Abstract

The volcanic fissure at Holuhraun, Iceland started at the end of August 2014 and continued for six months to the end of February 2015, with an extensive lava flow onto the Holuhraun plain. This event was associated with large SO₂ emissions, amounting up to approximately 4.5 times the daily anthropogenic SO₂ emitted from the 28 European Union countries, Norway, Switzerland and Iceland. In this paper we present results from EMEP/MSC-W model simulations where we added 750 kgs⁻¹ SO₂ emissions at the Holuhraun plain from September to November (SON), testing three different emission heights. The three simulated SO₂ concentrations, weighted with the OMI satellite averaging kernel, are found to be within 30% of the satellite observed SO₂ column burden. Constraining the SO₂ column burden by the satellite data, while using the kernel along with the three simulated height distributions of SO₂, we estimate that the median of the daily burdens may have been between 13 and 40 kt in the North Atlantic area under investigation. We suggest this to be the uncertainty in the satellite derived burdens of SO₂, mainly due to the unknown vertical distribution of SO₂. Surface observations in Europe outside Iceland showed concentration increases up to >500 µgm⁻³ SO₂ from volcanic plumes passing. Three well identified episodes, where the plume crossed several countries, are compared in detail to surface measurements. For all the events, the general, timing of the observed concentration peaks compared quite well to the model results. The overall changes to the European SO₂ budget due to the volcanic fissure are

estimated. Three-monthly wet deposition (SON) of SO_x in the 28 European Union countries, Norway and Switzerland is found to be more than 30 % higher in the model simulation with Holuhraun emission compared to a model simulation with no Holuhraun emission. The largest increases, apart from extreme values on Iceland, are found on the coast of Northern Norway, a region with frequent precipitation during westerly winds. On three month average (during SON 2014) over Europe, SO_2 and $\text{PM}_{2.5}$ surface concentrations, due to the volcanic emissions, increased by only ten and six percent, respectively. Although the percent increase of $\text{PM}_{2.5}$ concentration is highest over Scandinavia and Scotland, an increase in PM exceedance days is found over Ireland and the already polluted Benelux region (up to 3 additional days), where any small increase in particulate matter concentration leads to an increase in exceedance days.

1 Introduction

Increased seismic activity in the Bárðarbunga volcano was recorded by the Icelandic Met Office from the middle of August 2014 (<http://en.vedur.is/earthquakes-and-volcanism/volcanic-eruptions/holuhraun/>). The activity continued in the volcano but some tremors appeared also towards the Holuhraun plain, a large lava field north of the Vatnajökull ice cap, the latter covering the Bárðarbunga and Grimsvötn volcano. On August 31 a continuous eruption started at Holuhraun with large amounts of lava pouring onto the plain and large amounts of sulphur dioxide (SO_2) emitted into the atmosphere (Sigmundsson et al. 2015). Thordarson and Hartley (2015) estimated SO_2 emissions from the magma at Holuhraun to range between 30 ktd^{-1} and 120 ktd^{-1} over the first three months of the eruption, with a maximum during the first two weeks of September. Schmidt et al. (2015) also found that among several model simulations with different emission fluxes, the model simulations with the largest emission (120 ktd^{-1}) compared best with satellite observations at the beginning of September. In comparison, Kuenen et al. (2009) estimated the daily anthropogenic emission from the 28 European Union countries for 2009 to be 13.9 ktd^{-1} , while the 2013 estimate is 9.8 ktd^{-1} (EMEP, 2015). The eruption ended in February 2015 and during the 6 months of eruption a total of approximately $11 (\pm 5) \text{ Tg SO}_2$ may have been released (Gislason et al. 2015), and the total lava field from the fissure measured 85 km^2 in area with a lava volume estimated to amount to 1.4 km^3 (vedur.is). It is of interest to investigate the impact of these volcanic emissions on SO_2 levels in Europe in 2014. In the last

decades, measures have been taken to reduce SO₂ emissions, triggered by the Convention on Long-range Transboundary Air Pollution (LRTAP), in Europe. Significant reductions of 75% in emission between 1980 and 2010 are confirmed by observations (Tørseth et al., 2012). The impact of volcanic eruptions with SO₂ emissions can thus perturb the European atmospheric sulphur budget to a larger extent than before and potentially lead to new acidification of lakes and soils if the eruption would last over a long time period.

For comparison, the big 1783 Icelandic Laki eruption lasted eight months and released a total amount of estimated 120 Tg of SO₂. The resulting sulphuric acid caused a haze observed in many countries of the northern hemisphere and increased mortality in Northern Europe (Grattan et al., 2003, Thordarson and Self, 2003, Schmidt et al., 2011). The fissure at Holuhraun was much weaker than the Laki fissure, both in terms of amount of SO₂ released and probably also the height of the eruptive column. Thordarson and Self (1993) estimated that the Laki erupted at emission heights up to 15 km, while the observations of the Holuhraun eruptive cloud saw the plume rising up to 5 km (vedur.is). Ground level concentrations exceeded the Icelandic hourly average health limit of 350 µgm⁻³ over large parts of Iceland (Gislason et al. 2015). The World Health Organization (WHO) has a 10 minute limit of 500 µgm⁻³ and a 24-hour limit of 20 µgm⁻³. High hourly mean surface concentrations of SO₂ were measured in Ireland (524.2 µgm⁻³), but then also in Austria (247.0 µgm⁻³) and Finland (180 µgm⁻³) (Schmidt et al. 2015, Ialango et al. 2015).

A climate impact of high SO₂ emissions may be suspected, such as a cooling of climate due to an increase in aerosol burdens. Gettelman et al. (2015) using a global climate model found a small increase in cloud albedo due to the Holuhraun emissions resulting in -0.21 Wm⁻² difference in radiative flux at the top of the atmosphere. If the event had happened earlier in the summer a larger radiative effect could be expected (-7.4 Wm⁻²). Understanding the atmospheric sulphur budget associated to such events is thus of great interest also for climate science. Unlike the two previous big eruptions in Iceland, Eyjafjallajökull in 2010 and Grímsvötn in 2011, this eruption did not emit important amounts of ash. However, uncertainties in volcanic source estimates, time varying emissions from a volcano type of point source and dependence of transport on initial injection height are similar problems for SO₂ and ash plumes. For eruptions where both ash and SO₂ are emitted, SO₂ can act as a proxy for ash (Thomas and Prata et al, 2011; Sears et al., 2013), however separation will occur because of density differences and different eruption heights (Moxnes et al., 2014).

Proven capability of modelling the transport of a volcanic plume can be useful for judging future eruption scenarios where SO₂ or ash can cause a problem.

The Holuhraun eruption is worth being analysed for several gas and aerosol transport and transformation processes, this study will mainly focus on simulated air quality effects and the perturbed sulphur budget due to the volcanic SO₂ emissions during the first three months of the eruption. Several stations in Europe reported high concentrations of SO₂ during this time and case studies are chosen to evaluate simulated plume development over Europe. The transport is modelled with the EMEP MSC-W chemical transport model, one of the important models used for air quality policy support in Europe during the last 30 years (Simpson et al. 2012). The first two months of the eruption are well covered by satellite observations. Both station and satellite data are compared to model results to understand the amplitude and magnitude of the sulphur budget perturbation. The effect of the injection height on the model results is studied by sensitivity simulations. Finally the perturbed European sulphur budget, is documented and discussed to investigate the impact of increased SO₂ emission from a Icelandic volcano on European pollution levels.

2 Methods

2.1 Model description

The model simulations of the transport of the SO₂ Holuhraun emissions are done with the 3-D Eulerian chemical transport model developed at the Meteorological Synthesizing Centre-West (MSC-W) for the European Monitoring and Evaluation Programme (EMEP). The EMEP MSC-W model is described in Simpson et al. (2012). SO₂ is oxidized to sulphate in both gas and aqueous phase. In gas phase the oxidation is initiated by OH and is controlled by local chemistry. In aqueous phase the oxidants ozone, hydrogen peroxide and oxygen catalysed eventually by metal ions contribute to the oxidation. The dry deposition in the model is parameterized for different land types. Both in-cloud and sub-cloud scavenging are considered for wet deposition.

