## 17 **Abstract**

18 We use the technique of Observing System Simulation Experiments (OSSEs) to quantify the impact of  
19 spaceborne carbon monoxide (CO) total column observations from the Sentinel-5 Precursor (S-5P) platform  
20 on tropospheric analyses and forecasts. We focus on Europe for the period of northern summer 2003, when  
21 there was a severe heat wave episode associated with extremely hot and dry weather conditions. We describe  
22 different elements of the OSSE: (i) the Nature Run (NR), i.e., the “Truth”; (ii) the CO synthetic observations;  
23 (iii) the assimilation run (AR), where we assimilate the observations of interest; (iv) the control run (CR), in  
24 this study a free model run without assimilation; and (v) efforts to establish the fidelity of the OSSE results.  
25 Comparison of the results from AR and the CR, against the NR, shows that CO total column observations  
26 from S-5P provide a significant benefit (at the 99% confidence level) at the surface, with the largest benefit  
27 occurring over land in regions far away from emission sources. Furthermore, the S-5P CO total column  
28 observations are able to capture phenomena such as the forest fires that occurred in Portugal during northern  
29 summer 2003. These results provide evidence of the benefit of S-5P observations for monitoring processes  
30 contributing to atmospheric pollution.

31

## 32 **1. Introduction**

33 Over the last decade, the capabilities of satellite instruments for sensing the lower troposphere have  
34 improved, and opened the way for monitoring and better understanding of atmospheric pollution processes,  
35 e.g., tropospheric chemistry (Jacob, 2000), long-range transport (HTAP, 2007), and emissions (e.g. Streets,  
36 2013 and references therein). Satellite instruments provide global measurements of many pollutants (e.g.,  
37 ozone; carbon monoxide, CO; nitrogen dioxide, NO<sub>2</sub>; and aerosols), including information on their trans-  
38 boundary transport, and complement in situ measurements from ground-based stations (e.g., the European  
39 Monitoring and Evaluation Programme (EMEP)), <http://www.nilu.no/projects/ccc/emepdata.html>, and  
40 Airbase, <http://acm.eionet.europa.eu/databases/airbase/>, networks). Low Earth Orbit (LEO) satellite  
41 platforms have the advantage of providing observations with global coverage, but at a relatively low  
42 temporal resolution. Geostationary Earth Orbit (GEO) satellite platforms provide observations at a  
43 continental scale, i.e., not global, but at a much higher temporal resolution.

44  
45 Satellite data, either in synergy with ground-based and airborne measurements and/or assimilated into  
46 models such as chemistry transport models (CTMs), contribute to an improved understanding of tropospheric  
47 chemistry and dynamics and improved forecasts of atmospheric pollutant fields (see, e.g., Elbern et al.,  
48 2010). As part of an integrated observing strategy, satellite measurements provide a global view on air  
49 quality (AQ). The challenge for future space-borne missions will be to assess directly the local scales of  
50 transport and/or chemistry for tropospheric pollutants (1 hour or less, 10 km or less) and to facilitate the use  
51 of remote sensing information for improving local- and regional-scale (from country-wide to continental  
52 scales) AQ analyses and forecasts. Building on this effort, various LEO satellite platforms and/or  
53 constellations of GEO satellite platforms will help extend AQ information from continental scales to global  
54 scales (e.g., Lahoz et al., 2012, and references therein for LEO/GEO platforms; Barré et al., 2015, for GEO  
55 platforms).

56  
57 An atmospheric species of interest for monitoring AQ is CO, owing to its relatively long time-scale in the  
58 troposphere; its distribution provides information on the transport pathways of atmospheric pollutants.  
59 Spaceborne instruments on LEO satellite platforms demonstrate the potential of remote sensing from space

60 to determine the CO distribution and its main emission sources at the global scale (Edwards et al., 2004,  
61 2006; Buchwitz et al., 2006; Warner et al., 2013; Worden et al., 2013; George et al., 2015; Fu et al., 2016,  
62 and references therein). These LEO satellite platforms include MOPITT (Measurements Of Pollution In The  
63 Troposphere), AIRS (Atmospheric InfraRed Sounder), TES (Tropospheric Emission Spectrometer), IASI  
64 (Infrared Atmospheric Sounding Interferometer), and CrIS (Cross-track Infrared Sounder) operating in the  
65 thermal infrared (TIR) and SCIAMACHY (SCanning Imaging Absorption spectroMeter for Atmospheric  
66 ChartographY) operating in the short-wave infrared (SWIR), respectively. By contrast, to our knowledge,  
67 there are no GEO satellite platforms measuring the CO distribution. However, despite their potential, owing  
68 to limited revisit time, and relatively coarse spatial resolution, LEO instruments are not optimal for  
69 monitoring regional and local aspects of air quality.

70

71 Copernicus is the current European Programme for the establishment of a European capability for Earth  
72 Observation (<http://www.copernicus.eu/pages-principales/services/atmosphere-monitoring>). The main  
73 objective of the Copernicus Atmospheric Services is to provide information on atmospheric variables (e.g.,  
74 essential climate variables, ECVs; [https://www.wmo.int/pages/prog/gcos/index.php?name=](https://www.wmo.int/pages/prog/gcos/index.php?name=EssentialClimateVariables)  
75 [EssentialClimateVariables](https://www.wmo.int/pages/prog/gcos/index.php?name=EssentialClimateVariables)) in support of European policies regarding sustainable development and global  
76 governance of the environment. The Copernicus Atmospheric Services cover: AQ, climate change/forcing,  
77 stratospheric ozone and solar radiation. The services rely mainly on data from Earth Observation satellites.

78

79 To ensure operational provision of Earth Observation data, the space component of the Copernicus  
80 programme includes a series of spaceborne missions developed and managed by the European Space Agency  
81 (ESA) and the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT).  
82 Among them, three missions address atmospheric composition. These are the Sentinel-5 (S-5) and Sentinel-5  
83 Precursor (S-5P) from a LEO satellite platform, and the Sentinel-4 (S-4) from a GEO satellite platform. The  
84 goal of the S-4 is to monitor key atmospheric pollutants (e.g., ozone; NO<sub>2</sub>; sulphur dioxide, SO<sub>2</sub>; bromine  
85 monoxide, BrO; and formaldehyde) and aerosols at relatively high spatio-temporal resolution over Europe  
86 and North Africa (8 km; 1 hour). We expect launch of the S-4 mission in 2021 with a lifetime of 8.5 years.  
87 The goal of the S-5 and S-5P platforms is to provide global daily measurements of atmospheric pollutants

88 (e.g., CO, ozone, NO<sub>2</sub>, SO<sub>2</sub>, BrO, and formaldehyde), climate related trace gases (e.g., methane, CH<sub>4</sub>) and  
89 aerosols, at relatively high spatial resolution (from below 8 km to below 50 km, depending on wavelength).

90

91 The S-5P is the ESA pre-operational mission required to bridge the gap between the end of the OMI (Ozone  
92 Monitoring Instrument) and the SCIAMACHY missions and the start of the S-5 mission planned for 2020  
93 onwards. The S-5P scheduled launch is in 2017 with a 7 years design lifetime. The S-5P will fly in an early  
94 afternoon sun-synchronous LEO geometry with an Equator crossing mean local solar time of 13:30, chosen  
95 to allow the instrument to measure the strong pollution signal present in the afternoon. We describe the  
96 TROPospheric Monitoring Instrument (TROPOMI) onboard S-5P in section 2.2. In contrast, the Infrared  
97 Atmospheric Sounding Interferometer (IASI) onboard Metop platform collects measurements at a local solar  
98 time of 09:30 (when the pollution signal is relatively weak) and thus has a lower predictive value (Veefkind  
99 et al., 2012, and references therein). The S-5P LEO platform will address the challenge of limited revisit time  
100 from LEOs by providing unprecedented high spatial resolution of 7x7 km, and with its SWIR band,  
101 improved sensitivity in the Planetary Boundary Layer (PBL) compared to a TIR instrument such as IASI.  
102 The PBL varies in depth throughout the year, but is contained within the lowermost troposphere (heights 0-3  
103 km), and typically spans the heights 0-1 km.

