18 Abstract

19 Both primary biological aerosol particles (PBAP) and oxidation products of biogenic volatile
20 organic compounds (BVOC) contribute significantly to organic aerosols (OA) in forested
21 regions. However, little is known on their relative importance in diurnal time scales. Here, we
22 report biomarkers of PBAP and secondary organic aerosols (SOA) for their diurnal variability
23 in a temperate coniferous forest in Wakayama, Japan. Tracers of fungal spores, trehalose,
24 arabitol and mannitol, showed significantly higher levels in nighttime than daytime ($p < 0.05$),
25 resulting from the nocturnal sporulation under near saturated relative humidity. On the contrary,
26 BVOC oxidation products showed higher levels in daytime than nighttime, indicating
27 substantial photochemical SOA formation. Using tracer-based methods, we estimated that
28 fungal spores account for 45% of organic carbon (OC) in nighttime and 22% in daytime,
29 whereas BVOC oxidation products account for 15% and 19%, respectively. To our knowledge,
30 we present for the first time highly time-resolved results that fungal spores overwhelmed
31 BVOC oxidation products in contributing to OA especially in nighttime. This study emphasizes
32 the importance of both PBAPs and SOAs in forming forest organic aerosols.

33
34 **Keywords:** primary biological aerosol particles; fungal spores; biological volatile organic
35 compounds; organic aerosols.

36 1. Introduction

37 Biogenic particles and gases emitted from various vegetation types affect earth climate,
38 biogeochemical cycles of carbon and nitrogen, air quality and human health. Particles such as
39 fungal and fern spores, bacteria, viruses, algae, vegetation debris and pollen are directly emitted
40 and thus termed as primary biological aerosol particles (PBAP) (Després et al., 2012; Elbert et
41 al., 2007). Being mostly in the size range of 0.1–100 μm , PBAPs often contribute to a large
42 mass fraction of organic aerosols (OA) but a small fraction of total particles (Pöschl et al.,
43 2010). On the other hand, biogenic volatile organic compounds (BVOC) are highly reactive
44 and thus subjected to photooxidation to form fine particles of secondary organic aerosols (SOA)
45 and gas/particle partitioning of the reaction products (Claeys et al., 2004). There are substantial
46 progresses in understanding the source strengths, composition and atmospheric transformations
47 of biogenic particles, however, their contributions to OA and hence forces of their effects on
48 climate are still uncertain.

49 Global PBAP emission is as high as 1000 Tg y^{-1} (Jaenicke, 2005). Fungal spore is the
50 dominant component with the emission strengths of 8 to 186 Tg y^{-1} (Després et al., 2012;
51 Elbert et al., 2007; Heald and Spracklen, 2009). Fungal spores (1–30 μm) could account for up
52 to 45% of coarse particulate matter (Fröhlich-Nowoisky et al., 2009). In contrast, global
53 bacteria emissions are much smaller with abundances of 0.04–1.8 Tg y^{-1} (Burrows et al., 2009).
54 Pollen could contribute up to 65% of total PBAP mass in the flowering season, although their
55 number contribution is only ~1% of total PBAP (Manninen et al., 2014). Certain PBAPs
56 showed close correlations with atmospheric cloud condensation nucleus (CCN) and ice nucleus
57 (IN) (Hiranuma et al., 2015; Huffman et al., 2013). However, simulations indicated that PBAPs
58 are of regional importance for IN formation as they contribute very little to global average ice

59 nucleation rates (Hoose et al., 2010; Spracklen and Heald, 2014). Unveiling PBAP mass
60 concentrations is necessary to provide benchmarks for simulating its nucleation potentials and
61 the effect on the climate.