The simulations use the EMEP-MACC (Monitoring Atmospheric Composition and Climate) model configuration. The horizontal resolution of the model simulations is 0.25° (longitude) x 0.125° (latitude). There are 20 vertical layers up to about 100 hPa, with the lowest layer around 90 meters thick. The model is driven by meteorology from the European Centre of

Medium-Range Weather Forecasts (ECMWF) in the MACC model domain (30° west to 45° east and 30° to 76° north). Iceland is in the upper north-western corner of the domain, which implies losses of sulphur from the regional budget terms in sustained southerly and easterly flow regimes. The meteorology fields used have been accumulated in the course of running the MACC regional model ensemble forecast of chemical weather over Europe (<http://macc-raq-op.meteo.fr>), of which the EMEP MSC-W model is part of. For our hindcast type simulations here, only the fields from the first day of each forecast are used. The meteorology is available with a three hourly interval. All model simulations are run from September through November 2014.

Emission from the Holuhraun fissure is set to a constant 750 kgs⁻¹ SO₂ (65 ktd⁻¹) for the entire simulation from the total 2.0 ± 0.6 Tg SO₂ emitted in September estimated in Schmidt et al. (2015). For all model runs the anthropogenic emissions are as standard for our EMEP MACC model configuration. Table 1 shows an overview of the four different model runs that are used in this study. The column height observed both at ground and airborne instruments, varied during the eruption (Schmidt et al., 2015), the mean height was however around 3 km over the period. For the best guess, base case simulation, called *bas_hol*, volcanic emissions at Holuhraun are distributed equally from the ground up to a 3 km emission column height. To test the sensitivity towards emission height, two additional model simulations are done. One simulation where the volcanic emission is distributed from the ground up to 1 km called *low_hol*, and a simulation where the volcanic emission is distributed between 3 km and 5 km called *high_hol*. To derive the impact purely due to the emissions from Holuhraun, a simulation with no Holuhraun emissions is performed, called *no_hol*. Sensitivity runs with an almost doubled constant emission rate of 1400 kgs⁻¹, and a time varying emission term given in Thordarson and Hartley (2015) were also studied. These resulted in an almost linear increase in concentrations and deposition, and did not compare better to observations and will therefore not be presented here. The sensitivity to height of the emission appeared to be more important and is shown here in more detail.

Anthropogenic SO₂ emissions in the model are described in Kuenen et al. (2014). There is a yearly total SO₂ emission of 13.2 Tga⁻¹ corresponding to 2009 conditions, the same year that is used in the reference MACC model configuration. The difference to actual 2014 conditions is assumed to be unimportant here. The inventory includes 2.34 Tga⁻¹ SO₂ in yearly ship emissions over the oceans. Over the continents the yearly emissions are 5.08 Tga⁻¹ SO₂ for the

28 EU countries, and $5.53 \text{ Tga}^{-1} \text{ SO}_2$ for the non-EU countries in the MACC domain (including Iceland) covered by the MACC domain.

2.2 Observations

The satellite data used in this study stem from the Ozone Monitoring Instrument (OMI) aboard NASA AURA (Levelt et al., 2006). The satellite was launched in July 2004 as part of the A-train earth observing satellite configuration and follows a sun-synchronous polar orbit. The OMI measures backscattered sunlight from the Earth atmosphere with a spectrometer covering UV and visible wavelength ranges. Measurements are therefore only available during daytime. The background SO_2 concentrations are often too low to be observable, but increases in SO_2 from volcanic eruptions can produce well distinguishable absorption effects (Brenot et al. 2014). Pixel size varies between $13 \text{ km} \times 24 \text{ km}$ at nadir and $13 \text{ km} \times 128 \text{ km}$ at the edge of the swath. OMI satellite data are affected by “row anomalies” due to a blockage affecting the nadir viewing part of the sensor, which affects particular viewing angles and reduces the data coverage. The zoom-mode of OMI reduces the coverage on some days. The coverage is also reduced by missing daylight, e.g. winter observations from high latitudes are absent. Therefore data from only the two first months from September until the end of October are used in this study.

The retrievals are described in Theys et al. (2015). The sensitivity of backscatter radiation to SO_2 molecules varies with altitude (generally decreasing towards the ground level) and therefore the algorithms use an assumed height distribution for estimating the integrated SO_2 column density. Since often little information is available at the time of eruption and the retrievals produce results daily (even for days with no eruption) an assumed a priori profile is used for the vertical SO_2 distribution. The satellite retrievals used here assume an a priori profile with a plume thickness of 1 km that is centred at 7 km, similar to the method described in Yang et al. (2007). As found in Schmidt et al. (2015), this is too high for the Bárðarbunga eruption. Therefore, the retrieved SO_2 column densities may be too low. To compare the vertical column density (VCD) from the model to the one from satellite retrievals, the averaging kernel from the satellite has to be used. Each element of an averaging kernel vector defines the relative weight of the true partial column value in a given layer to the retrieved vertical column (Rodgers, 2000). Cloud cover also changes the averaging kernel and a spatio-temporally changing kernel is part of the satellite data product (an averaging kernel is provided for each satellite pixel).

1 To apply the averaging kernel on model data, the satellite data are regridded to the model grid
2 so that those data from satellite pixels nearest to any given model grid point are used for that
3 grid point. A smaller area than the whole model domain was chosen to study and compare to
4 the satellite data, 30° west to 15° east and 45° to 70° north (red boxes in Fig. 1). The Aura
5 satellite does five overpasses over the domain during daytime, swaths are partly overlapping
6 in the northern regions. For the grid cells where the swaths overlap, the satellite observations
7 are averaged to produce daily average fields. There are also regions that are not covered by
8 satellite observation that will not be taken into account in the model data post processing. To
9 make comparable daily averages of the model data, the closest hour in the hourly model
10 output are matched to the satellite swath time and only grid points that are covered by satellite
11 are used. The profiles for the averaging kernel in the satellite product are given on 60 levels,
12 the values from these levels are interpolated to model vertical levels. The new adjusted model
13 VCD is then calculated by multiplying the interpolated averaging kernel weights to the SO₂
14 concentration in each model layer, integrating all layers with the height of each model layer.

15 Because of noise in the satellite data small retrieved VCD values are highly uncertain. A
16 threshold limit is sought to identify those regions that have a significant amount of SO₂.
17 Standard deviation for the satellite data is calculated over an apparently SO₂ free North
18 Atlantic region (size 10 x 15 degrees lat lon respectively), and is found to be around 0.13 DU.
19 Effects of varying cloud cover are ignored. An instrument detection limit is three times the
20 standard deviation of a blank, so we assume that with a threshold value set to 0.4 DU we
21 exclude satellite data below detection limit. Any grid point with a value above this threshold
22 in the satellite data is used along with the corresponding model data. Daily mass burdens for
23 the North Atlantic region are calculated by summing up all the SO₂ VCD in the grid cells
24 above the threshold. Finally we convert here and there in the manuscript DU to mass burdens
25 to facilitate comparison to models and mass budgets. One DU is $2.69 \cdot 10^{20}$ molecules per
26 square metre, which corresponds to a column burden of 28.62 milligrams SO₂ per square
27 meter (mgm⁻²).