104

105 A method to objectively determine the added value of future satellite observations such as from the S-4, S-5  
106 and S-5P platforms, and to investigate the impact of different instrument designs, is that of Observing  
107 System Simulation Experiments (OSSEs) commonly based on data assimilation (e.g., Lahoz and Schneider,  
108 2014). The OSSEs have been extensively used and shown to be useful in the meteorological community to  
109 test the impact of future meteorological observations on the quality of weather forecasts (Nitta, 1975; Atlas,  
110 1997; Lord et al., 1997; Atlas et al., 2003). In a recent paper, Timmermans et al. (2015) review the  
111 application of OSSEs to assess future missions to monitor AQ. The OSSEs are increasingly being used by  
112 the space agencies to assess the added value of future instruments to be deployed as part of the Global  
113 Observing System (e.g., work on the ESA Earth Explorer ADM-Aeolus; Tan et al., 2007).

114

115 Although the usefulness of OSSEs is well established, they have limitations, discussed in Masutani et al.  
116 (2010a, b). A frequent criticism of OSSEs is that they are overoptimistic, largely owing to the difficulties of

117 representing the real Earth System (e.g., the atmosphere), even with state-of-the-art numerical models.  
118 Nevertheless, even if overoptimistic, OSSEs provide bounds on the impact of new observing systems. For  
119 example, if additional instruments provide no significant impact within an OSSE, they are unlikely to do so  
120 in reality.

121

122 In this paper, we describe a regional-scale OSSE over Europe for northern summer 2003 (1 June – 31  
123 August) to explore the impact of S-5P CO total column measurements on lowermost tropospheric air  
124 pollution analyses, with a focus on CO PBL concentrations. The severe heat wave experienced in Europe  
125 during northern summer 2003, and the concomitant atmospheric pollution and fire episodes, had a strongly  
126 negative societal impact, being responsible for the deaths of over 14,000 people in France (Vautard et al.,  
127 2005). This period had extremely hot and dry weather conditions and the long lasting atmospheric blocking  
128 conditions significantly contributed to the accumulation of pollutants in the PBL owing to the extended  
129 residence time of the air parcels (Solberg et al., 2008). The spatial distribution of the enhanced levels of CO  
130 and ozone was much more widespread over Europe during that summer than in previous ones (Lee et al.,  
131 2006; Ordoñez et al., 2010). These exceptional weather conditions also resulted in several extreme wildfire  
132 episodes over the Iberian Peninsula and the Mediterranean coast (Barbosa et al., 2004). Tressol et al. (2008)  
133 point out that between 6 and 10 August 2003 the contribution of biomass burning to measured CO levels in  
134 the lowermost troposphere reached 35% of the total CO field at these levels, a value comparable to typical  
135 European anthropogenic emissions which represent 30% of this total CO field. Thus, the three-month period  
136 1 June - 31 August 2003 includes both extreme and normal conditions, and provides an opportunity to study  
137 the full range of pollution levels that occur in a summer season over Europe. A better knowledge of the CO  
138 distribution improves its forecast and allows a better knowledge of the long-range transport of pollution  
139 plumes. In addition, CO, being one of the ozone precursors, information on it likely improves the ozone  
140 distribution calculated by the model.

141

142 The OSSE study domain covers the larger part of Europe (5W-35E, 35N-70N), and we perform the OSSE  
143 simulations at the spatial resolution of 0.2 degrees (latitude and longitude). This corresponds to a spatial  
144 resolution of ~20 km (meridionally) and ~15 km (zonally, at 45N). With this spatial resolution, we can track  
145 long-range transport plumes of CO. The length of the study period ensures we can sample different

146 meteorological situations typical for summertime, and provides an acceptable compromise between run-time  
147 restrictions and provision of sufficient information for statistically significant results. The focus of this OSSE  
148 is CO concentrations and the goal is to evaluate the benefit of S-5P CO columns after assimilation in a  
149 chemistry transport model, in particular CO concentrations at the surface.

150

151 The structure of the paper is as follows. In Sect. 2 we describe the various components of the OSSE; in Sect.  
152 3 we present the results from the OSSE for S-5P during northern summer 2003 over Europe. Finally, Sect. 4  
153 provides conclusions and identifies further work. A guiding principle in the OSSE set-up in this paper is to  
154 avoid overoptimistic results.

155

## 156 **2. The OSSE set-up**

157 The OSSE concept consists of simulating observations and their associated errors from a representation of  
158 reality (the “Nature Run” or NR) and providing this information to a data assimilation system to produce  
159 estimates of the NR states. Thereafter, one compares these estimates of the NR states from an assimilation  
160 run, AR (where the observation of interest has been assimilated), and from a control run, CR (in this case a  
161 free model run), against the NR. The performance of the AR and the CR against the NR quantifies the benefit  
162 of the observation of interest.

163

164 The OSSEs are widely used in the meteorological community for assessing the usefulness of new  
165 meteorological satellite data. Recent examples (not exhaustive) include the work of Lahoz et al. (2005),  
166 Stoffelen et al. (2006), and Tan et al. (2007); Masutani et al. (2010a) reviews the OSSE methodology and  
167 provides a comprehensive list of references of OSSEs for meteorological applications. By contrast, there are  
168 relatively few studies concerning OSSEs for AQ applications (Edwards et al., 2009; Timmermans et al.,  
169 2009a, b; Claeys et al., 2011; Zoogman et al., 2011; 2014a, b; Yumimoto, 2013). In a recent review,  
170 Timmermans et al. (2015) comment that documented AQ OSSEs have demonstrated the benefits that could  
171 accrue from proposed and planned satellite platforms for AQ monitoring and forecasting. In the study  
172 described in this paper, the set-ups for the NR, and the CR and AR, use different models, thereby avoiding  
173 the identical twin problem typically associated with overly optimistic OSSE results (see, e.g., Masutani et al.,

174 2010a). In Sects. 2.1-2.5 we describe the various elements of the OSSE study described in this paper. Figure  
175 1 provides a schematic showing the relationships between the various elements in an OSSE. In this study, we  
176 use the LOTOS-EUROS model as the NR and the MOCAGE (Modèle de Chimie Atmosphérique de Grande  
177 Echelle) Chemistry Transport Model as the CR (for details of these models, see Sects. 2.1 and 2.4,  
178 respectively)

179

## 180 **2.1 The Nature Run**

181 A key element of an OSSE is the NR that defines the true state used to evaluate analyses and/or forecasts  
182 using simulated observations. The NR commonly consists of a long, free-running forecast evolving  
183 continuously in a dynamically consistent way (Masutani et al. 2010a, b). For this study, the basis of the NR  
184 consists of two high-resolution free model simulations performed with: (i) the regional LOTOS-EUROS air  
185 quality model (Schaap et al., 2008), and (ii) the global chemistry transport model TM5 (Huijnen et al., 2010).  
186 We obtain the NR by combining the LOTOS-EUROS CO profiles from the surface to 3.5 km with the TM5  
187 CO profiles from 3.5 km to the top of the atmosphere (identified by the TM5 model top at 0.1 hPa). We use  
188 spatial interpolation to merge the values near the boundary between the two models at a height of 3.5 km.  
189 The model simulations used to construct the NR have a spin-up period of three months. We archive the NR  
190 output data on an hourly basis.