62 The most widely studied BVOCs are isoprene (C_5H_8), monoterpenes ($C_{10}H_{16}$) and
63 sesquiterpenes ($C_{15}H_{24}$). Global emission of isoprene ($309\text{--}706\text{ Tg C yr}^{-1}$) accounts for $\sim 50\%$
64 of total BVOC (Acosta Navarro et al., 2014; Guenther et al., 2006). Monoterpenes ($\sim 10\%$ of
65 total VOCs) and sesquiterpenes are other important SOA precursors (Ziemann and Atkinson,
66 2012). Atmospheric oxidation of these BVOCs depends on oxidant levels (NO_x and O_3),
67 humidity, light and temperature. Recent studies indicated that biogenic SOA production could
68 be enhanced under the input of anthropogenic oxidants (Carlton et al., 2010). Under pristine
69 conditions, BVOC oxidation and SOA formation are often accompanied by new particle
70 formation, involving in precipitation through increasing CCN and IN numbers (Pöschl et al.,
71 2010). The formation of SOA is often in the fine particle size (Pöschl et al., 2010), however, the
72 relative importance of PBAPs and SOA in contributing to OA is still ambiguous.

73 Various observational methods have been applied to explore PBAPs and SOA in natural
74 environment both qualitatively and quantitatively. Applications of ultraviolet aerodynamic
75 particle sizers and wideband integrated bioaerosol sensor based on fluorescence provided much
76 information on the abundances and size distributions of PBAP (Huffman et al., 2010; Pöhlker et
77 al., 2012). In situ observations of SOA are frequently conducted using aerosol mass
78 spectrometer (AMS) (Zhang et al., 2007). BVOC could also be monitored on real time using
79 Proton Transfer Reaction – Mass Spectrometry (PTR–MS) technology (Blake et al., 2009).
80 Detections of organic tracer compounds using gas chromatography combined with mass
81 spectrometry (GC/MS) make it possible to compare both PBAP and SOA sources

82 simultaneously (Graham et al., 2003). Progresses are achieved in boreal forest (Kourtchev et
83 al., 2008) and the Amazon (Graham et al., 2003). However, few studies focused on the mid-
84 latitudinal forest with high time resolution (Miyazaki et al., 2012; Mochizuki et al., 2015).

85 In this study, we collected daytime and nighttime samples in a mid-latitude forest in
86 Wakayama, Japan and analyzed the organic samples for various PBAP and SOA tracers using
87 GC/MS. We report for the first time that fungal spores overwhelm BSOA in contributing to
88 aerosol organic carbon (OC). We also report diurnal variations of PBAP tracers that reflect the
89 natural rhythm of the forest.

90

91 **2. Experimental**

92 **2.1 Site and sampling**

93 Aerosol sampling was conducted in August 20–30, 2010 during a field campaign at
94 Wakayama Forest Research Station, Kyoto University, in the Kii Peninsula, Japan (34.07 °N,
95 135.52 °E, ca. 750 m above sea level) (Han et al., 2013; Han et al., 2014). The dominant
96 species of the forest vegetation are coniferous trees of *Cryptomeria japonica* (Japanese cedar),
97 *Chamaecyparis obtuse* (Japanese cypress) and *Pinus densiflora* (Japanese red pine). Previous
98 studies indicated that monoterpenes are abundantly emitted from these tree species (Matsunaga
99 et al., 2011; Mochizuki et al., 2011). Total suspended particulate (TSP) samples were collected
100 on pre-combusted (450 °C, 6 h) quartz filters (Pallflex 2500QAT-UP, 20 cm × 25 cm) using a
101 high-volume air sampler (Kimoto AS-810B) at a flow rate of $\sim 60 \text{ m}^3 \text{ h}^{-1}$ at the ground level.
102 Each of the quartz samples were kept in a sealed glass jar at $< -20 \text{ }^\circ\text{C}$ during transport. The
103 quartz filters were then stored at $\sim -20 \text{ }^\circ\text{C}$ in the laboratory prior to chemical analysis. We
104 believe that the chemical losses were not large under the low temperature and sealed condition

105 (Kawamura et al., 2010). During the campaign, four field blanks were collected following the
106 sampling procedures, except for the running of pump for only 10 seconds.