28 Data of SO₂ and PM_{2.5} surface concentrations are collected by the European Environment
29 Agency (EEA) through the European Environment Information and Observation Network
30 (EIONET). We make use of two preliminary subsets of this data, one obtained from work
31 within the MACC project to produce regular air quality forecasts and reanalysis (only SO₂),
32 and a second one obtained from EEA as so called up-to-date (UTD) air quality data base, state

spring 2016. The two different subsets cover observation data from different countries, and have not yet been finally quality assured at the time of writing this paper. We use only station data, which contain hourly data. However, there are missing data and some stations have instruments with high detection limits making it difficult to create a continuous measurement series with good statistics. Therefore, in this study only some outstanding episodes with high concentrations of SO₂ and documented trans-national transport of a volcanic plume are analysed. For the first six day period between 20 and 26 September 2014, high concentrations of SO₂ were measured over Great Britain and countries further to the south. For the second six day period, a month later (20 to 26 October), the plume was also detected over Great Britain, but was transported further east towards Germany. For the last plume studied, lasting from 29th October to 4th November, the volcanic emission was transported eastward to the coast of Norway and countries to the south. Recent daily deposition data are taken from the EBAS data base (ebas.nilu.no) for those stations where the data are already available. Model data to represent the station values are picked from hourly data at model surface level in the grid cell where the station is located.

3 Results

3.1 Comparison to satellite data

Observations by satellite provide information about SO₂ location and column density. Fig. 1a shows as an example the VCD from the OMI satellite overpasses on 24 September 2014. Fig. 1b and Fig. 1c show the modelled and the kernel weighted VCD from the base simulation (bas_hol). The observed satellite SO₂ cloud and the model simulated SO₂ cloud show similar shape and location. The kernel weighted model column densities are smaller than the original model VCDs. More weight is given by the averaging kernel to model layers higher up, close to the reference height of 7 km, where there is less SO₂ in our case, with emissions and transport happening in the lower part of the troposphere. The reduced kernel weighted column densities are closer to the column densities observed by the satellite. There are however some spatial differences of where the maximum column densities are located.

A quantitative comparison is attempted here by integrating all satellite - and corresponding model data - above the North Atlantic, between Iceland and Europe, into daily mean column burdens. Fig. 2 shows time series from September to October of daily satellite coverage and daily mass burdens considered over the area where satellite VCD values exceed the 0.4 DU

1 detection limit as explained above. The area covered by valid satellite observations at the
2 beginning of the period is around 70 percent of the domain used here (red boxes in Fig. 1).
3 Towards the end of the period, the satellite coverage is only around 40 percent because of the
4 increasing solar zenith angle (a satellite zenith angle cut-off of 75° is used for the satellite
5 data). On some days, the satellite cover is even lower because of the OMI zoom mode. The
6 percentage of the satellite data that is above the detection limit is low over the entire two
7 month period, only reaching around ten percent at the end of September and at the beginning
8 of October.

9 On most days, the satellite daily mass burden is above the model value, ignoring the days
10 where the OMI zoom mode is responsible for a small coverage. The average satellite derived
11 SO_2 mass burden assuming a 7 km reference height is 11.2 kt, while the kernel weighted
12 model burden in `bas_hol` is 8.7 kt SO_2 . The highest values are found at the beginning of the
13 period, 42.1 kt SO_2 on 7 September, for the model, and 37.4 kt SO_2 , on 20 September for the
14 satellite. Taking into account the area in which the satellite observed SO_2 is found above
15 detection limit, the satellite average column loadings are calculated to reach 70 mgm^{-2} for
16 September. Also the peaks in the middle of October, visible in Fig 2b, exhibit a satellite
17 average column loading of 62 mgm^{-2} .

18 The daily values of SO_2 mass burden are decreasing over time, especially during October.
19 There is also a positive bias of the model against the satellite in the end of October. At the
20 same time the satellite coverage is decreasing along with an increasing solar zenith angle. To
21 further investigate whether this is responsible for the general decrease in mass burdens and
22 the increasing bias of the simulated versus observed VCDs, a new aggregation domain further
23 south is used. All the area where satellite observations may be possible until the end of
24 October (61.25° north) is used to calculate another set of daily column burdens for satellite
25 and model data (see Fig. 2c). Satellite coverage in this southerly domain is not decreasing
26 over time, but it is also not covering Iceland, so the SO_2 from Holuhraun first needs to be
27 transported south before it can be detected. The plume is transported that far south four times
28 over the two-month period as the peaks in column burden values in Fig. 2c show. In this
29 southerly area the daily accumulated mass burdens are similar in September and in October,
30 supporting the hypothesis that the apparent decrease in mass burden in Fig. 2b is due to
31 reduced satellite coverage.

Percentile values from the distribution of the daily mass burden in September and October 2014 from all the three model simulations, original and kernel weighted are shown in Fig. 3. Note that the mass burdens are accumulated in the same area in the North Atlantic, where at least 0.4 DU SO₂ was observed by OMI. Looking at the original model data, the model simulation with emissions in the lowest kilometre (low_hol) has the highest daily mass burden values (median: 25.4 kt), followed by the best guess simulation, bas_hol (median: 22.5 kt), while the run with the emission highest in the atmosphere (high_hol) exhibits the smallest mass burden (median: 15.9 kt). The higher values in the low_hol simulation can be explained by less wind and dispersion at low altitudes and thus a more concentrated SO₂ cloud than in the two other model simulations.

The kernel weighted model data represent what can be directly compared to the satellite data. As shown in Fig.3, and illustrated already in Fig. 1, the kernel weighted model column burden values are much smaller than the original ones, because the SO₂ plume was simulated to be much below 7 km altitude. The impact of the kernel weighting is quite different for the three model simulations. After the averaging kernel has been applied to the model data, the high_hol model simulation exhibits the highest daily burdens compared to the other two model simulations. The median for the bas_hol, low_hol and high_hol daily mass burden are 7.4 kt, 4.4 kt and 8.4 kt respectively, while the satellite mass burden median value is 7.0 kt. High burdens retrieved from satellite data, and high kernel weighted model burdens reflect that volcanic SO₂ is present at high concentrations and/or at high altitudes.

Analysis of the distribution of daily mass burdens allows investigating how many days with very high burdens were present. Comparing the satellite data to the kernel weighted model data we find that the satellite 75th percentile is larger than any of the model simulation's 75th percentiles. The satellite data contain some high daily burden values that result in a higher average burden and a higher 75th percentile. From our three model simulations, testing different emission heights, the best-guess bas_run has got the most similar distribution of daily burdens compared to the satellite data over the first two months.

3.2 Surface concentrations

SO₂ from the volcanic eruption on Holuhraun was measured at several surface stations during the period. Three different episodes with clear peaks in observed concentrations at stations

around Europe are described in the following paragraphs. Exemplary comparisons are shown and additional comparisons at other stations are available in the supplementary material.

A particular episode with very high surface concentrations of up to $500 \mu\text{gm}^{-3}$ SO_2 in Ireland in the beginning of September was studied by Schmidt et al. (2015). However, just very few Irish station data were in the data extract we obtained from the EEA for this episode and we decided to document the comparison for this episode in the supplementary material. The comparison supports, however, that our emission flux indeed might have been too small in the first days of September 2014.

Fig. 4 shows hourly time series for two stations over Great Britain and France from 20 September to 26 September. A maximum concentration of $44.3 \mu\text{gm}^{-3}$ SO_2 was measured 21 September 16 UTC at a station situated in Manchester (53.48°N and 2.24°W) near the west coast of Britain. None of the three model simulations reach the observed maximum values. However, the simulated concentration field shows areas south of the station nearby Manchester, where the volcanic SO_2 concentrations are around $50 \mu\text{gm}^{-3}$. Interestingly, the agreement of the model derived volcanic SO_2 time series is better in agreement with measurements than the total simulated SO_2 concentration (grey curve), indicating that the model may not resolve SO_2 transport from nearby pollution sources and that the station for these days is rather representative of long range transported volcanic SO_2 . Observed $\text{PM}_{2.5}$ concentrations at the station show, that over the period, the highest concentration ($52.1 \mu\text{gm}^{-3}$) – probably anthropogenic - is measured at the start of the period, when the model did not simulate any volcanic sulphur contribution. The next day, the plume has moved further south over France, the station is situated on the west coast of France in Saint-Nazaire (47.25°N and 2.22°W). The measurements show three peaks over three days, with the highest one ($38 \mu\text{gm}^{-3}$) measured on the 23 September at 12UTC. All the three model simulations have the peak concentrations earlier than the observed ones, and the concentrations from the model are lower than observed. The three simulations do, however, show increased concentrations at the site due to the volcanic eruption over the three days. The map shows that large parts of France had an increase in SO_2 surface concentrations during this time.

