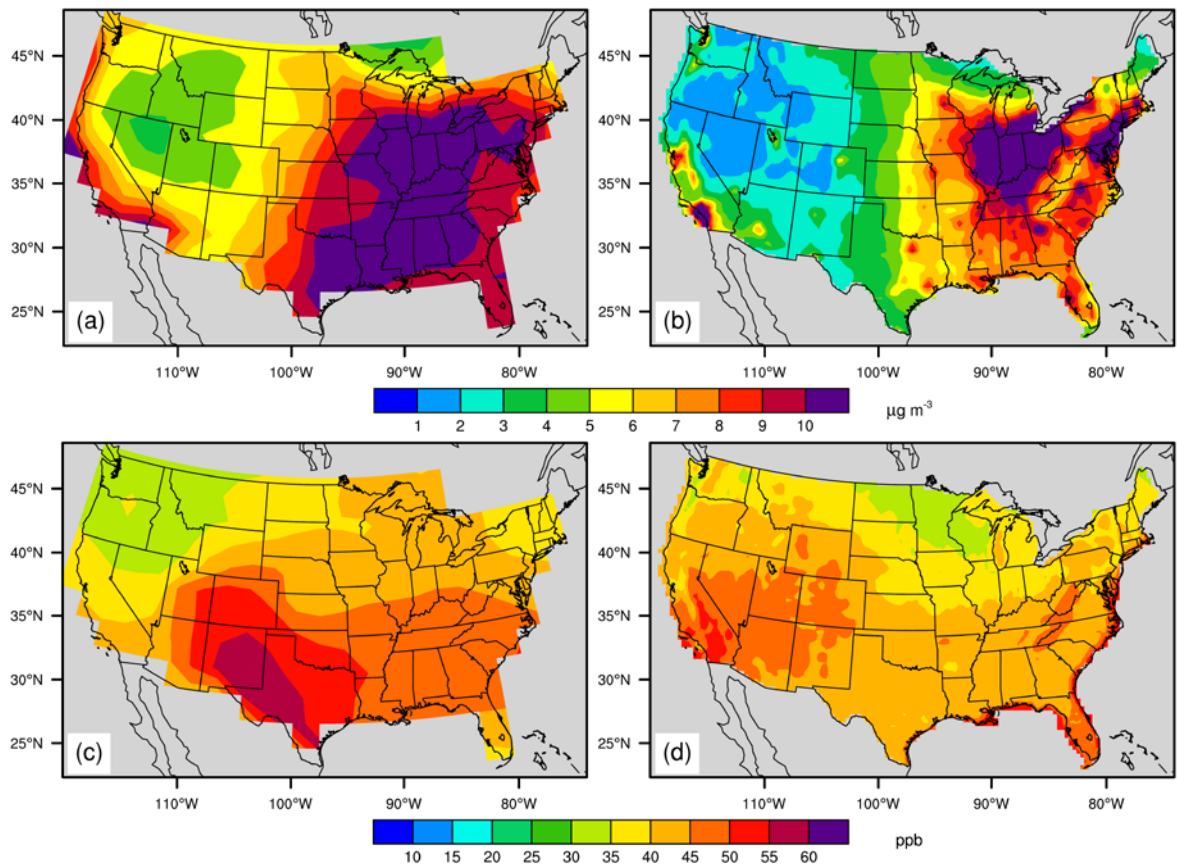

Figure S11. Comparisons for the simulated annual $PM_{2.5}$ (a, b) and O_3 (c, d) in 2000 (both are for three-year average) between MZ-4 (a, c) and CMAQ (b, d).