107 Nighttime (from ~18:00 to next ~6:00 local time, LT) and daytime (from ~6:00 to ~18:00
108 LT) samples were collected separately each day. Of the whole sampling period, the backward
109 trajectories were calculated using HYSPLIT dispersion model starting at every hour of the day
110 and for different starting height (500m, 1000m and 1500m above ground level) (Han et al.,
111 2013, 2014). It can be seen that the air masses were mainly originated from the Asian continent
112 or passed over the Japanese islands during August 20–25, which were expected to deliver
113 pollutants from anthropogenic sources. On the other hand, air masses were mainly originated
114 from the western North Pacific during August 26–30, which create an environment close to the
115 pristine forest. On August 23 and 28, samples were collected every 3 hours (namely, 6:00–9:00,
116 9:00–12:00, 12:00–15:00, 15:00–18:00, 18:00–21:00, 21:00–24:00, 24:00–3:00, and 3:00–6:00
117 LT). A total of 36 samples were collected during the campaign.

118 **2.2 Chemical analysis**

119 For the determination of organic molecular tracers in aerosols, filter samples were first
120 extracted with dichloromethane/methanol and derivatized by N,O-bis-
121 (trimethylsilyl)trifluoroacetamide (BSTFA) mixed with pyridine to convert OH groups to
122 trimethylsilyl (TMS) ethers and COOH groups to TMS esters (Simoneit et al., 2004). The
123 extracts were kept at ~ -20 °C and then organic compounds were quantified within 24 h by
124 GC/MS using an Agilent 7890A GC equipped with HP-5ms capillary column (30 m × 0.25 mm
125 × 0.25 μm) coupled to Agilent 5975C mass-selective detector (MSD). Individual compounds
126 were identified by comparing the mass spectra with those of authentic standards or literature
127 data and quantified by comparing the peak areas with the internal standard (C₁₃ n-alkane) (Zhu

128 et al., 2015b). Recoveries for the authentic standards or surrogates were generally better than
129 80%, except for pinonic acid of ~60%, as obtained by spiking standards to pre-combusted
130 quartz filters following extraction and derivatization. No peak was found for the target
131 compounds in the field and laboratory blanks. The analytical errors by duplicate analyses were
132 less than 15%. The detection limits of the reported compounds were 105–557 $\text{pg } \mu\text{l}^{-1}$, which
133 correspond to ambient concentrations of 12–64 pg m^{-3} under a typical sampling volume of 700
134 m^3 and usage of 10 cm^2 filter section.

135 Aerosol OC was determined using a thermal/optical carbon analyzer (Sunset Laboratory Inc.,
136 USA) following the Interagency Monitoring Protected Visual Environments (IMPROVE)
137 thermal evolution protocol (Birch and Cary, 1996). The analytical error in replicate analyses
138 was within 8%. Samples were corrected for field blanks, in which OC level was < 5% of the
139 samples. Inorganic ions were measured using an ion chromatograph (761 Compact IC,
140 Metrohm, Switzerland). SO_4^{2-} and NO_3^- were discussed in the study. The detection limits were
141 $\sim 0.1 \text{ ng m}^{-3}$. The laboratory analytical error was within 5%. Samples were corrected for field
142 blanks.

143 Statistical significances of daytime and nighttime organic tracers were evaluated based on
144 Student's t-test at $p < 0.05$ and $p < 0.01$ level, respectively. To explore the effects of
145 anthropogenic pollutant inputs on BSOA formation, linear correlations (Pearson) between SOA
146 tracers and NO_3^- and SO_4^{2-} were investigated. The contributions from various sources to OC
147 were estimated using tracer-based methods using conversion factors according to the preceding
148 studies.