Fig. 5 shows the time series for three stations over Scotland and Germany a month later, from 20 to 26 October. The high_hol simulation shows low concentrations over the Scottish Grangemouth station (56.01°N and 3.70°W), but the bas_hol and low_hol have a plume with high concentrations over the station on 20 October. There are no measurements at this time to

compare the model values to. The timing of the second plume on 21 October for the two models is a few hours early and the modelled concentrations higher than observed ($6.09 \mu\text{gm}^{-3}$), especially in the low_hol simulation. The map shows a narrow plume from Iceland south to Scotland and the station lies on the edge of this plume. On 22 October, the volcanic SO_2 is measured at stations in Germany. Fig. 5d shows the plume reaching from Iceland into the North Sea, transported east and south compared to the situation from the day before. The two stations Kellerwald (51.15°N and 9.03°E) and Bremerhaven (53.56°N and 8.57°E) experience the plume differently. While for Bremerhaven the peak observed ($41.0 \mu\text{gm}^{-3}$) is short in duration, the peak lasts for one day at Kellerwald with an observed maximum of $10.2 \mu\text{gm}^{-3}$. The map shows that the plume is narrow for all three stations and the local spatial gradient is large.

A third plume is illustrated in Fig. 6 over Northern Europe, occurring from the end of October to the beginning of November. Fig. 6a shows the measured SO_2 concentrations at a station in Oslo, Norway (59.92°N and 10.76°E). There are four peaks measured from 29 October to 31, the highest one on 29 October ($50.4 \mu\text{gm}^{-3}$). The models runs show contribution from Holuhraun SO_2 over the same three days, but do not reach the high measured concentrations, especially the first plume is underestimated. On October 30, the plume is transported south east to Poland. The Polish station in Sopot (54.43°N and 18.58°E) experiences a short peak that the model simulates to happen a few hours earlier. The bas_hol simulation exhibits the most similar concentration evolution among the three model experiments.

Fig. 7 shows wet deposition for the whole three-month period at the K rvatn station (62.78°N and 8.88°E) in Norway. There are high levels, both observed and modelled during the last part of September. The model exhibits a clear peak value on 27 September, while the observations record deposition spread out over several days. Summed over the whole period, the observed deposition amounts to $15.9 \text{ gSm}^{-2}\text{y}^{-1}$ while the model simulated $20.0 \text{ gSm}^{-2}\text{y}^{-1}$. Comparisons at other stations in Norway show similar results (supplementary information).

3.3 Effects of the eruption on European pollution

The above results show that, despite the Holuhraun eruption releasing large amounts of SO_2 , the stations in Europe often measured an increase in SO_2 concentration only as short peaks (Gr slason et al. 2015, Schmidt et al. 2015). The model makes it possible to investigate the general impact on European air quality by Holuhraun volcanic emissions. Table 2 summarizes

characteristic SO_x budget terms and surface concentrations for the European continental land area in the countries mentioned in table 2. Concentration and deposition over the oceans are not included. To isolate the effect of the Holuhraun eruption on Iceland itself the deposition and concentrations over Iceland are given in brackets.

The table shows, that the Holuhraun emission flux in the study period corresponds to over 4.5 times the anthropogenic emission from the 31 European countries considered here (not including ship emissions). The anthropogenic emissions from Iceland are only 18 kilotons, the SO₂ emissions from Iceland increase by more than 300 times.

Over the three months, there is 1.32 times more SO_x wet deposition for the base run with Holuhraun emission than the reference simulation with no Holuhraun emission (no_hol). Table 2 shows that wet deposition over Europe is quite dependent on the emission height. The simulation with the emission highest in the atmosphere (high_hol) exhibits the highest wet deposition in Europe. For dry deposition, a ten percent increase over Europe is found for all the three model simulations with Holuhraun emissions. Close to the source, over Iceland, the deposition levels are very dependent on emission height, dry deposition ranging from 8 to 409 kilotons.

Fig. 8 shows the total deposition over Europe for the standard MACC model simulation with no Holuhraun emission (no_hol), the base model simulation (bas_hol), and the percent increase between these two model runs. Areas that experience the highest percent increase are also areas that have low levels in the model simulation with no emission at Holuhraun. Due to the Holuhraun emissions Iceland has the highest SO_x deposition in Europe, and the coast of northern Norway shows depositions on the same level as the more polluted Eastern Europe. Even though the previous section indicated that the model has higher wet deposition levels in northern Norway than observed, it also showed that it is very likely that the observed increases in SO_x deposition levels are due to the Holuhraun emissions.

The averaged SO₂ surface concentration over Europe is under normal conditions higher than over Iceland, the volcanic emission caused the concentration level over Iceland to increase by a factor of 177 (for the low_hol simulation). Over the rest of Europe the increase is about the same for all three Holuhraun simulations, even though the time series showed that the different simulations had peaks arriving at often different times. Vertical mixing, on average, levels off initial differences in emission height for volcanic plumes arriving in Europe.

The small increases in PM_{2.5} concentrations over Europe, as shown in table 2, are due to increased sulphate production from volcanic SO₂. However, PM_{2.5} is a collection of all aerosols under 2.5 µm, and the volcanic sulphate is changing total aerosol mass therefore relatively little. The table shows that Iceland has a lower average concentration than the rest of Europe for all the four runs, even though Iceland is the source for the increase in aerosol pollution levels. The high_hol model simulation has a higher increase in PM_{2.5} concentration over Europe than the two other simulations. By contrast, the low_hol simulation finds highest sulphate and SO_x deposition on Iceland itself, and possibly over the nearby ocean, which will lead to a smaller contribution to pollution levels over the rest of Europe.

The distribution of PM_{2.5} from the no_hol and bas_hol simulation, plotted in Fig. 9, shows the same polluted and clean areas as in Fig. 8, although the increase is lower. Over north-west Norway and northern Norway the increase is over 100 percent, Fig. 9b shows that although the percentage increase is high, the PM_{2.5} concentrations in these areas are still among the least polluted in Europe. The high deposition levels in this region indicate that some of the PM_{2.5} is scavenged out.

WHO recommends a 24 hourly average mean concentration level of 25 µgm⁻³ for PM_{2.5} not to be exceeded over three days over a year (WHO, 2005). Fig. 10a shows that over the Benelux region, northern Germany and northern Italy this limit value is exceeded by up to ten days during the three months studied. As the previous plot showed, these are regions with high average PM_{2.5} concentrations. Because the daily concentrations are already high, any increase in days in the model bas_hol simulation due to the Holuhraun emissions is also occurring in these regions, and the areas with the highest percent increase do not experience any days over the limit. The Figure also shows that Northern Ireland experienced up to two exceedance days due to the volcanic eruption.

4 Discussion

The bias and variances between the model data and the satellite observations can be due to several factors. a) The model emission flux may be under or overestimated compared to the real emissions, model VCDs are therefore too low / too large compared to the observed ones. b) The areas for which the column mass burdens have been computed depend on the VCD detection limit and the actual satellite data, so the retrieved model burdens depend on the position of the identified and observed SO₂ cloud. If a simulated plume is displaced into an

1 area where the satellite does not show any valid signal or no signal above detection limit, then
2 this part of the model plume is ignored and may lead to underestimates by the model. c) The
3 presence of clouds can increase the uncertainty of the satellite retrieval. d) The fluctuating real
4 height of the SO₂ plume may introduce additional bias between model and satellite VCDs.
5 Schmidt et al. (2015) presented IASI (Infrared Atmospheric Sounding Interferometer) plume
6 heights for the Bárðarbunga SO₂ plume between 5.5 km to 1.6 km derived from an area of
7 500 km around the volcanic location, and a mean IASI centre of mass height between 2.7 km
8 to 0.6 km.