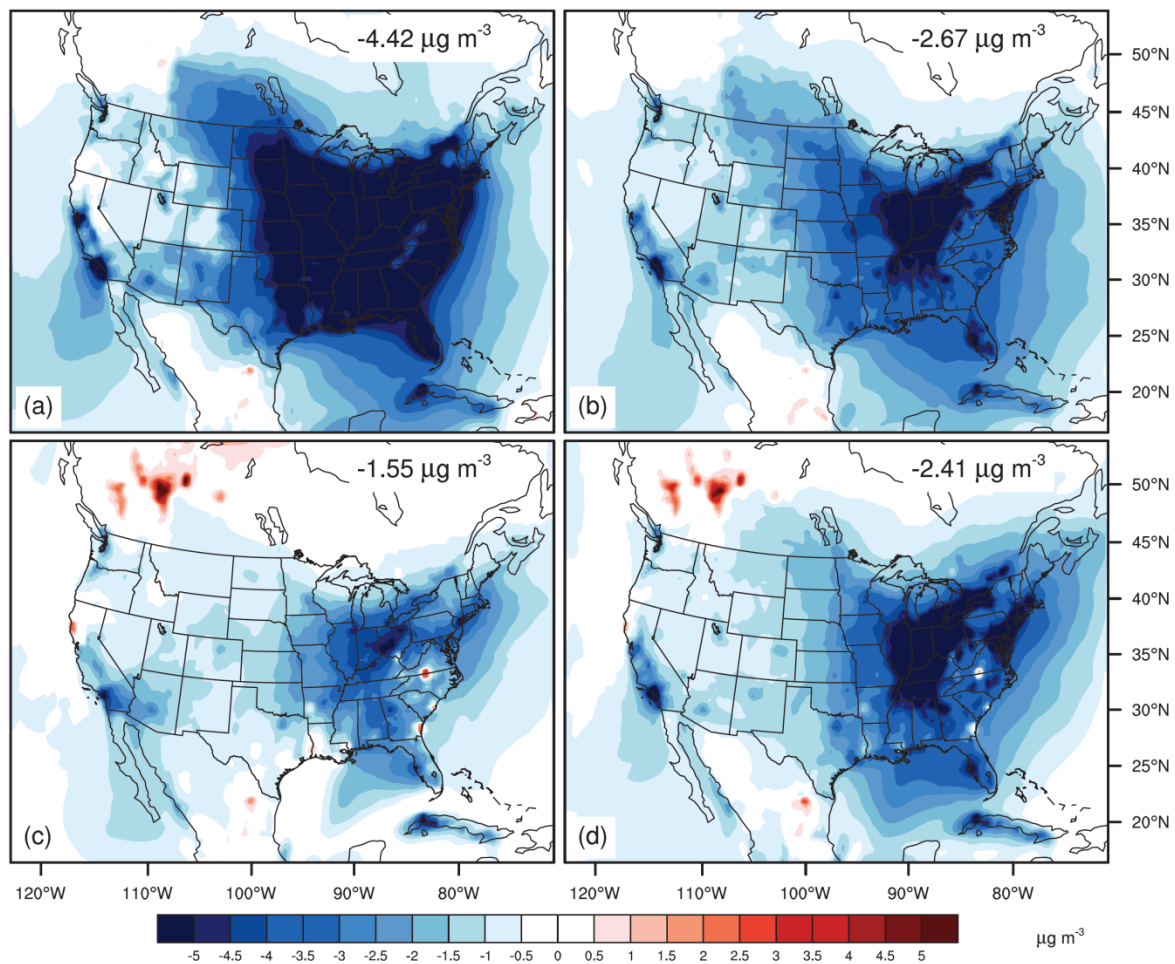

Figure S12. Seasonal distributions of $\text{PM}_{2.5}$ changes ($\mu\text{g m}^{-3}$) between S_REF in 2050 and S_2000 for (a) winter, (b) spring, (c) summer and (d) fall. The three-year annual average over the U.S. is $-2.76 \mu\text{g m}^{-3}$.

Figure S13. As Fig. S12 but for the changes between S_RCP45 in 2050 and S_2000. The U.S. three-year average is $-3.23 \mu\text{g m}^{-3}$.