149

150 **3. Results and discussion**

151 3.1 PBAP tracers reflecting diurnal rhythm of fungal spores and pollen

152 3.1.1 Fungal spore tracers

153 Four primary saccharides (trehalose, glucose, fructose and sucrose) and four sugar alcohols
154 (arabitol, mannitol, inositol and erythritol) were detected in the forest aerosols as PBAP tracers.
155 Trehalose, arabitol and mannitol were the major species of fungus and have been used as
156 tracers for fungal spores (Jia and Fraser, 2011). These compounds showed significantly higher
157 levels in nighttime (262 ± 168 , 156 ± 102 and 349 ± 243 ng m⁻³ for trehalose, arabitol and
158 mannitol, respectively) than in daytime (128 ± 90.2 , 76.0 ± 54.9 and 183 ± 139 ng m⁻³,
159 respectively) (T-test, $p < 0.05$, Figure 1d–f). High abundances of these fungal spore tracers
160 were resulting from the nocturnal sporulation under near saturated relative humidity (Figure 2).
161 In nighttime, the mean relative humidity was 96% in the sampling period. Nevertheless, the
162 mean daytime relative humidity was still as high as 88%. Such a moist environment caused
163 enrichment of fungal spores and their discharges, resulting high abundances of their tracer in
164 aerosols. The sum of trehalose, arabitol and mannitol contributed to 70% of total PBAP tracer
165 mass, demonstrating an important role of fungi in regulating the land-atmosphere exchange in
166 the forest region.

167 Diurnal profiles of fungal spore tracers showed similar pattern on August 23 and August 28,
168 two typical days representing regional and local phenomenon, respectively. Minima of
169 trehalose, arabitol and mannitol appeared around the noontime and increased dramatically in
170 the evening on both days (Figure 3). On August 23, fungal spore tracers peaked at 21:00–24:00
171 LT and decreased slowly thereafter. In comparison, these compounds peaked slightly earlier at
172 18:00–21:00 LT on August 28. The maxima of these compounds on August 23 were higher by
173 a factor of ~1.5 than those on August 28. This phenomenon was likely related to the

174 precipitation that occurred at 13:00–17:00, August 23 (Figure 2), which favors the growth and
175 release of fungal spores.

176 3.1.2 Other PBAP tracers and levoglucosan

177 Sucrose, a key component of pollen grain (Yttri et al., 2007), showed significantly higher
178 levels ($p < 0.01$) in daytime ($31.9 \pm 17.7 \text{ ng m}^{-3}$) than nighttime ($14.6 \pm 14.2 \text{ ng m}^{-3}$) (Figure
179 1c). The diurnal profile of sucrose showed peaks in the afternoon (Figure 3a), indicating the
180 flowering time of the vegetation. As the blossom season of the dominant coniferous trees is
181 March–April in the region, the source of sucrose is likely from the pollen of the widely
182 distributed floor vegetation, *Ambrosia artemisiifolia*, *Artemisia indica*, and plants of *Poaceae*
183 family, which are flowering during the sampling period.

184 Glucose and fructose are originated dominantly from plant debris (Medeiros et al., 2006; Zhu
185 et al., 2015a), and sometimes from microorganisms and soil dust (Rogge et al., 2007; Simoneit
186 et al., 2004). There was no serious continental outflow of Asian dust over the sampling period
187 (based on observations by Japan Meteorological Agency). Insignificant diurnal variations of
188 these two compounds imply that they were emitted both in the daytime and the nighttime in the
189 forest possibly from plants and microorganisms (Figure 1a–b, 3a). The diurnal variation of
190 planetary boundary layer height could also contribute to the observed variations of glucose and
191 fructose and other PBAP tracers. In the daytime, enhanced vertical mixing might cause dilution
192 effect to the observed PBAP tracers. While in the nighttime, the low wind speed favors the
193 buildup of PBAP tracers in the canopy (Figure S1), resulting in the elevated levels (Figure 3a,
194 b). Interestingly, the mass concentrations of glucose were one order of magnitude higher than
195 those of fructose. This might be related to the higher abundance of glucose in trees. For

196 example, tissues of a wide range of subtropical plants were found to contain more glucose than
197 fructose (Baker et al., 1998).