191

192 To construct the NR, we run the LOTOS-EUROS model at a horizontal resolution of about 7 km nested into  
193 the TM5 model, the latter run with a zoom domain over Europe at 1x1 degrees resolution. The TM5 model  
194 has 34 layers with a model top at 0.1 hPa. The LOTOS-EUROS model describes air pollution in the  
195 lowermost troposphere. It has four vertical layers following the dynamic mixing layer approach. The first  
196 layer is a fixed surface layer of 25 metres thickness, the second layer (boundary layer) follows the mixing  
197 layer height, and there are two reservoir layers spanning the rest of the atmosphere up to 3.5 km. The implicit  
198 assumption of the LOTOS-EUROS model is the presence of a well-mixed boundary layer, so constituent  
199 concentrations are constant up to the top of the Planetary Boundary Layer. The meteorological data used as  
200 input for the LOTOS-EUROS model come from the European Centre for Medium-Range Weather Forecasts  
201 (ECMWF). Prescription of surface anthropogenic emission is from the TNO-MACC-II emission database

202 (Kuenen et al., 2014), and fire emissions are from the MACC global fire assimilation system (GFAS v1;  
203 Kaiser et al., 2012).

204

205 In the design of an OSSE, it is important to demonstrate that the NR exhibits the same statistical behaviour  
206 as the real atmosphere in every aspect relevant to the observing system under study (Masutani et al., 2010a,  
207 b). For the LOTOS-EUROS model used to build the lowermost levels of the NR, there is extensive  
208 verification by comparison with European data and by frequent participation in international model  
209 comparisons. This is the case for ozone and particulate matter (see Hass et al., 2003; Cuvelier et al., 2007;  
210 van Loon et al., 2007; Stern et al., 2008; Manders et al., 2009; Curier et al., 2012; Marécal et al., 2015). To  
211 evaluate the NR, we compare the surface CO data to available in situ ground-based CO measurements over  
212 Europe during northern summer 2003 (1 June – 31 August). For this comparison, we use the ground-based  
213 stations from the Airbase database. We consider all types of ground-based stations from this database  
214 because of the limited number of available measurements, but we discard stations with less than 75% of  
215 hourly data within a month. This provides 171 ground-based stations for the comparison against the NR  
216 (note this approach results in a paucity of stations over France).

217

218 Figure 2 shows the location of the selected Airbase ground-based stations measuring CO over Europe during  
219 northern summer 2003 (top panel), and the time-series of CO concentrations during 1 June – 31 August  
220 2003, measured by the selected Airbase ground-based stations and simulated by the NR and the CR (bottom  
221 panel - see Sect. 2.4 for the definition of the CR). Note that most ground-based stations selected are located  
222 in polluted areas, where big emission sources of CO are present. We form the time-series from the ground-  
223 based stations by averaging spatially over all the sites. We form the NR time-series similarly, but interpolate  
224 the NR surface data to the station location. We do not add random observation errors to the NR time-series.

225

226 From Fig. 2, we see that, generally, the NR captures reasonably well the features of observed CO temporal  
227 variability during the three phases characterizing the summer of 2003: before, during and after the heat wave  
228 (the heat wave occurred on 31 July – 15 August). One can notice that the observed and simulated CO time-  
229 series exhibit some high frequency component due principally to the fact that the 171 sites representing these  
230 time series are mostly located in emission source areas (there are only 5 background rural sites among the

231 171 sites selected). The CO diurnal pattern over a background rural site during the course of a summer day  
232 shows a peak between 7h and 8h in the morning. However, in polluted regions, the CO diurnal pattern shows  
233 more variability. The correlation coefficient,  $\rho$ , between the ground-based data and NR time-series shown in  
234 the middle panel is 0.71. From this, we conclude that the NR has a realistic representation of the CO diurnal  
235 cycle. Note that CO concentration levels in the NR are slightly lower than observed ones. The bias of the NR  
236 with respect to observed CO concentrations fluctuates around -10 % on average during normal conditions  
237 and reaches -20% within the heat wave period. This means that the NR reproduces the surface concentrations  
238 with a negative bias (NR lower than ground-based stations) between 10 and 20%. Nonetheless, the simulated  
239 CO concentrations and those measured by the ground-based stations generally fall within the same range of  
240 values (between 200 and 400  $\mu\text{gm}^{-3}$ ). Thus, for the OSSE period considered, we conclude that the NR is  
241 representative of the variability of actual observations over the European domain, albeit with a negative bias.

242

243 Additionally, from Fig. 2 the behaviour of the CO time-series from the CR compared to the NR, is similar to  
244 the behaviour of the NR CO time-series compared to the Airbase data. This suggests that the NR from  
245 LOTOS-EUROS model from which we sample the S-5P simulated observations is reasonably realistic. This  
246 reduces the likelihood that the OSSE produces overoptimistic results.

247

## 248 **2.2 The S-5P CO simulated measurements**

249 The S-5P will deploy the TROPOspheric Monitoring Instrument (TROPOMI) jointly developed by The  
250 Netherlands and ESA (Veefkind et al. 2012). The TROPOMI instrument has heritage from both the OMI and  
251 the SCIAMACHY missions. The TROPOMI instrument will make measurements in the UV-visible  
252 wavelength range (270-500 nm), the near infrared, NIR (675-775 nm) and the shortwave infrared, SWIR  
253 (2305-2385 nm). It will deliver a key set of gas and aerosol data products for air quality and climate  
254 applications, including ozone,  $\text{NO}_2$ , formaldehyde,  $\text{SO}_2$ , methane and CO.

255

256 To enable sounding of the lower atmosphere at finer scales, TROPOMI has an unprecedented spatial  
257 resolution of  $7 \times 7 \text{ km}^2$  at nadir. This relatively high spatial resolution is necessary for air quality applications  
258 at local to regional scales. It will resolve emission sources with 15% of accuracy and 10% precision  
259 (Veefkind et al., 2012), and will obtain an acceptable fraction of cloud-free spectra. In contrast to the

260 advantages provided by the relatively high spatial resolution of S-5P and design improvements, the  
261 SCIAMACHY CO data needs averaging in time (roughly one month) and space (5x5 degrees) to obtain  
262 realistic CO distributions at comparable uncertainty (Galli et al., 2012). Furthermore, TROPOMI will have a  
263 wide swath of 2600 km to allow for daily global coverage. The relatively high radiometric sensitivity of S-5P  
264 will allow measurements at low albedo (order of 2%; Veefkind et al., 2012), thus helping track smaller  
265 pollution events and improving the accuracy of air quality assessments and forecasts. The use of S-5P CO  
266 total column measurements with inverse modelling techniques will also help quantify biomass burning  
267 emissions and map their spatial distribution. The simultaneous measurements of CO and, e.g. NO<sub>2</sub>, will  
268 provide additional information on wildfires and other pollution episodes (Veefkind et al., 2012).

269

270 We use the NR results to generate a set of synthetic S-5P observations. This involves several steps. 1)  
271 Generating realistic S-5P orbits and geolocation and viewing/solar geometries for the appropriate overpass  
272 time. 2) Using the ECMWF modelled cloud distributions to generate effective cloud fractions. 3) Generating  
273 lookup tables for the averaging kernels and observation errors. 4) Collocation and application of the NR to  
274 derive a set of synthetic observations for three summer months and three winter months. We discuss these  
275 steps in the sub-sections below.

276

### 277 ***2.2.1 Orbit simulator***

278 We use the System Tool Kit (STK, available from AGI, <http://www.agi.com/products/>) to generate the S-5P  
279 orbit geometry and the geolocation of the edges of the swath as a function of time. Based on these  
280 characteristics, we generate the location of the individual observations with a spatial distance of 7 km. We  
281 apply time and longitude shifts to the STK-generated orbits to obtain the orbits for the three summer and  
282 three winter months of this study. Subsequently, we compute the solar and viewing geometries. Finally, we  
283 maintain segments of the orbits that have an overlap with the modelling domain.