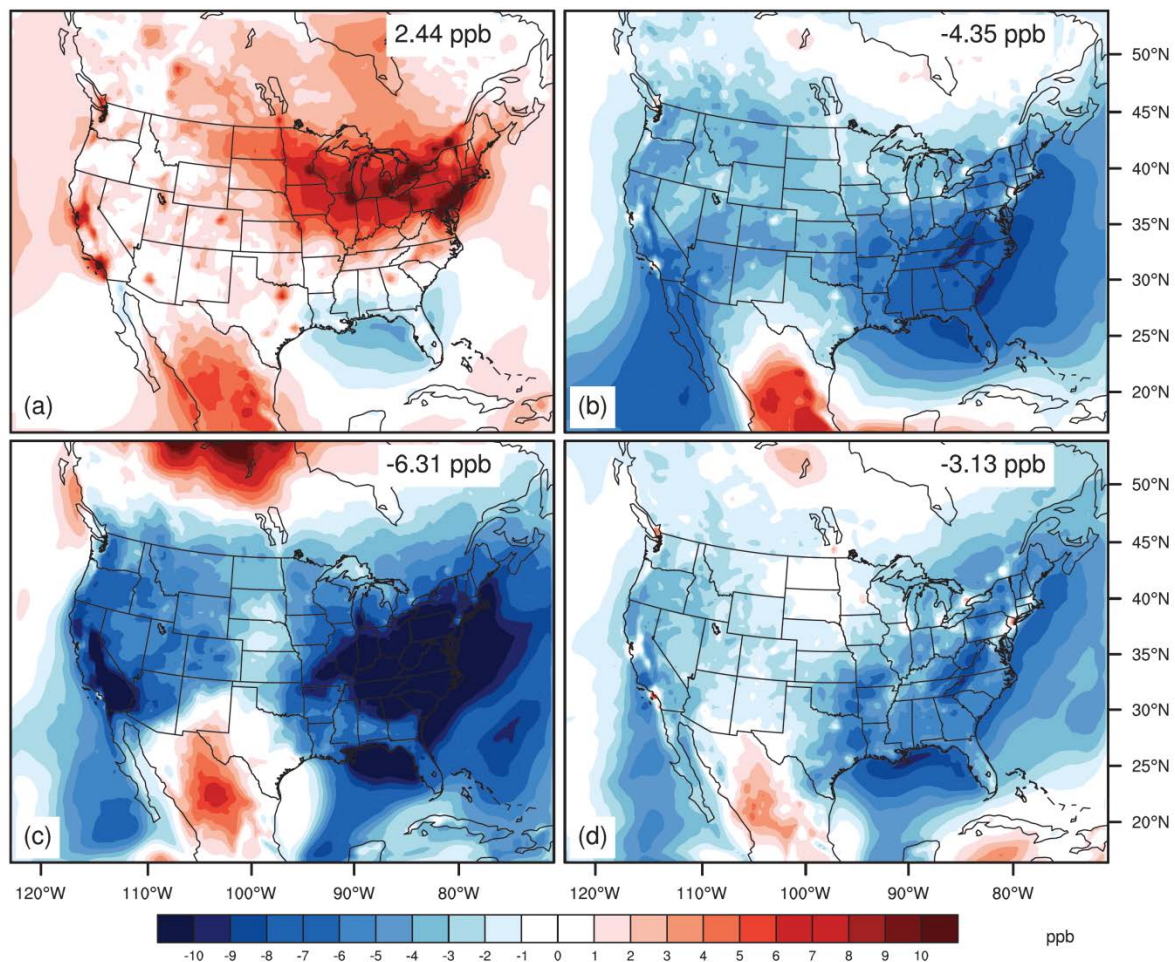

Figure S14. Seasonal distributions of O₃ changes (ppb) between S_REF in 2050 and S_2000 for (a) winter, (b) spring, (c) summer and (d) fall. The three-year annual average over the U.S. is -2.84 ppb.

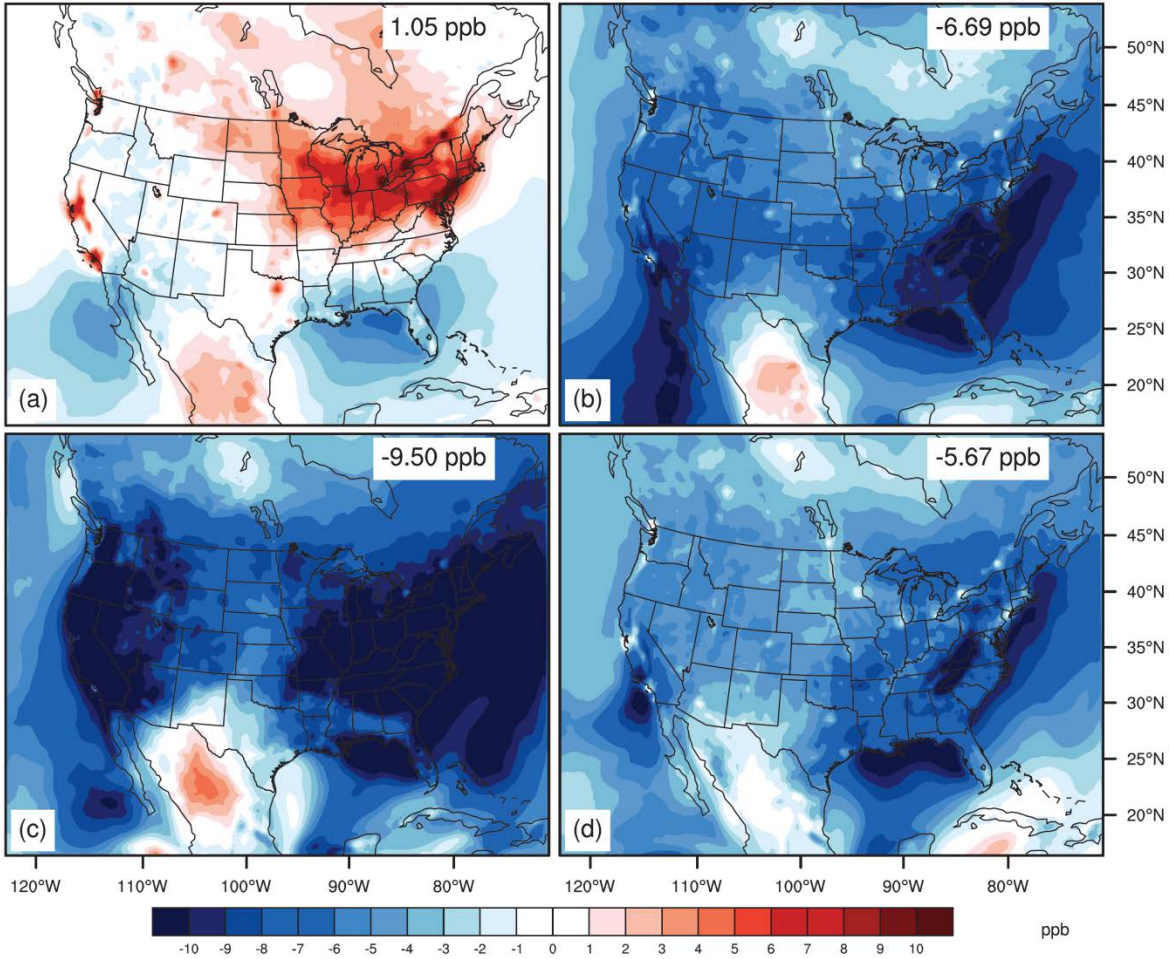

Figure S15. As for Fig. S14, but for the changes between S_RCP45 in 2050 and S_2000. The three-year U.S. average is -5.20 ppb.