9 Schmidt et al. (2015) presented a comparison between model, satellite and ground
10 observations for September. Mass burdens from OMI were derived using observed plume
11 heights from the IASI instrument on the MetOp satellite. Both satellite data sets were
12 compared with the model NAME (Numerical Atmospheric-dispersion Modelling
13 Environment), a Lagrangian model, which was run for September, with sensitivity runs
14 testing both emission height and emission flux. The model simulation with a plume height of
15 3 km and doubled emission flux (~1400 kgs⁻¹) matched well with the OMI satellite data for
16 the first days, while for the rest of September another simulation matched better, where
17 emissions were similar to the constant emission term used in our study (~700 kgs⁻¹). Their and
18 our study show that for the first days and at the end of September, the satellite data exhibit
19 higher values than a model using an emission rate of 700-750 kgs⁻¹ SO₂. Our Holuhraun
20 emission term in the three model simulations is constant throughout the simulations both with
21 respect to the respective three emission heights and emission flux (see table 1). Maximum
22 fluxes of 1300 kgs⁻¹ were reported by Barsotti (2014). Gislason et al. (2015) estimated a 2.5
23 times above average emission term during the first two and a half weeks of the eruption. Our
24 assumption of a constant emission term is thus certainly a simplification.

25 However, here we suggest that overall understanding of the height of the plume is as
26 important to achieve model agreement with the satellite data as emission intensity variations.
27 The emission height is also variable, dependent on initial volcanic eruption characteristics and
28 meteorological conditions like wind speed and stratification (Oberhuber et al. 1998). Table 1
29 contains the original mass burdens and the kernel weighted mass burdens as described in
30 section 3.1. It also contains a scaled burden estimate, assuming that each of the three
31 simulations should be corrected for bias against the satellite derived burden. This scaling
32 assumes that in each model simulation the height distribution may be correct. The resulting

1 mass burdens from the three simulations differ by 60%, computed as standard deviation. This
2 may be seen as an uncertainty estimate associated with our limited knowledge of the real
3 height of emission and dispersion of the SO₂ plume from Bárðarbunga.

4 A better source estimate for the eruption is beyond the scope of this study, however the
5 fluctuations both in flux magnitude and emission height can explain some of the differences
6 between satellite observed and simulated concentrations, especially in the first days of
7 September.

8 Surface concentration comparisons presented in this study and in the supplementary material
9 show that the volcanic SO₂ was observed as short singular peaks lasting a few hours or as a
10 sequence of several peaks spread over a few days. Three episodes are picked where
11 transnational transport is documented. The biggest difference between simulated and
12 measured concentrations is found for the first of the three studied plumes during 20 to 26
13 September in Manchester (station GB0613A), Great Britain and Saint-Naizaire (station
14 FR23181), France, with up to a factor of four differences. Both the measured and simulated
15 concentrations during the September event were higher than the two later events, pointing to a
16 more efficient transport of SO₂ in this event. Higher emission fluxes up to a factor of 2 are
17 supported by the satellite comparison on some of the days in the end of September. Changes
18 in emission flux for the EMEP/MSC-W have been shown to have an almost linear change in
19 concentrations (not shown here); even with doubled emissions during this event the model
20 would still simulate surface concentrations well below those observed. Station data
21 comparisons presented in Schmidt et al. (2015) for these days are similar, indicating that
22 models have difficulties representing this period.

23 The discrepancies found between model and observations suggest that the volcanic SO_x
24 budget terms and average European surface concentrations presented in Table 2 contain error.
25 Especially the model surface concentrations seem to be low compared to observations;
26 however the map plots in Fig. 4, 5, 6 show, that sometimes modelled concentrations nearby
27 the stations reached the observed levels. The area averaged volcanic concentration
28 contribution presented in table 2 may therefore be close to reality. A more thorough study
29 with a completed quality controlled data set is needed to estimate better the increase in SO₂
30 concentrations due to the eruption at the stations in the 2014 volcanic eruption episode.

31 Transport from an Icelandic volcano to Europe is caused by northerly and north-westerly
32 winds. For the first plume 20 to 26 September, where the model shows low concentrations

1 compared to the observations, there had been southerly winds for some time before strong
2 northerly winds transported the SO₂ cloud southward over Great Britain and France.
3 Compared to the other two episodes, the SO₂ surface concentration due to Holuhraun are
4 higher over a larger area during this episode. The difficulty of the model to simulate the SO₂
5 transport correctly is connected to the uncertainty in the emission term, the meteorology
6 fields, the chemical reactions and deposition. Overall the comparison to observations shows,
7 that our best guess bas_hol model simulation matches best with the observed satellite column
8 burdens, their time evolution and for some stations with the magnitude and timing of the
9 observed surface concentration peaks.

10 The results in this study show that the sulphur deposition from September to November over
11 Northern Norway was at the same level as found in the most polluted regions in Europe. The
12 emission ceilings aim, set by the Gothenburg Protocol, was to reduce the SO_x emissions by 63
13 % by 2010 compared to the 1990 levels in the European area of the convention of long-range
14 transport of air pollutants (EMEP, 2015). Most countries have accomplished these reductions,
15 and the sulphur deposition levels over Europe have decreased. The Holuhraun eruption
16 changed the picture in some areas. Comparing observed deposition levels at Tustervatn
17 station in central Norway, the simulated deposition is higher than the yearly observed
18 averages since 1980. Monthly observed values at this station during the 2011 Grimsvötn
19 eruption show almost as high values as the bas_hol simulation. The time series from the
20 Kårvatn station also shows that the increases are due to the Holuhraun volcanic eruption.
21 Northern Norway is more susceptible for volcanic impact because of the geographical
22 position, in addition to high frequency of precipitation on the western coast of Norway.
23 Comparing the mean deposition levels over the three months in 2014 over Norway to model
24 simulations with emissions from previous years, they are double to the early 1990s (EMEP,
25 2015). Southern Norway experienced a sulphur deposition decrease of 40 % from 1980 to
26 1995 due to emission abatement in Europe (Berge et al. 1999). The highest contributors to
27 high deposition levels over Southern Norway were the UK and Germany (18 % and 15 %
28 respectively). Norway also experienced in 2014 a high percent increase in PM_{2.5}
29 concentrations. The PM_{2.5} levels over Scandinavia are low, and a small increase in the
30 concentrations leads to high percent increases. The increase over land shows a similar pattern
31 as the results found in Schmidt et al. (2011) for a hypothetical Laki eruption. Even though the
32 highest increase is over Scandinavia and Scotland, the concentrations are too low to exceed

the 25 $\mu\text{g m}^{-2}$ limit. Already polluted regions like the Benelux region experience more days with exceedances as well as North Ireland.

5 Conclusions

The increase in emitted SO_2 to the atmosphere caused by the volcanic eruption at Holuhraun were observed by satellite and detected at several stations over Europe (Schmidt et al. 2015, Gislason et al., 2015). Model simulations with the EMEP MSC-W model with emissions from Holuhraun over the period from September to November 2014 have been done to investigate the model capability to simulate such events, and also to study the impact of the increased emissions on concentrations and depositions over Europe.