198 Being exclusively produced by the thermal depolymerization and dehydration of cellulose
199 and hemicellulose, levoglucosan has been used as a specific tracer for biomass burning
200 (Simoneit et al., 1999; Zhu et al., 2015b). Levoglucosan showed significantly higher levels ($p <$
201 0.05) in daytime ($2.52 \pm 2.08 \text{ ng m}^{-3}$) than nighttime ($1.14 \pm 0.94 \text{ ng m}^{-3}$). Moreover, we found
202 higher levels of levoglucosan in August 20–25 ($2.97 \pm 1.64 \text{ ng m}^{-3}$) than August 26–30 ($0.53 \pm$
203 0.44 ng m^{-3}); those concentrations in the latter period are close to the regional background level
204 from Okinawa Island (Zhu et al., 2015b). In the nighttime, levoglucosan may have been
205 deposited to the canopy as a result of dampened vertical mixing and relatively low wind speed
206 (Figure S1). In addition, local burning activities could also contribute to the daytime elevation
207 of levoglucosan although they might be insignificant.

208 **3.1.3 Daytime abundances of SOA tracers**

209 A total of 11 compounds were detected as SOA tracers. Six isoprene-tracers, including 2-
210 methylglyceric acid (MGA), two 2-methyltetrols (2-methylthreitol and 2-methylerythritol,
211 MTLs), and three C5-alkene triols (3-methyl-2,3,4-trihydroxy-1-butene, cis-2-methyl-1,3,4-
212 trihydroxy-1-butene and trans-2-methyl-1,3,4-trihydroxy-1-butene, MTHBs), showed higher
213 levels in daytime (Figure 1j–l). Similar daytime abundances were also found for 4
214 monoterpene-tracers; pinonic acid (PNA), pinic acid (PA) ($p < 0.05$), 3-hydroxyglutaric acid
215 (HGA) and 3-methyl-1,2,3-butanetricarboxylic acid (MBTCA) (Figure 1m–p). Total isoprene-
216 SOA tracers (281 ± 274 and $199 \pm 207 \text{ ng m}^{-3}$ in daytime and nighttime, respectively) were
217 more abundant by a factor of ~ 5 than total monoterpene-SOA tracers (54.6 ± 50.2 and $36.3 \pm$
218 33.6 ng m^{-3} , respectively). Isoprene is more abundantly emitted than monoterpenes from this

219 coniferous forest. This is consistent with the observations at a mountain site in central Japan
220 (Fu et al., 2014). Sesquiterpene-tracer, caryophyllinic acid, showed consistently low levels in
221 both daytime ($1.22 \pm 1.23 \text{ ng m}^{-3}$) and nighttime ($0.94 \pm 0.83 \text{ ng m}^{-3}$) (Figure 1q). The daytime
222 abundances of isoprene- and monoterpene-tracers reflected the production of SOA by the
223 photooxidation of BVOC in the forest.

224 **3.2 Influence of anthropogenic oxidant on SOA formation**

225 The diurnal profile of SOA tracers showed a clear single peak pattern in the afternoon on
226 August 28–29. Total isoprene-tracers peaked at 15:00–18:00 (28.4 ng m^{-3}), while total
227 monoterpene-tracers peaked slightly earlier at 12:00–15:00 (12.7 ng m^{-3}) (Figure 3c–d). Their
228 afternoon peaks are consistent with the maxima of ambient temperature and solar radiation
229 (Figure 2). These results indicate that SOA is formed by photooxidation of isoprene and
230 monoterpenes emitted from local vegetation under natural conditions. Our results are consistent
231 with the afternoon peaks of semi-volatile oxygenated organic aerosol (SVOOA) component
232 determined by the positive matrix factorization of the AMS spectra collected during the same
233 campaign (Han et al., 2014), which were produced by photooxidation of freshly emitted BVOC
234 from the local forest.

235 Interestingly, on August 23–24, days with regional anthropogenic oxidant input, isoprene-
236 and monoterpene-tracers showed not only afternoon peaks at 12:00–15:00, but also nighttime
237 peaks (Figure 3c–d) following the intensive precipitation during 13:00–17:00 (Figure 2). These
238 results suggest that SOA is continuously produced even in nighttime with sufficient oxidants.
239 AMS observation in the same campaign indicated that highly oxidized low volatility
240 oxygenated organic aerosols (LVOOA) are even more abundant than that of SVOOA on

241 August 23–24, especially in nighttime (Han et al., 2014). Nighttime production of SOA was
242 also observed in the United States (US) (Zhao et al., 2013).