Figure S16. Comparison of air quality changes over the U.S. for REF in 2050 relative to 2000, for this study (black triangle), and MZ4 from WEST2013 (red circle), for (a) the annual average PM_{2.5}, and (b) annual average O₃ surface concentration. Values shown are the average of three years for both CMAQ and MZ4.

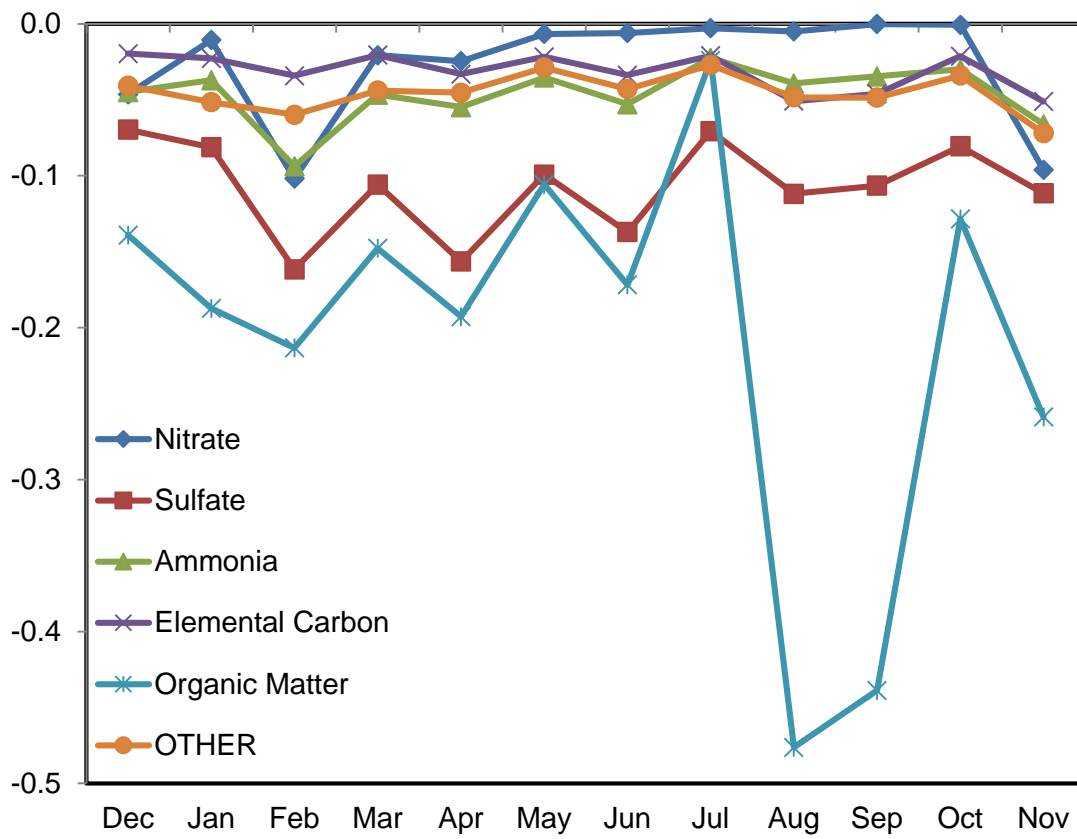

Figure S17. Seasonal distributions of total co-benefits for major PM_{2.5} components ($\mu\text{g m}^{-3}$).