The first two months of the model simulations are compared to satellite retrievals from OMI. The retrievals use an assumed plume height of 7 km. Averaging kernels from the satellite data are applied on the model data to compare the model data to the satellite. Because of the weighting, the satellite retrieved mass burden values are dependent on both vertical placement and amount of SO_2 . Two sensitivity model simulations with different Holuhraun emission height are compared to the satellite data together with the best guess base simulation. After the kernel is applied, the results are more comparable to the satellite data. Constraining the SO_2 column burden by the satellite data, while using the kernel along with the three simulated height distributions of SO_2 , we estimate that the median of the daily burdens may have been between 13 and 40 kt in the North Atlantic area under investigation.

The model simulations are also compared to observed concentrations at stations over Europe for three different events with high concentrations measured due to the Holuhraun emissions. For all the events, the timing of the model peaks is well compared to the observed peaks in concentration. There is a better timing in the two model simulations where the emissions are injected lowest into the atmosphere, than for the sensitivity run with the highest emission height. Due to a special transport pattern of SO_2 during the first event, observed concentrations are higher here than during the later events, and the difference between models and observations is largest. $\text{PM}_{2.5}$ concentration during this first event is comparable to observations. Uncertainties in the model simulations increase by the length of transport, and some near misses of the narrow plumes can clearly explain differences between model and observation. To make a better assessment of model performance during the whole volcanic eruption, better quality checked station data is needed. Comparison between the model and wet deposition observations over Norway show significant and high contributions from the

eruption, although the model over-predicts values at the stations studied and other stations to be found in the supplementary material.

Studying the changes in pollution levels over Europe, increased SO_x wet deposition is most remarkable. In the three month base simulation there is 32 % more sulphate wet deposition found than in the model simulation with no Holuhraun emission, accounted for over the 28 European Union countries, Norway and Switzerland. The regions that have the highest increase, apart from Iceland, are Northern Scandinavia and Scotland, regions that are among the least polluted in Europe. Especially the coast of Northern Norway, with a percent increase in total deposition of over 1000%, shows levels equal to the most polluted regions in Europe. Seen against the long-term record of observed levels of deposition since 1980 at the Tustervatn station in central Norway, the 2014 deposition values stand out and are only exceeded during the Grimsvötn eruption in 2011. We also find that high SO_x wet deposition values measured at the Kårvatn station in 2014 on the coast of western Norway are very likely due to the Holuhraun emissions.

The difference in SO₂ concentrations over Europe between the no_hol and model simulations with Holuhraun emission is around 13 percent and increases occur as short peaks in concentration levels from a few hours to some days. Due to the underestimation seen at stations during September, the uncertainty of this number is large and the simulated volcanic contribution is possibly too small. For PM_{2.5} concentration, the volcanic increase is six percent, and the model shows better agreement with station observations. The biggest difference in percent increase is seen over Scandinavia and Scotland, however these regions are among the cleanest in Europe, also with the added sulphur caused by the Holuhraun emissions. The areas that show an increase in number of days with over 25 µgm⁻² PM_{2.5} concentrations are those already polluted. Even with high emissions from the volcanic fissure at Holuhraun, the increase in pollution levels over Europe was relatively small, with only transient episodes associated with high increases in SO₂ concentration.

Acknowledgements

Most of the work done for this paper is funded by the Norwegian ash project financed by the Norwegian Ministry of Transport and Communications and AVINOR. Model and support is also appreciated through the Cooperative Programme for Monitoring and Evaluation of the Long-range Transmission of Air Pollutants in Europe (No: ECE/ENV/2001/003). The observations are made available through the EEA UTD database

1 (<http://fme.discomap.eea.europa.eu/fmedatastreaming/AirQuality/AirQualityUTDExport.fmw>
2) and the MACC project (MACC III project number 633080) obtained with the much
3 appreciated help of Álvaro Valdebenito. Wenche Aas and Paul Eckhardt are thanked for
4 provision of recent measurements of wet deposition measurements in Northern Norway,
5 included in the EBAS database. This work has also received support from the Research
6 Council of Norway (Programme for Supercomputing) through CPU time granted at the super
7 computers at NTNU in Trondheim.

Table 1. Overview of model runs and the Holuhraun SO₂ emission height assumptions and flux; given are also medians of daily mass burdens of SO₂ for September to October 2014 in the North Atlantic as described along with Fig. 2 and Fig. 3.; last column contains scaled mass burdens, assuming 7.0 kt of SO₂ burden derived from satellite data (see text in discussion).

Model simulation name	Emission injection layer [km]	Emission flux [kg s ⁻¹]	Burden original [kt]	Burden kernel weighted [kt]	Mass burden scaled [kt]
bas_hol	0 - 3	750	22.5	7.4	21.4
low_hol	0 - 1	750	25.4	4.4	40.3
high_hol	3 - 5	750	15.9	8.3	13.4
no_hol		0			

Table 2. Emissions, depositions and concentrations for the 28 European Union member states, Norway and Switzerland for the three months September, October, November 2014; Emissions and depositions are totalled over the three month period, concentrations are the

1 mean over the period for the 31 countries. Numbers in brackets are the contribution from
2 Iceland, for emission and deposition. For concentrations, the number represents the average
3 over Iceland. See simulation names and set-up in table 1.

Simulations:	no_hol	bas_hol	low_hol	high_hol	bas_hol/no_hol
Emissions SO ₂	1 257	1 257	1 257	1 257	1
[kilotons]	(18)	(5 980)	(5 980)	(5 980)	(5.68)
SO _x Wet deposition	1 043	1 382	1 285	1 465	1.32

Figure 1. SO₂ column density: a) for the satellite swaths on 24 September 2014; b) for corresponding, consistently co-located original model data in the base simulation bas_hol; c) for these model data with the satellite averaging kernel applied. The red box indicates the area where the statistics of satellite and model data in fig.2 and 3 are acquired.

Figure 2. a) Time series of the daily reference area covered by valid satellite observations (blue triangles) in percent of the total area of the domain used for the statistics (30°W - 15°E and 45° - 70°N, see Fig. 1). Green triangles show the reference area in percent where satellite derived SO₂ VCD is above 0.4 DU; b) Time series of accumulated daily SO₂ mass burdens in reference area from satellite data (“sat”, black dots) and from model base run with averaging kernel applied (“hol_bas ker”, red dots; c) Shows the same as b) but over a smaller area just south of 61.15°N.

Figure 3. Distribution of daily SO₂ mass burden values in the area where satellite derived SO₂ exceeds 0.4 DU (# 61; values from Fig. 2) as box and whisker plots; shown for the model simulations, original data (3 left boxes) and kernel weighted data (3 following boxes), and the satellite data. The boxes shown represent the 25th percentile, the median, and the 75th percentile values, lower whiskers the minimum value and upper whiskers the maximum value.