243 Moreover, on days with regional input of oxidants, the SOA tracer levels were 1–2 orders of
244 magnitude higher than those under natural conditions both in daytime and nighttime.

245 Meanwhile, we found positive relations between SO_4^{2-} and isoprene-SOA tracers as well as
246 monoterpene-SOA tracers (Table 1). These phenomena could be explained by the following
247 reasons. Firstly, regional BSOA could be transported along with anthropogenic oxidants.

248 Observations at Okinawa island, southern Japan indicated that the variations of monoterpene-
249 SOA tracers and caryophyllinic acid are related to the continental outflow of BVOC oxidation
250 products (Zhu et al., 2016). Secondly, the earlier generation products of BVOC oxidation tend
251 to shift to the particle phase during gas/particle partitioning given their semivolatility nature
252 (Cahill et al., 2006), such a shift might be more prominent on days with aged regional aerosols
253 accompanied by a daytime increase of organics determined by AMS (Han et al., 2014). The
254 third possibility is that the anthropogenic oxidants might promote BSOA formation. We focus
255 on the third possibility and further testified this hypothesis.

256 We examined the degrees of BSOA tracer buildups in daytime as compared to nighttime
257 ($\Delta\text{BSOA} = \text{mean daytime BSOA tracer levels} - \text{mean nighttime BSOA tracer levels}$) (Table 2).
258 ΔBSOA values on August 20–25 were higher by more than 1 order of magnitude than that on
259 August 26–30. These results implied that, although transported BSOA might contribute to their
260 elevation, anthropogenic oxidants substantially promoted the SOA formation in Wakayama
261 forest. A recent field study in the southeastern US suggested that the formation of methyltetrols
262 is mediated by SO_4^{2-} , being consistent with our results (Xu et al., 2015). They also reported that
263 NO_3^* radical was involved in the nighttime monoterpene oxidation. However, inorganic NO_3^-

264 did not correlate with monoterpene-SOA tracers during nighttime, indicating that the
265 contribution of NO_3^\bullet radical to nighttime monoterpene oxidation is not clear in Wakayama
266 aerosols, which deserve further investigations.

267 **3.3 OC fractions from fungal spores and BVOC oxidation**

268 The contributions of each source component to OC were estimated using tracer-based
269 methods. OC fractions from fungal spores were estimated based on mannitol levels assuming
270 that there were 1.7 pg mannitol and 13 pg OC per spore (Bauer et al., 2008). The secondary
271 organic carbon (SOC) fraction resulting from VOC oxidation was estimated following
272 Kleindienst et al. (2007) based on the chamber experiment. Contributions of plant debris to OC
273 were estimated based on glucose following Puxbaum and Tenze-Kunit (2003). Contributions of
274 biomass burning aerosols to OC were estimated based on levoglucosan following Zhu et al.
275 (2015b). It is noteworthy that, although each tracer methods gave a reasonable estimate in the
276 original studies, uncertainties would be introduced in the current study considering the site
277 differences. Still, the estimations are inferable for the contributions from each source to OC in
278 the forest aerosols.

279 Fungal spores contribute a major fraction (45%) to OC in nighttime. In daytime, although the
280 mass fraction was about half to that in nighttime (22%), fungal spores are still the largest
281 known source of OC (Figure 4). In comparison, BVOC oxidation products (BSOC) contribute
282 to 15% and 19% of OC in nighttime and daytime, respectively. Interestingly, the large BSOC
283 fraction of OC mainly occurred on days with anthropogenic influences (August 20–25) (17% in
284 daytime and 23% in nighttime). On days close to natural conditions (August 26–29), BSOC has
285 a small contribution to OC (4.0% in nighttime and 4.7% in daytime). The larger contributions
286 of BSOC to OC might be associated with the BSOC that are transported from the Asian

287 continent, a stimulating effect of anthropogenic oxidants on daytime BSOA formation, as well
288 as the enhanced gas to particle conversion of BVOC. These results suggest that increased fossil
289 fuel combustion and the subsequent oxidant emissions would cause a larger contribution of
290 BSOA to OA, which may in part compensate the human-caused global warming by acting as
291 CCN. Such effects are supposed to be incorporated into model simulations of the future climate
292 in the Anthropocene.