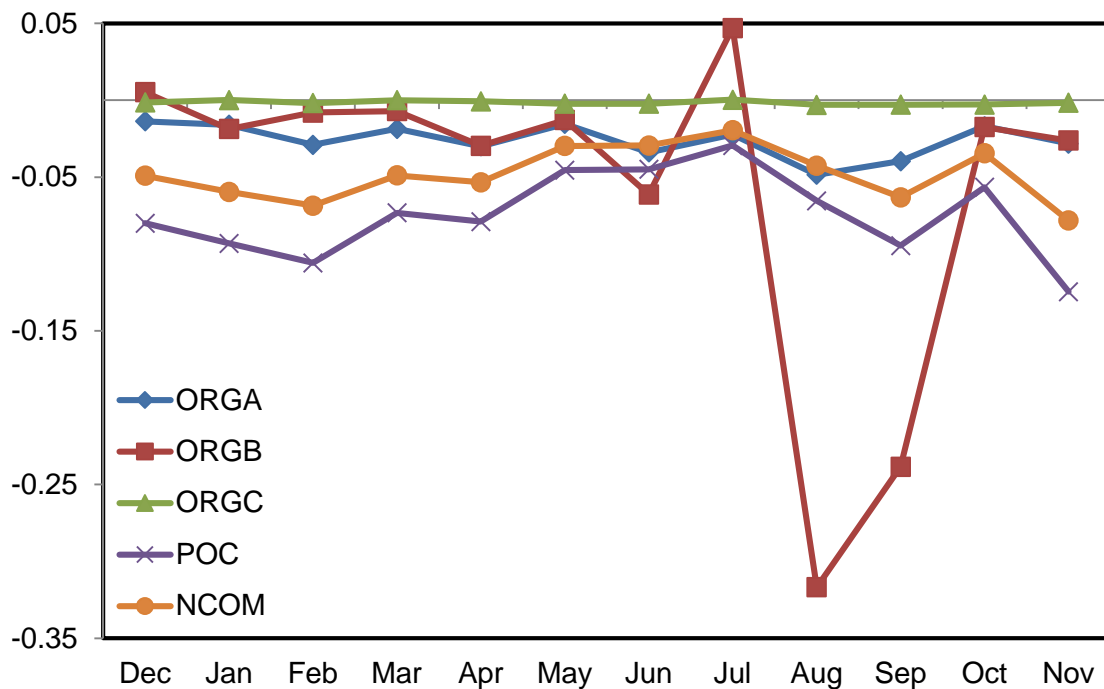

Figure S18. Seasonal distributions of total co-benefits for organic matter (OM, $\mu\text{g m}^{-3}$), including SOA from anthropogenic source (ORGA), SOA from biogenic source (ORGB), SOA from aqueous-phase oxidation (ORGC), Primary organic carbon (POC) and non-carbon organic matter (NCOM).