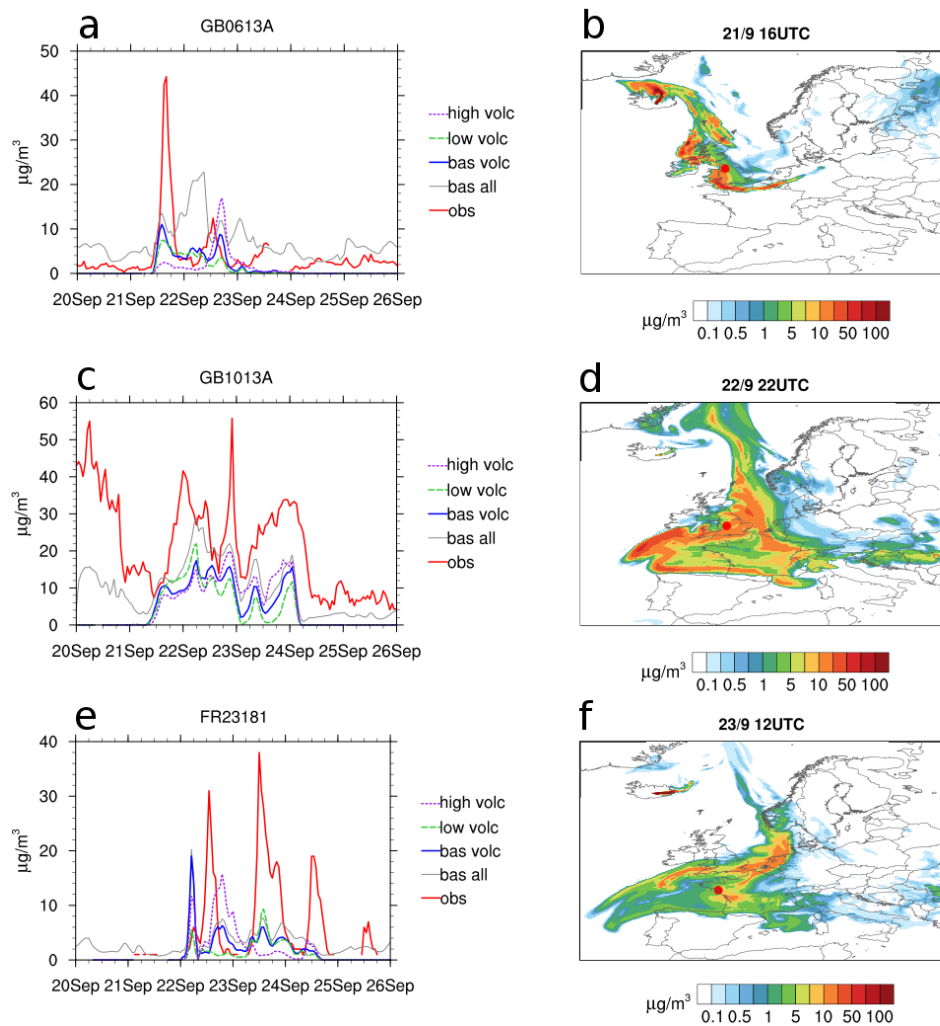

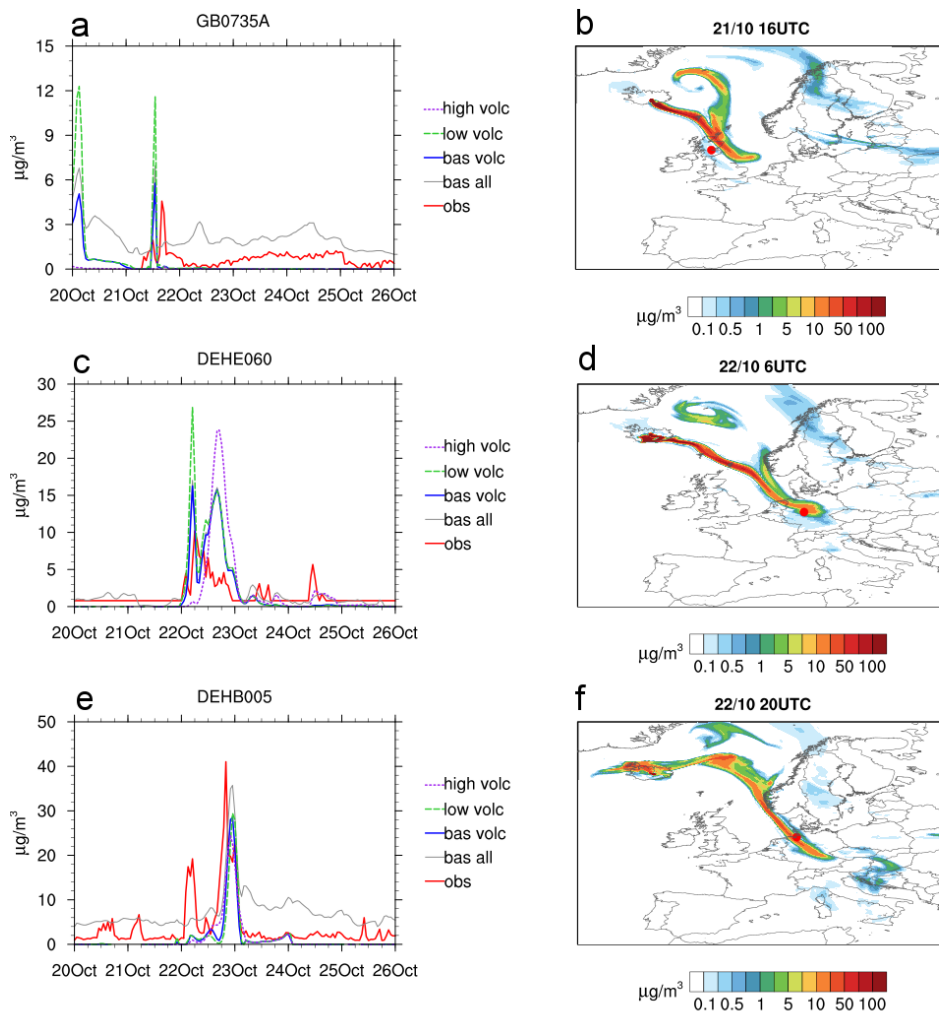

Figure 4. Left panels: Time series of surface concentrations from 20 to 26 September 2014 for two stations, GB0613A, Manchester, SO₂ (top), PM_{2.5} (middle) and FR23181, Saint-Nazaire, SO₂ (bottom). The red line shows the measured surface concentrations, the grey line represents the modelled surface concentration in bas_hol (“bas all”). By subtracting from the modelled surface concentrations in the three model runs (bas_hol, low_hol and high_hol) the no_hol simulation values, the concentration due to volcanic eruption is calculated and shown in the blue, green and pink line respectively. Right panels: Corresponding map of simulated surface concentration due to the volcanic eruption from bas_hol, corresponding to the blue line in the left panels, for the time of the maximum observed concentration. The red dot on the map marks the position of the station.

1
2 Figure 5. The same as Fig. 4, but from 20 to 26 October 2014 for three different stations
3 GB0735A Grangemouth in Scotland, DEHE060 Kellerwald and DEHB005 Bremerhaven in
4 Germany, all SO₂.

1
2 Figure 6: The same as Fig. 4 but from 29 October to 4 November 2014 for NO0088A Oslo,
3 Norway and PL0050A in Sopot Poland, both SO₂.

4
5 Figure 7. The same as Fig. 4, but September-November 2014 daily time series of SO_x total
6 deposition at the Kårvatn station in Norway.