284

### 285 ***2.2.2 Cloud properties***

286 We obtain cloud fields from the high-resolution operational weather forecast archive of the ECMWF. We  
287 retrieve meteorological fields of liquid water content, ice water content, specific humidity and cloud fraction

288 at a resolution of 0.25 x 0.25 degrees for June-August 2003 and November 2003 - January 2004. We convert  
289 these quantities to cloud optical properties. The optical properties determine the reflectance, and we use them  
290 to estimate effective cloud fractions and effective cloud top heights as retrieved from the satellite  
291 observations (Acarreta et al., 2004). We compare the distribution of effective cloud fractions with the  
292 distribution of effective cloud fractions obtained from OMI observations, and find a reasonable agreement  
293 for summer and winter months. We derive the cloud fractions at the resolution of the ECMWF 0.25 x 0.25  
294 degrees grid. This is close to 30 x 30 km<sup>2</sup> at the Equator and decreases as a function of latitude. The ground  
295 pixel of OMI UV-2 and VIS channels is 13 x 24 km<sup>2</sup> at nadir increasing to 13 x 128 km<sup>2</sup> at edges of the  
296 swath. We consider that the ECMWF grid cells and OMI pixels are of comparable size for comparing the  
297 cloud fraction distributions (close to 0.5 million pixels or cells in each distribution). We model clouds as  
298 simple Lambertian reflectors and ignore any wavelength dependency of cloud fraction.

299

300 We use these effective cloud fractions (and corresponding cloud radiance fractions) to provide weights to the  
301 cloud-free and cloud-covered fractions of the surface scene. We use the cloud altitude for the computation of  
302 the averaging kernel.

303

### 304 ***2.2.3 Averaging kernel and measurement uncertainty lookup tables***

305 Because of the large number of observations that will become available from the S-5P instrument, full  
306 radiative transfer calculations for each observation separately are not feasible. We thus choose to build look-  
307 up tables for a set of geometries based on a radiative transfer code that employs the adding-doubling method  
308 in combination with optimal estimation (using the radiative transfer toolbox DISAMAR; de Haan, 2012).  
309 Look-up tables are set up for the averaging kernels (1D vectors as a function of altitude) and the  
310 measurement uncertainty. Results are stored for a number of surface albedos, cloud/surface pressures, solar  
311 zenith angles, viewing zenith angles and relative azimuth angles. We provide the look-up table details in  
312 Table 1. We provide the kernels on 21 pressure levels between 1050.0 and 0.1 hPa. We specify the  
313 uncertainties for clear-sky and cloudy-sky separately.

314

315 Each simulation with DISAMAR consists of a forward calculation of the satellite-observed spectrum,  
316 followed by a retrieval step based on the optimal estimation method (Rodgers, 2000). We convert instrument

317 noise, listed in Table 1, into uncertainties for the retrieved CO column. We take a-priori trace gas profiles  
318 from the CAMELOT study (Levelt et al., 2009). As indicated above, we assume that both the cloud and the  
319 surface are Lambertian reflectors. Kujanpää et al. (2015) provide further details of this procedure.

320

321 The albedo is a major influence on the uncertainty, because it directly determines the signal observed by the  
322 instrument. We show this dependence in Fig. 3. Over land, albedo values are typically of the order of 0.1-0.2,  
323 with typical column errors of the order of 2 DU, or about  $10^{17}$  molecules  $\text{cm}^{-2}$ . Because typical CO columns  
324 over Europe are  $2 \times 10^{18}$  molecules  $\text{cm}^{-2}$ , this is a relatively small error of the order of 5%. These numbers are  
325 in good agreement with the results presented in the CO ATBD of TROPOMI (document available from  
326 <https://sentinel.esa.int/web/sentinel/user-guides/sentinel-5p-tropomi/document-library> ). Over the ocean, the  
327 albedo is very low, and the noise dominates the signal. To simulate this behaviour in a realistic way we have  
328 added the albedo values 0.005, 0.01 and 0.02 to the albedo list in the look-up tables.

329

330 We note that the uncertainties reported here are substantially lower than reported for SCIAMACHY (e.g.  
331 Gloudemans et al., 2008). This reflects a difference in specifications of the instruments, and the fact ice  
332 build-up on the detectors affected the SCIAMACHY observations. Real TROPOMI observations will show if  
333 the result that these are relatively small errors is realistic.

334

#### 335 ***2.2.4 Synthetic observations generation***

336 The generation of the synthetic observations consists of the following steps:

- 337 • Co-location of the Nature run vertical profiles of CO to the locations of the observations.
- 338 • Computation of the effective cloud fraction, cloud radiance fraction, and cloud pressure from the  
339 ECMWF cloud fields co-located to the observations.
- 340 • Co-location of the NIR albedo map (surface albedo at 2300 nm is interpolated from a climatology  
341 provided by SRON and based on SCIAMACHY observations; P. Tol, personal communication) to  
342 the locations of the observations.
- 343 • Extract interpolated values for the observation kernel and uncertainties from the look-up table.

- 344 • Compute the synthetic observation from the inner product of the kernel with the nature run CO  
345 profile. We do this for both a clear sky and a fully cloudy situation, using the cloud pressure.
- 346 • Add random noise amount to each observation, by drawing numbers from a Gaussian distribution  
347 with a width determined from the uncertainty estimate.
- 348 • Compute the partially clouded synthetic observation by weighting the clear and cloudy results with  
349 the cloud radiance fraction (Vidot et al., 2011; Landgraf et al., 2016).

350

351 Over land, and in clear sky cases, the averaging kernel is close to 1, showing that the S-5P instrument is  
352 observing the vertical column to a good approximation (see Fig. 4). In cloud-covered cases the kernel equals  
353 0 for layers below the cloud pressure (yellow line in Fig. 4). For low-albedo cases (over ocean), Rayleigh  
354 scattering becomes non-negligible, and the kernel decreases towards the surface, but the noise is dominant in  
355 this case.

356

357 We show the results of this process in Fig. 5. The figure demonstrates the high resolution of the NR (about 7  
358 km) and the corresponding simulated amount of detail. The bottom panel shows the corresponding CO  
359 observations. Over land, the NR features are clearly present due to the relatively low uncertainty. Over the  
360 ocean and Mediterranean, noise dominates the signal. We observe an improved information content near  
361 Iceland, related to thick cloud cover, where the higher signal reduces the relative noise.

362

### 363 **2.3 Pre-processing of S-5P CO total column observations**

364 This section describes the pre-processing of S-5P CO total column observations prior to assimilation into the  
365 MOCAGE model (Peuch et al., 1999) for the OSSE simulations. Using the MOCAGE model for the AR and  
366 CR simulations avoids the identical twin problem associated with using the same model for both the NR and  
367 the OSSE simulations, which typically produces overoptimistic results (Arnold and Dey, 1986; Stoffelen et  
368 al., 2006). Section 2.4 provides further details of the MOCAGE model.

369

370 The S-5P will produce large amounts of data owing to its wide swath and relatively high spatial resolution of  
371 about  $7 \times 7 \text{ km}^2$ . Thus, a pre-processing step is necessary to reduce the data volume for the data assimilation

372 experiments. For this study, we consider only pixels inside the OSSE simulation domain (Note that retrieval  
 373 pixels in each single cross-track are essentially instantaneous measurements of CO<sub>2</sub>). This has the advantage  
 374 of alleviating the data volume burden. However, a single cross-track over Europe could have more than  
 375 80,000 valid retrieval pixels. Furthermore, each individual pixel is associated with an averaging kernel vector  
 376 given at 34 vertical pressure levels, from the surface up to the top of the atmosphere (identified as 0.1 hPa).