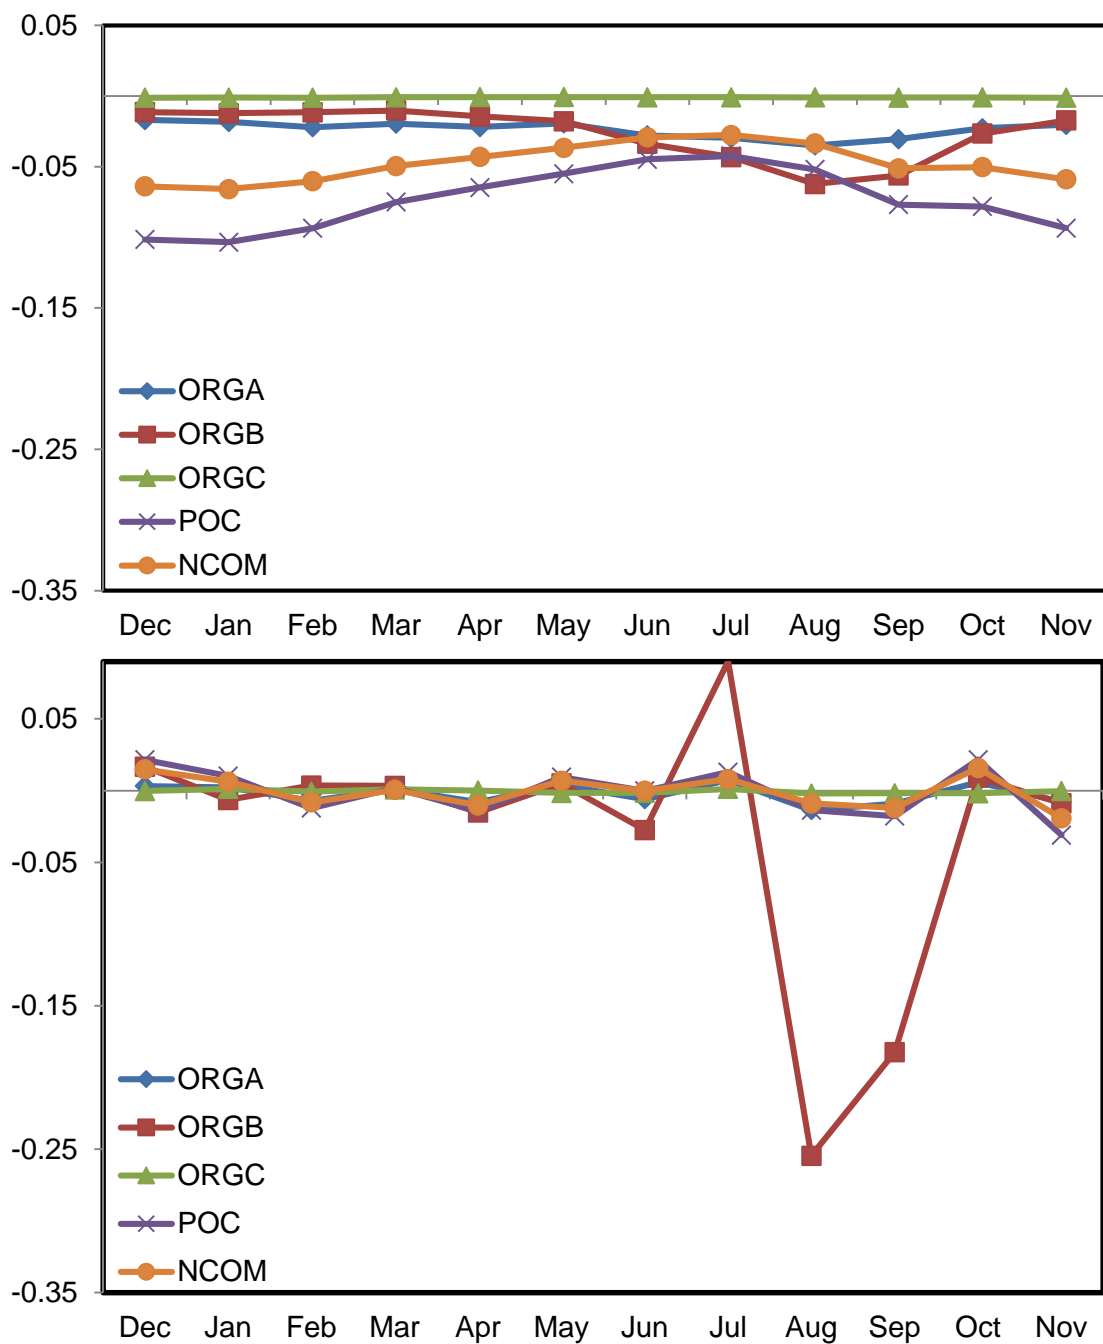

Figure S19. Monthly mean emission co-benefits (top) versus climate co-benefits (bottom) for organic matter (OM, $\mu\text{g m}^{-3}$), including SOA from anthropogenic source (ORGA), SOA from biogenic source (ORGB), SOA from aqueous-phase oxidation (ORGC), Primary organic carbon (POC) and non-carbon organic matter (NCOM).

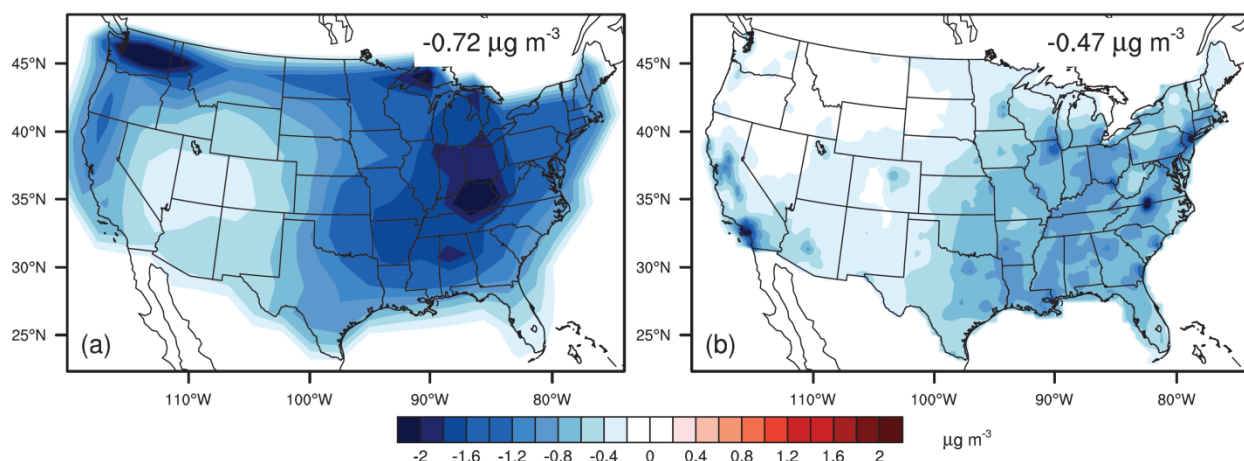

Figure S20. The total co-benefits for $PM_{2.5}$ ($\mu\text{g m}^{-3}$) in (a) WEST2013 and (b) this study. Both the results from WEST2013 and this study are using three-year averages.