293 It is noteworthy that the contribution of plant debris to OC (5.6% in nighttime and 4.6% in
294 daytime) could not be neglected. These fractions account for only the primary OC sources
295 based on glucose level, and could be underestimated. Nevertheless, there are still quite amounts
296 of OC not being determined (34% and 51% in nighttime and daytime, respectively). Other than
297 the uncertainties introduced by the tracer methods, a notable fraction of OC could be
298 contributed from humic-like substances that are chemically and physically similar with
299 terrestrial and aquatic humic and fulvic acids (Graber and Rudich, 2006). Mono- and di-
300 carboxylic acids, originating from a broad range of primary organic compounds, could
301 contribute 38–44% of OC (Legrand et al., 2013). Pollen could also contribute to OC because of
302 its large size. Amines are another source of OC, but not well studied (Sintermann and Neftel,
303 2015). These sources from various sectors need to be further characterized for an unambiguous
304 understanding of the sources of forest aerosols.

305 Among few studies on the observation-based quantification of OC/OA sources of forest
306 aerosols, our results are in accordance with those in the Amazon rainforest, where primary
307 biological aerosol and SOA accounted for 68.5% and 18.8% of total particle masses, without
308 consideration of the diurnal variations (Pöschl et al., 2010). At an urban site with various OA
309 sources, Bakersfield, California, Zhao et al. (2013) reported that SOA accounted for 78% and

310 66% of OA during the daytime and the nighttime, respectively, while primary sources
311 accounted for 15% of OA. Under a changing climate and uncertain anthropogenic emission
312 scenario, although OA could be contributed by complicated sources in a pristine forest
313 environment, our results demonstrate that biogenic particles and gases are rather the major
314 sources of organic aerosols in the forest atmosphere.

315

316 **4. Conclusions**

317 We collected daytime and nighttime samples in a mid-latitude coniferous forest in
318 Wakayama, central Japan. Focusing on fungal spores and BSOA, we quantified organic tracers
319 containing information of various aerosol sources. Nighttime higher levels of trehalose and
320 sugar alcohols were clarified under near saturated relative humidity, indicating the flourishing
321 of fungal sporulation. BSOA tracers were more abundant in the daytime, indicating their
322 photooxidation production among other sources. Enhanced BSOA tracer levels were observed
323 on days with notable input of anthropogenic oxidant. Using tracer-based methods, we estimated
324 that fungal spores contribute dominantly to OC in forest aerosols not only in the nighttime, but
325 also in the daytime. The study emphasizes the importance of fungal spores in affecting biogenic
326 aerosols in forest ecosystem.

327

328 **Acknowledgement**

329 This study was supported in part by the Japan Society for the Promotion of Science (Grant–
330 in–Aid Nos. 19204055 and 24221001), the Environment Research and Technology
331 Development Fund (B-0903) from the Ministry of the Environment, Japan, and the Program for
332 Improvement of Research Environment for Young Researchers from Special Coordination

333 Funds for Promoting Science and Technology commissioned by Ministry of Education,
334 Culture, Sports, Science and Technology, Japan. The authors thank the faculty and staff of
335 Wakayama Forest Research Station (WFRS), Field Science Education and Research Center of
336 Kyoto University, Japan, for the use of the site for aerosol sampling. The authors also thank Y.
337 Han for her contribution to the aerosol sampling, and Y. Han and K. Kawana for their
338 cooperation in the field observation. The meteorological data were provided by WFRS. The
339 authors appreciate the experimental support of P. Fu and technical support of W. Zhang. The
340 data of this study is available upon request to C. Zhu.