377

378 Figure 4 shows an example of averaging kernels at the surface, as well as the averaging kernels  
 379 representative of retrievals including pixels with different cloud fractions (less than 10%, greater than 30%,  
 380 and greater than 80%). In addition, we discard data points with standard deviation exceeding 20% of the  
 381 retrieval or with solar zenith angles larger than 80%. The retrieval over sea is noise-dominated. Because of  
 382 this, we only consider CO<sub>2</sub> partial columns above cloudy sea scenes with cloud fraction more than 80% and  
 383 cloud top heights between the surface and 650 hPa. Finally, we apply a spatially weighted mean to bin the  
 384 measurements into 0.2° x 0.2° grid boxes (~20 x 15 km at 45N), the assimilation model resolution; this is the  
 385 set-up used for the OSSE assimilation experiments (CR and AR), and is described in El Amraoui et al.  
 386 (2008a). It combines the MOCAGE model and the PALM (Projet d'Assimilation par Logiciel Multiméthode)  
 387 data assimilation module. Sections 2.4-2.5 provide further details of the CR and AR set-ups.

388

389 The weighted mean for pixels falling in the same model grid box is:

390

$$\bar{c} = \frac{\sum_i w_i c_i}{\sum_i w_i}$$

391

392

393 where  $\bar{c}$  is the weighted average,  $c_i$  a single column measurement, and  $w_i (=1/\sigma_i^2)$  is the inverse of the  
 394 variance corresponding to measurement  $c_i$ , and is the weight assigned to this single measurement. The  
 395 inverse of the variance associated with the weighted average is

396

$$\frac{1}{\bar{\sigma}^2} = \sum_i w_i$$

397

398

399 The spatial binning not only reduces considerably the data volume but also results in an improved spatial  
400 representativeness of the CO measurements by reducing the random error of each data pixel.

401

## 402 **2.4 The Control Run**

403 To generate the CR, it is important to use a state-of-the-art modelling system, which simulates the  
404 observational data representing, for example, a current operational observational system. An important  
405 requirement for an effective OSSE is to generate the CR with a model different from the one used to  
406 construct the NR to avoid the identical twin problem (see Sect. 2.3). If the model from which we extract  
407 hypothetical observations is the same as the assimilating model, the OSSE results tend to show unrealistic  
408 observation impact and overly optimistic forecast skill (Arnold and Dey, 1986; Stoffelen et al., 2006).  
409 Consequently, by using two independent models the OSSE will simulate more realistically the assimilation  
410 of real observations. This allows us to design an OSSE that is not too overoptimistic.

411

412 In this OSSE study, the CR is a free model run using MOCAGE. The MOCAGE model is a three-  
413 dimensional CTM developed at Météo France (Peuch et al., 1999) providing the evolution of the atmospheric  
414 composition in accordance with dynamical, physical and chemical processes. It provides a number of  
415 configurations with different domains and grid resolutions, as well as various chemical and physical  
416 parameterization packages. Current use of MOCAGE includes several applications: e.g., the Météo-France  
417 operational chemical weather forecasts (Dufour et al., 2004); the Monitoring Atmospheric Composition and  
418 Climate (MACC) services (<http://www.gmes-atmosphere.eu>; Marécal et al., 2015); and studies of climate  
419 trends of atmospheric composition (Teyssède et al., 2007). Validation of MOCAGE simulations against a  
420 large number of measurements took place during the Intercontinental Transport of Ozone and Precursors  
421 (ICARTT/ITOP) campaign (Bousserez et al., 2007).

422

423 In this study, we use a two-way nesting configuration to generate the CR and the AR (we describe the AR  
424 set-up in Sect. 2.5): a global grid with a horizontal resolution of 2x2 degrees and a regional grid (5W-35E,  
425 35N-70N) with a horizontal resolution of 0.2x0.2 degrees. The MOCAGE model includes 47 sigma-hybrid  
426 vertical levels from the surface up to 5 hPa. The vertical resolution is 40 to 400 m in the boundary layer (7  
427 levels) and approximately 800 m near the tropopause and in the lower stratosphere. The chemical scheme

428 used is RACMOBUS, which combines the stratospheric scheme REPROBUS (REactive Processes Ruling  
429 the Ozone BUdget in the Stratosphere; Lefèvre et al., 1994) and the tropospheric scheme RACM (Regional  
430 Atmospheric Chemistry Mechanism; Stockwell et al., 1997). The RACMOBUS scheme includes 119  
431 individual species, of which 89 are prognostic variables, and considers 372 chemical reactions.

432

433 We force the CR (and the AR) every 3 hours with the ARPEGE analysis (Courtier et al., 1991). We prescribe  
434 the surface anthropogenic emission using the MACC-I emission database ([https://gmes-  
435 atmosphere.eu/about/project\\_structure/input\\_data/d\\_emis/](https://gmes-atmosphere.eu/about/project_structure/input_data/d_emis/)). We do not include the fire emissions in the  
436 CR and AR experiments described in this paper, as their a-priori distribution is unknown. This means that  
437 any signature of fire emissions in the AR (see Sect. 2.5) can only come from assimilation of the CO  
438 measurements. Note that for the NR, the surface anthropogenic emissions come from the MACC-II  
439 inventory, which helps to differentiate the CR from the NR. Similar to the NR, the CR has a spin-up period  
440 of three months.

441

## 442 **2.5 The Assimilation run**

443 We assimilate simulated S-5P total column CO observations derived from the LOTOS-EUROS NR into the  
444 MOCAGE CTM at a 0.2 degrees spatial resolution using the MACC extended domain (5W-35E, 35N-70N).  
445 The assimilation system used in this study is MOCAGE-PALM (e.g., El Amraoui et al., 2008a) developed  
446 jointly by Météo-France and CERFACS (Centre Européen de Recherche et de Formation Avancée en Calcul  
447 Scientifique) in the framework of the ASSET European project (Lahoz et al., 2007b). The assimilation  
448 module used in this study is PALM, a modular and flexible software, which consists of elementary  
449 components that exchange the data (Lagarde et al., 2001). It manages the dynamic launching of the coupled  
450 components (forecast model, algebra operators and input/output of observational data) and the parallel data  
451 exchanges. Massart et al. (2009) used the assimilation system MOCAGE-PALM to assess the quality of  
452 satellite ozone measurements. The MOCAGE-PALM assimilation system also helps identify and overcome  
453 model deficiencies. In this context, its assimilation product has been used in many atmospheric studies in  
454 relation to ozone loss in the Arctic vortex (El Amraoui et al., 2008a); tropics/mid-latitudes exchange  
455 (Bencherif et al., 2007); stratosphere-troposphere exchange (Semane et al., 2007); and exchange between the  
456 polar vortex and mid-latitudes (El Amraoui et al., 2008b). For this OSSE, to speed up the assimilation

457 process we use the 3D-Var version of PALM. In the OSSE, the MOCAGE model provides the CR and by  
458 assimilating the simulated CO data from the NR, the MOCAGE model provides the AR. Thus, we produce  
459 the CR and AR outputs with a model different from that used to produce the NR (see Sect. 2.1).

460

461 A key element of the data assimilation system is the background error covariance matrix (the **B**-matrix)  
462 (Bannister, 2008). It has a large impact on the 3D-Var analysis used in this study and, thus, it is important to  
463 use a form of **B** that is as realistic as possible. In MOCAGE-PALM, we base the **B**-matrix formulation on the  
464 diffusion equation approach (Weaver and Courtier, 2001). It can be fully specified by means of the 3-D  
465 standard deviation field (square root of the diagonal elements of **B**, in concentration units or as a percentage  
466 of the background field) and 3-D fields of the horizontal ( $L_x$  and  $L_y$ ) and vertical ( $L_z$ ) local correlation  
467 length-scales. We can estimate the **B**-matrix elements more efficiently using an ensemble method (Bannister,  
468 2008). This technique consists of feeding an ensemble of states through the data assimilation system to  
469 simulate the important sources of error. However, this approach is time-consuming and, therefore, not used in  
470 this study.