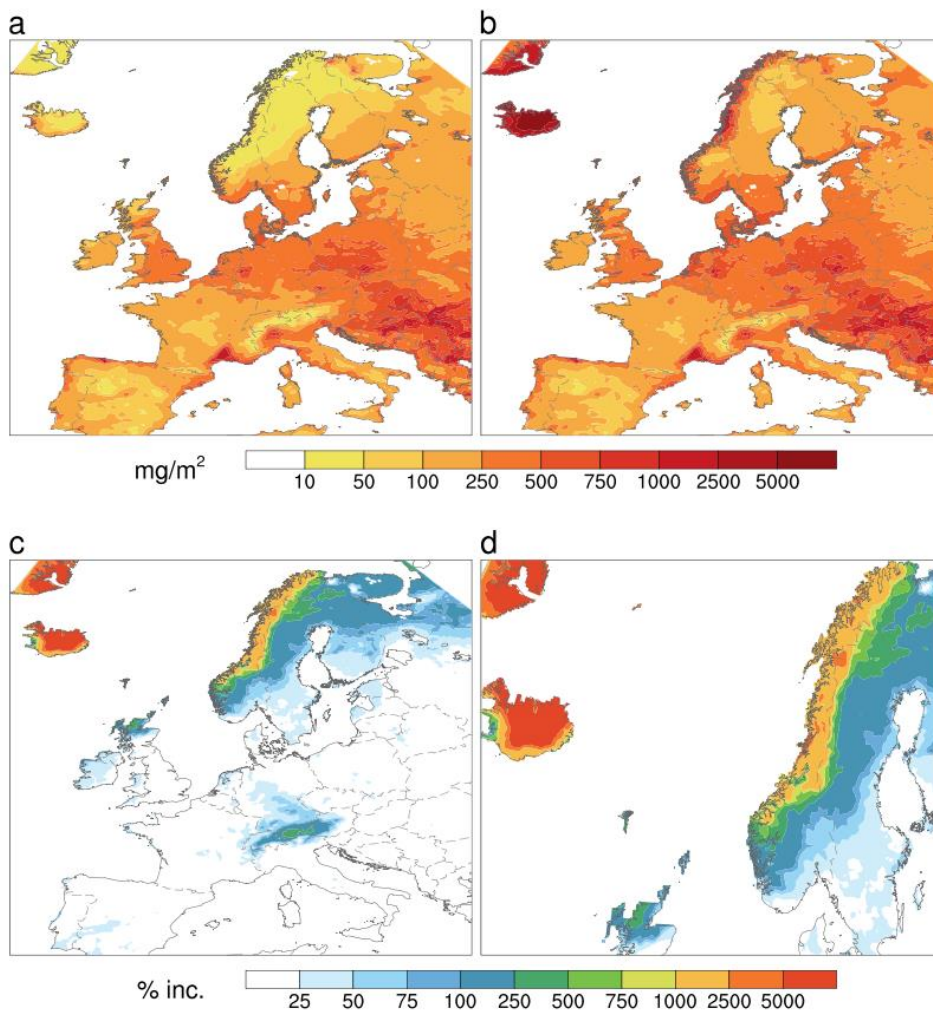

Figure 8. a) Simulated total deposition of SO_x (wet and dry) over Europe from September to November 2014 for no_hol; and b) bas_hol simulations; c) percent increase in SO_x deposition due to the Holuhraun emissions; d) shows the same as c) but zoomed into Norway and Northern Europe.

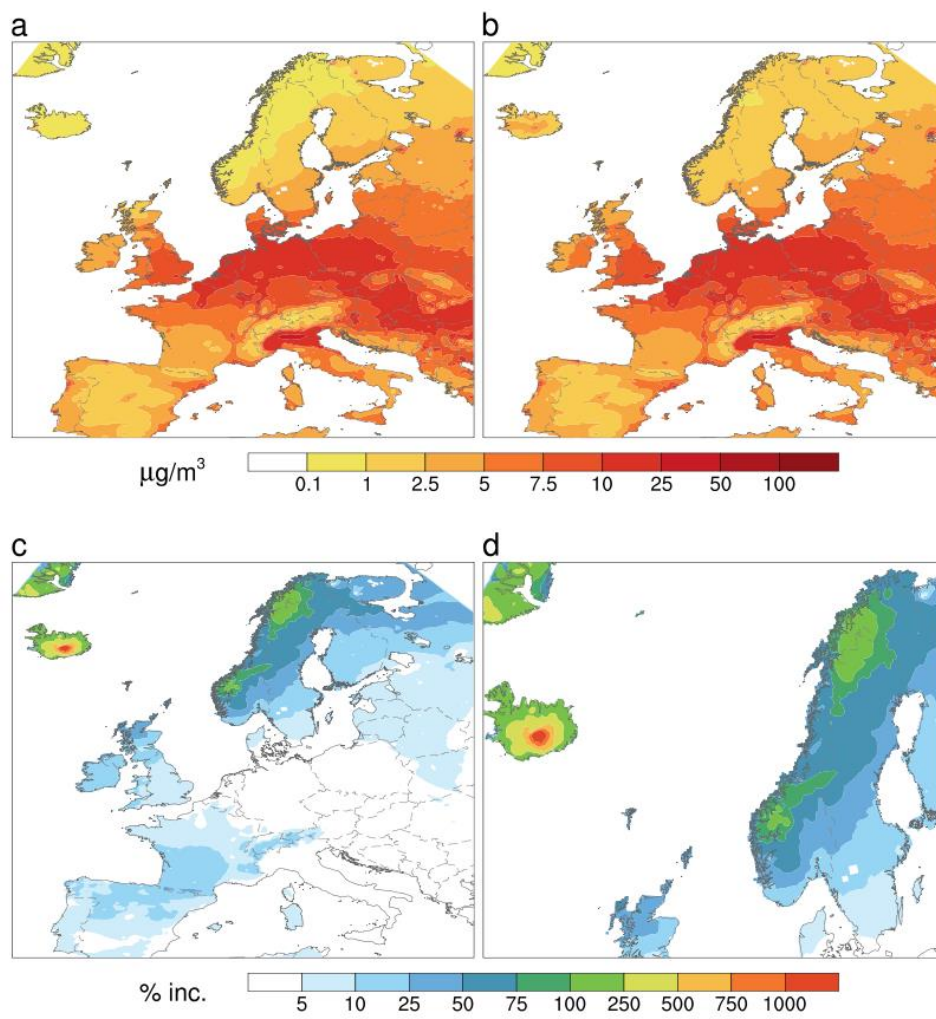

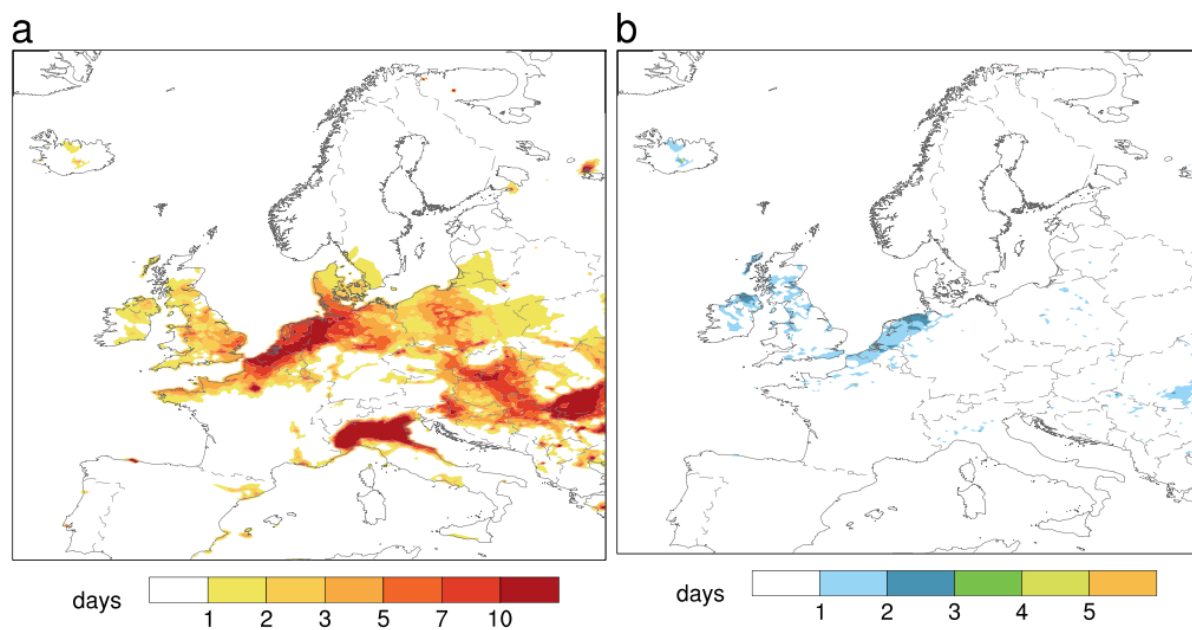

Figure 9. Show the same as Fig 8, but for average PM_{2.5} concentration over the three months.

1
 2 Figure 10. a) Number of days with exceedances of PM_{2.5} in the period September trough to
 3 November, 2014, for the bas_hol model simulation. b) The increase in days of PM_{2.5}
 4 exceedance from no_hol to bas_hol simulation, attributable to volcanic emissions.