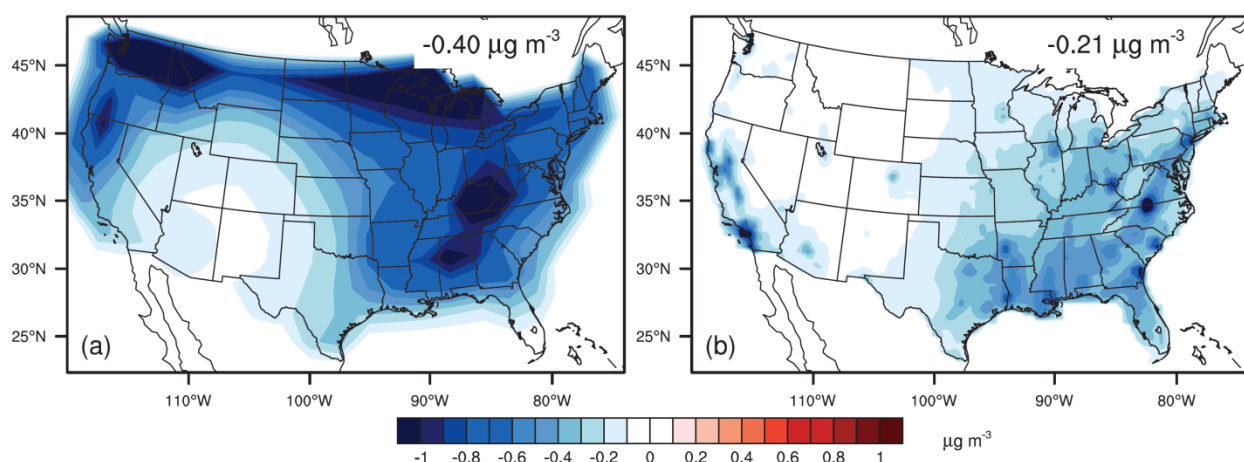

Figure S21. As for Fig. S20 but for OM ($\mu\text{g m}^{-3}$, including primary OC, SOA and NCOM).

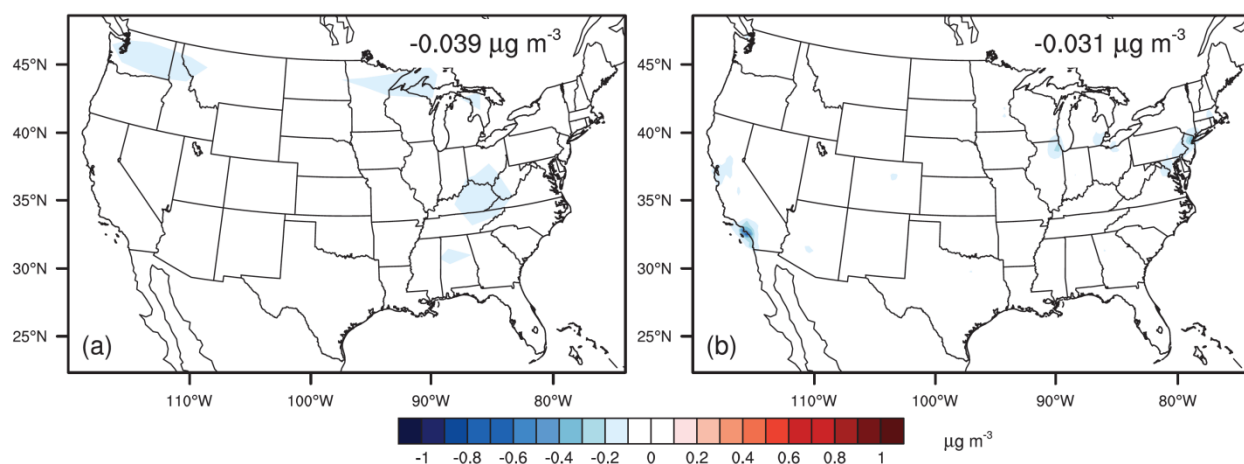

Figure S22. As for Fig. S20 but for EC ($\mu\text{g m}^{-3}$).

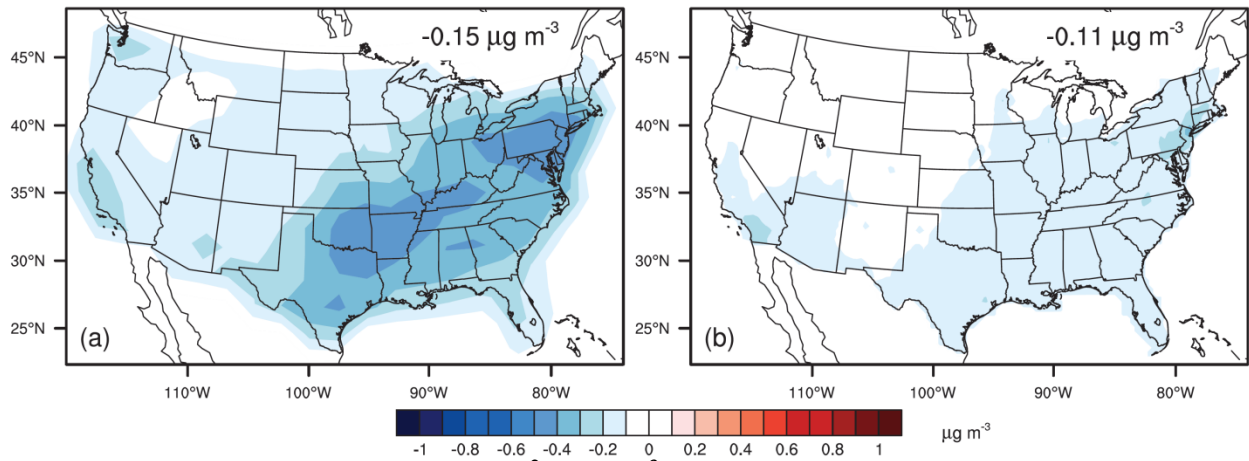

Figure 23. As for Figure S20 but for SO_4^{2-} ($\mu\text{g m}^{-3}$).