471

472 For this study, we use a simple parameterization for the **B**-matrix, where  $L_x$  and  $L_y$  are assumed  
473 homogeneous and equal to 35 km (about two model grid lengths); and  $L_z$  is constant and set to one vertical  
474 model layer. As in Emili et al. (2014), the background standard deviation 3-D field is parameterized as a  
475 vertically varying percentage of the background profile, which decreases from values of 25% at the surface  
476 to values of 15% in the upper troposphere, and decreases further throughout the stratosphere to values of 5%  
477 in the upper stratosphere (not shown). We base these settings on several 1-day assimilation trials; they ensure  
478 reasonable values of standard self-consistency tests, e.g., providing chi-squared ( $\chi^2$ ) values close to 1 (see  
479 Fig. 6 in Sect. 3.1). Furthermore, a value of  $L_x$  and  $L_y$  of 35 km corresponds to more than one grid length of  
480 the model, allowing the model to resolve these features. The data assimilation procedure will weight both the  
481 observations and the model 1-hour forecasts (from the last analysis point), and will update locations not  
482 coincident with the observations through the correlation length-scales. Table 2 summarizes the parameters  
483 used for the assimilation experiments.

## 484 **3. Results**

### 485 **3.1 Evaluation of the assimilation run**

486 In this section, we evaluate the impact of the assimilation of the S-5P CO total column. First, we evaluate the  
487 consistency of the assimilation run by separating the clear-sky pixels from their cloudy counterparts (Sect.  
488 3.1.1). Second, to further understand the impact on the surface CO field of the simulated S-5P CO total  
489 column measurements, we investigate the analysis increment ( $\delta x$ ) to provide a quantitative diagnostic of the  
490 quality of the analysis for a selected date, 15 June 2003 (Sect. 3.1.2).

491

#### 492 **3.1.1 Consistency of the assimilation run**

493 We perform two OSSEs. The first one includes all pixels in the OSSE domain, regardless of whether they are  
494 cloudy or clear-sky and the second only includes clear-sky pixels. We consider a pixel to be clear when the  
495 cloud fraction is less than 10%. Comparison of the ARs from these two OSSEs indicates that the impact of  
496 including all pixels is small. The largest differences between the respective ARs in relation to the NR are 4%  
497 in regions over North Europe (North Sea and Scandinavia), with the AR for clear-sky pixels closer to the NR  
498 (not shown). We can explain these results by the fact the summer generally has low amounts of cloud.  
499 Consequently, we only present the results from the OSSE with all pixels.

500 To evaluate the AR, we calculate the  $\chi^2$  diagnostic associated with the Observation minus Forecast (OmF)  
501 differences (see, e.g., Lahoz et al., 2007a). Here, we normalize the OmF differences by the background error.  
502 We also calculate histograms of the Observation minus Analysis (OmA) differences, the observation and the  
503 simulation from the CR (observation-minus-control run, hereafter OmC) differences, and the OmF  
504 differences. We use the observational error to normalize the differences building the histograms of OmA,  
505 OmC and OmF.

506

507 Figure 6 (top panel) shows the chi-squared time-series for OmF and its associated auto-correlation function  
508 calculated over the three-month period of the OSSE experiments, computed as daily averages. The chi-  
509 squared diagnostic starts with a maximum of about 1.56, and takes values down to 0.75, with a mean of 0.9  
510 over the OSSE three-month period. The chi-squared time-series is nearly stable since it exhibits relatively

511 small variability (a standard deviation of about 0.14). Furthermore, the auto-correlation of the chi-squared  
512 statistic drops to zero, with no correlation after a time delay of 20 days. The calculation of the auto-  
513 correlation shows that the chi-squared statistic is uncorrelated after a time lag of 20 days; this means that  
514 after this time the mathematical expectation  $E(\chi^2)$  is equal to the average of the chi-squared statistics. We  
515 find  $E(\chi^2) = 0.90$ , which is close to the theoretical value of 1 (see Lahoz et al., 2007a). This result indicates  
516 that the a-priori error statistics as represented in the **B**-matrix slightly overestimate the actual error statistics  
517 from the OmF differences.

518

519 To test whether the observations, forecast and analysis fields, and their associated errors, are consistent with  
520 each other, we calculate the histograms of OmA, OmF and OmC only over land (normalized by the  
521 observation error) over the three-month period (Fig. 6, bottom panel). For a properly set up assimilation  
522 system, the OmF and OmA normalized histograms should be close to a Gaussian distribution with mean zero  
523 and standard deviation one. Figure 6 (bottom panel) shows that the OmA and OmF differences are close to a  
524 Gaussian distribution centred near to or at zero. The OmF has a mean and standard deviation of 0.10 and  
525 1.73, respectively, whereas the OmA has nearly a zero mean and a standard deviation of 1.05. This indicates  
526 that the centre of the OmA histogram is closer to zero and more peaked than the histogram of OmF. We  
527 expect this, since the analyses should be closer to the observations than the forecasts. Furthermore, the  
528 histogram for OmA indicates that the errors in the **R**-matrix, the observational counterpart of the **B**-matrix,  
529 are a good representation of the analysis error.

530

531 Based on the above results, we conclude that the background error covariance matrix, **B**, and its  
532 observational counterpart, **R**, prescribed in our assimilation system are reasonably well characterized (see,  
533 e.g., Lahoz et al., 2007a, for a discussion of the specification of errors in a data assimilation system).  
534 Furthermore, the above results are consistent with the assumption that the errors in the observations and the  
535 forecasts are Gaussian.

536

537 The shape of the OmC normalized histogram, which has a mean and standard deviation of 2.36 and 5.60,  
538 respectively, indicates the presence of a relatively large bias between the S-5P observations and the CR. The  
539 assimilation reduces this bias, as shown by the analyses being significantly closer to the observations than

540 the simulation from the CR. This shows that the assimilation of simulated S-5P CO total column  
541 observations has a significant impact on the CO forecasts and analyses.

542

### 543 *3.1.2 Study of increments*

544 To understand further the impact on the surface CO field of the simulated S-5P CO total column  
545 measurements, we calculate the analysis increment ( $\delta x$ ) for a single analysis time at 14:00 UTC on 15 June  
546 2003. We calculate this increment as the analysis minus the model first guess (1-hour forecast). The analysis  
547 increment provides a quantitative diagnostic of the quality of the analysis (see, e.g., Fitzmaurice and Bras,  
548 2008).

549

550 Figure 7 (top panel) shows the spatial distribution of  $\delta x$  at the model surface. One can see the spread of the  
551 impact of the simulated observations across large regions. This is owing to S-5P having a wide swath  
552 allowing it to sample larger regions. The most substantial corrections are over land, where there are sufficient  
553 observations to have an impact. Over sea, the increments tend to be negligible, as any observations found  
554 there have relatively large errors. Thus, there will not be much difference between the model first guess and  
555 the analysis. Likewise, this is also true in the regions outside the satellite footprint.

556

557 To provide further insight into the impact of S-5P CO measurements, we calculate latitude-height and  
558 longitude-height cross-sections at 48.8N, 2.6E, near Paris, for 15 June 2003. Figure 5 (bottom left and  
559 bottom right panels) shows a zoom of the zonal and meridional vertical slices of the analysis increment. We  
560 see significant corrections to the model first guess (identified by large increments) confined to a deep layer.  
561 These corrections are larger at the surface, and exhibit a second maximum around 650 hPa. This vertical  
562 structure is mainly attributable to the forecast error standard deviation (given as a vertically varying fraction  
563 of the local CO mixing ratio), the square root of the diagonal entry of the **B**-matrix, and which is higher in  
564 the boundary layer (where the value of the S-5P CO averaging kernel is close to 1). The shape of the S-5P  
565 analysis increments also exhibits a second peak around 650 hPa. The increments for this particular day thus  
566 show a clear impact from the S-5P CO measurements in the PBL and the free troposphere.

567

568 The shape of the S-5P increments is similar to that of typical SCIAMACHY analysis increments, which also  
569 extend through a deep layer and have a maximum at the surface (Tangborn et al., 2009). The fact that both  
570 these analysis increments stretch out over a deep layer is owing to similarities in the S-5P and SCIAMACHY  
571 averaging kernels - both are close to unity over cloud-free land (see Fig. 5). Note that the situation shown in  
572 Fig. 7 is a snapshot and depends on the particular conditions for this time. An average of the increments over  
573 the summer period would tend to show a uniform distribution in height.

574

## 575 **3.2 Evaluation of the summer OSSE**

### 576 *3.2.1 Summer averages*

577 Figure 8 shows the fields of surface CO from the CR, and the NR and the AR, averaged over the northern  
578 summer period. One can see the general change of CO over land between the CR (top left panel) and the AR  
579 (bottom panel). We can ascribe this to the contribution of simulated S-5P total column CO data sampled from  
580 the NR. This figure shows several differences between the CR and AR fields that indicate the superior  
581 behaviour of the AR in capturing features in the NR. For example, over Eastern Europe and Russia, the AR  
582 CO concentration values are closer to those in the NR (with a mean bias between -1.5 and +1.5 ppbv); in  
583 particular, the CR shows generally lower values than in the NR (mean bias around -6 ppbv). Nevertheless,  
584 over Portugal, where the NR shows the forest fires that occurred over the summer, the AR captures them  
585 only slightly better than the CR. We expect this relatively poor performance of the CR regarding fires, as the  
586 fires are not included in the CR set-up (see Sect. 2.4). Although the AR, in the operational set-up, captures  
587 the CO concentrations emitted by forest fires slightly better than the CR (through assimilation of CO  
588 measurements), the relatively poor temporal resolution of the S-5P ultimately limits its performance.  
589 However, the most important deficiency is due to the criterion used in the operational set-up in which we  
590 activate a data-screening test to discard observations far away from the model (see section 3.2.5). A  
591 geostationary satellite, given its relatively high temporal resolution, should be able to capture better the  
592 temporal variability of CO from these forest fires (Edwards et al., 2009).

593

### 594 *3.2.2 Statistical metrics*

595 In this section, we provide a quantitative assessment of the benefit from S-5P CO total column measurements  
596 on the CO surface analysis. For this, we perform a statistical analysis of the different OSSE experiments for  
597 northern summer 2003.

598

599 We calculate the mean bias (MB, in parts per billion by volume, ppbv), its magnitude reduction (MBMR,  
600 ppbv), and the root mean square error (RMSE, ppbv), and its reduction rate (RMSERR, %). Note that  
601 although recent papers have raised concerns over the use of the RMSE metric (Willmott and Matsuura, 2005;  
602 Willmott et al., 2009), Chai and Draxler (2014) discuss circumstances where the RMSE is more beneficial.  
603 We use the correlation coefficient,  $\rho$  to measure the linear dependence between two datasets, and the fraction  
604 of the true variability (i.e., variability represented by the NR) reproduced by the CR or AR.

605

606 For a single model grid box, we define the statistical metrics (MB, RMSE,  $\rho$ ) with respect to the NR as:

607

$$608 \quad MB(X) = \frac{1}{N} \sum (X - NR)$$

609

$$610 \quad MBMR = |MB(CR)| - |MB(AR)|$$

611

$$612 \quad RMSE(X) = \sqrt{\frac{1}{N} \sum (X - NR)^2}$$

613

$$614 \quad RMSERR = 100 \times \left(1 - \frac{RMSE(AR)}{RMSE(CR)}\right)$$

615

$$616 \quad \rho(X) = \frac{\sum (X - \bar{X})(NR - \bar{NR})}{\sqrt{\sum (X - \bar{X})^2 \sum (NR - \bar{NR})^2}}$$

617

618 where X denotes the CR or the AR; N is the number of data samples; the vertical bars denote the absolute  
619 value operator; and the overbar symbol represents the arithmetic mean operator. The MB metric gives the  
620 average value by which the CR or the AR differs from the NR over the entire dataset.

621

### 622 **3.2.3 Results of the statistical tests**

623 Figure 9 presents the zonal and meridional means of the difference between the CR and the AR averaged  
624 over the northern summer 2003 (1 June – 31 August). We also plot the confidence interval representing the  
625 areas where the AR is not significantly different to the CR at the 99% confidence limit (highlighted in the  
626 grey colour). These two figures show that there is benefit from the S-5P CO total column data over the first  
627 few bottom levels of the troposphere, i.e., the lowermost troposphere. Between the surface and 800 hPa, a  
628 negative peak is present in the zonal difference field (over Scandinavia), and in the meridional difference  
629 field (over Eastern Europe). Note that the zonal field shows two areas, one with positive values and the other  
630 with negative values representing a CR greater than the AR and a CR smaller than the AR, respectively. The  
631 positive peak, at a slightly higher level (i.e., lower pressure) than the negative peak, is representative of the  
632 Mediterranean Sea, whereas the negative peak is more representative of the land areas (Scandinavia and  
633 Eastern Europe). Figure 9 indicates that the S-5P CO corrects the model in the lower troposphere with a  
634 larger impact over land and with a smaller impact in the PBL. This is consistent with the behaviour of the  
635 analysis increments shown in Fig. 7.

636

637 Figure 10 shows the performance of the biases between the CR and the NR, and the AR and the NR at the  
638 surface, and averaged over the northern summer of 2003 (1 June – 31 August). The MBMR, which compares  
639 the magnitude of the CR vs NR and AR vs NR biases, indicates the geographical areas where the simulated  
640 S-5P CO total column data have the most impact. The MBMR shows that the AR is closer to the NR than the  
641 CR, almost everywhere in the domain (reflected by the prevalence of the red colours in the bottom left  
642 panel). This indicates that the simulated S-5P CO total column data generally provide a benefit at the surface,  
643 and especially over land areas where the CO sources are sparse. This suggests that owing to the relatively  
644 small variability of CO over remote land regions, the S-5P data can provide a larger benefit compared to  
645 regions where the variability is relatively high.

646

647 We also calculate the RMSE as well as the reduction rate of the RMSE, RMSERR (Figure 11), both keeping  
648 the systematic error (Fig. 11, top), and removing the systematic error (Fig. 11, bottom). We calculate the bias  
649 in the AR and CR by subtracting the NR field from each of them, producing an unbiased AR and CR. For the

650 case where we remove the systematic error, we perform the statistics on the unbiased AR and CR. If we  
651 examine the RMSE statistics, Fig. 9 shows that the CR gets closer to the NR over the Atlantic Ocean and  
652 over the Eastern domain including Russia and Scandinavia, when we remove the systematic error. For  
653 example, over these areas we obtain ~30 ppbv and ~10 ppbv for the RMSE keeping and removing the  
654 systematic error, respectively. For the reduction of the RMSE, RMSERR, the behaviour for the CR is similar  
655 overall, showing a reduction rate of 60% and 30-45% keeping and removing the systematic error,  
656 respectively. Note that over Scandinavia the reduction rate goes down from 60% to about 10% after  
657 removing the systematic error.

658

659 These results indicate that S-5P CO data show more benefit when keeping the systematic error in the  
660 calculation of the RMSE. Following our guiding principle of avoiding an overoptimistic OSSE, we consider  
661 only the values of RMSE obtained when we remove the systematic error. For this case, the average reduction  
662 rate for the AR is around 20-25% over land (except Scandinavia) and close to 10% over sea and over  
663 Scandinavia.