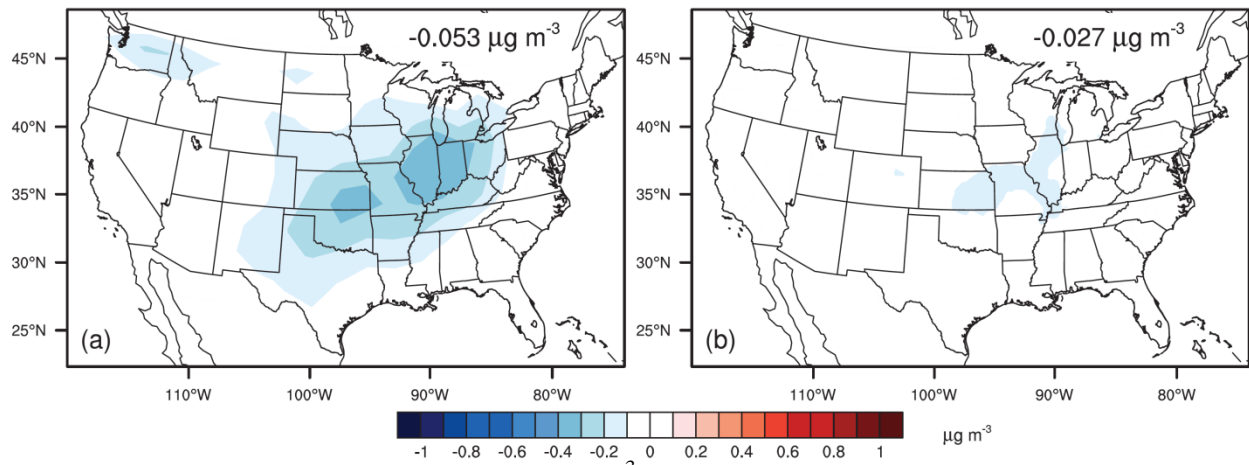

Figure S24. As for Fig. S20 but for NO_3^- ($\mu\text{g m}^{-3}$).

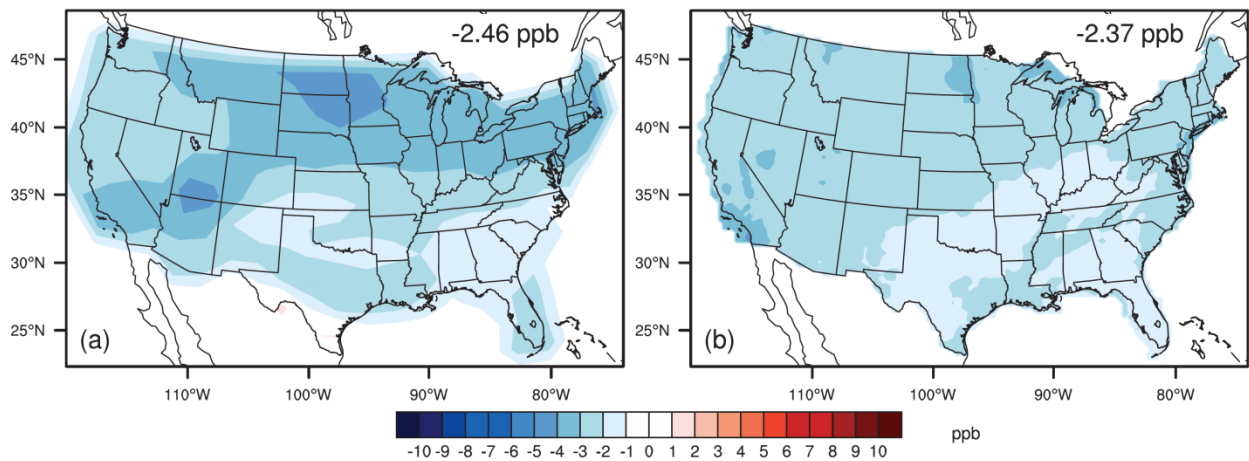

Figure S25. The total co-benefits for annual area-weighted O_3 (ppb) in (a) WEST2013 and (b) this study. Both WEST2013 and this study are using three-year averages.

Figure S26. The nine U.S. climate regions defined by the National Oceanic and Atmospheric Administration (<http://www.ncdc.noaa.gov/monitoring-references/maps/us-climate-regions.php>, accessed 5 December 2014).