664

665 In Figure 12, we show the correlation between the CR and the NR, and the correlation between the AR and  
666 the NR, at the surface for the three northern summer months (1 June – 31 August). The AR is closer than the  
667 CR to the NR with the correlation coefficient reaching 0.9 over land. By contrast, the correlation coefficient  
668 between the CR and the NR is typically less than 0.5, with very low values over Eastern Europe, where CO  
669 sources are sparse.

670

### 671 **3.2.4 Time-series at selected locations**

672 Figure 13 shows time-series from the NR, the CR and the AR over the three areas of the study domain  
673 represented by the squares shown in Figs. 10 (bottom panel) and 11 (right panels). (i) The Paris region (Fig.  
674 13, top panel). (ii) A region over Portugal (5°W-40°N), where forest fires occur during the northern summer  
675 (Fig. 13, middle panel). (iii) An area in the Eastern part of the study domain (25°E-53°N), where the  
676 reduction of RMSE (i.e., RMSERR) is much larger than for other regions (Fig. 13, bottom panel). For all  
677 three areas, the AR is generally closer to the NR than the CR, showing the impact of the simulated  
678 observations. We calculate the biases between the AR and CR vs the NR by computing the difference NR-X,

679 where X is AR or CR, and normalizing by the number of observations over the northern summer period. The  
680 biases are: (i) Paris region, CR: 48 ppbv, AR: 38 ppbv; (ii) Portugal, CR: 101 ppbv, AR: 83 ppbv; (iii)  
681 Eastern part of domain: CR: 21 ppbv, AR: 5 ppbv. Note that the AR and the CR capture the variability but  
682 not the values of the peaks. However, the LEO only samples at most twice a day over Paris and may not  
683 capture the peaks. In Fig. 13, we indicate the S-5P revisit time by the plus signs at the top of the panel and  
684 one can see that the peaks do not coincide with the time of the S-5P measurements. Another factor could  
685 also be that the emission inventory used in the AR has lower values than the one used in the NR.

686

687 Over Paris (top panel), the CR is already close to the NR and the impact of the S-5P CO simulated  
688 observations is small. Over Portugal (middle panel), the presence of fires is not seen in the CR (e.g., a  
689 maximum of CO at the beginning of the heat wave), as the fire emissions were not taken into account in the  
690 CR as they are not known a-priori (see Sect. 2.4). In contrast, over this specific location we see the impact of  
691 the fires on the CO concentrations in the AR with, however, much lower values than for the NR. During the  
692 fires, the CO concentrations in the AR over Portugal are larger than 500 ppbv, whereas the CR remains  
693 relatively unchanged with concentrations less than 200 ppbv. Over the Eastern part, where there are lower  
694 emissions compared for instance to Paris (bottom panel), the temporal variability is not high and the  
695 magnitude of the bias between the CR and the NR is small, but it is removed in the AR. Moreover, note that  
696 the operational screening test was still in force (see section below).

697

### 698 *3.2.5 Sensitivity tests for fire episode*

699 The assimilation system we use has a default criterion to discard CO column observations with values larger  
700 than 75% of the MOCAGE value. This criterion is not appropriate to situations resulting in excessive values  
701 in the CO concentrations, as is the case for forest fires. To understand further the performance of the OSSE  
702 over the period of the Portugal forest fires we perform a second OSSE without this default criterion. This  
703 second OSSE covers the period of the forest fires (25 July – 15 August). For this second OSSE, we compare  
704 the total column values and the surface values of the CO fields from the CR and the AR (Figs. 14-16,  
705 respectively).

706

707 Figure 14 shows the CO total column at 14:15 UTC on 4 August 2003 (during the period of the Portugal  
708 forest fires) from the NR (top left panel); the simulated S-5P observations (top right panel); the CR (bottom  
709 left panel); and the AR (bottom right panel). We can see that the AR captures the fire event, indicated by  
710 relatively high values of the CO total column over Portugal, whereas the CR does not. This confirms the  
711 results shown in Fig. 13, which highlight the benefit provided by the S-5P CO total column measurements, in  
712 particular regarding the capture of the signature of the Portugal forest fires. Note that the S-5P measurement  
713 is noise-dominated over the sea (top right panel). This accounts for the sharp edge in the CO total column  
714 field seen between the Iberian Peninsula and the Bay of Biscay for the AR (bottom right panel).

715

716 Figure 15 shows the time-series of the surface CO concentrations over the period 25 July – 15 August (that  
717 of the Portugal forest fires). In comparison to the original OSSE (see middle panel of Fig. 13), the AR is now  
718 closer to the NR, having now peak values of about 900 ppbv, instead of peak values of about 550 ppbv. The  
719 CR still has peak values less than 200 ppbv. This indicates that the relatively low values in the AR (in  
720 comparison to the NR) for the original OSSE shown in the middle panel of Fig. 13 result from the  
721 application of the default criterion to discard CO column observations that are far away from MOCAGE  
722 values. The results from Fig. 15 confirm those shown in Fig. 14, and reinforce the benefit provided by the S-  
723 5P CO total column measurements, in particular regarding the capture of the signature of the Portugal forest  
724 fires. This sensitivity test also shows the limitations of using standard operational criteria.

725

## 726 **4. Conclusions**

727 We perform a regional-scale Observing System Simulation Experiment (OSSE) over Europe to explore the  
728 impact of the LEO satellite mission S-5P carbon monoxide (CO) total column measurements on lowermost  
729 tropospheric air pollution analyses, with a focus on CO surface concentrations and the Planetary Boundary  
730 Layer (PBL). The PBL varies in depth throughout the year, but is contained within the lowermost  
731 troposphere (heights 0-3 km), and typically spans the heights 0-1 km. We focus on northern summer 2003,  
732 which experienced a severe heat wave with severe societal impact over Europe.

733

734

735 Our guiding principle in the set-up of this OSSE study is to avoid overoptimistic results. To achieve this, we  
736 address several factors considered likely to contribute to an overoptimistic OSSE. (i) We use different  
737 models for the NR and the OSSE experiments. (ii) We check that the differences between the NR and actual  
738 measurements of CO are comparable to the CO field differences between the model used for the OSSE and  
739 the NR. (iii) We remove the systematic error (calculated as the bias against the NR) in the OSSE outputs (AR  
740 and CR) and compare the unbiased results to the NR. (iv) We perform a quantitative evaluation of the OSSE  
741 results, including performing statistical significance tests, and self-consistency and chi-squared tests. Based  
742 on the specifications of the TROPOMI instrument, we anticipate relatively low CO column uncertainties of  
743 around 5% over the European continent. Finally, our approach was to study the performance of S-5P alone  
744 without taking into account other existing or future missions (i.e., MOPITT, CrIS or IASI).

745

746 The OSSE results indicate that simulated S-5P CO total column measurements during northern summer 2003  
747 benefit efforts to monitor surface CO. The largest benefit occurs over land in remote regions (Eastern  
748 Europe, including Russia) where CO sources are sparse. Over these land areas, and for the case when we  
749 remove the systematic error, we obtain a lower RMSE value (by ~10 ppbv) for the AR than for the CR, in  
750 both cases vs the NR. Over sea and Scandinavia, we also obtain a lower RMSE (by ~10%) for the AR than  
751 for the CR, in both cases vs the NR. Consistent with this behaviour, we find the AR is generally closer to the  
752 NR than the CR to the NR, with a correlation coefficient reaching 0.9 over land (NR vs AR). By contrast, the  
753 correlation coefficient between the CR and the NR is typically less than 0.5, with very low values over  
754 Eastern Europe, where CO sources are sparse. In general, for all the metrics calculated in this paper, there is  
755 an overall benefit over land from the S-5P CO total column measurements in the free troposphere, but also at  
756 the surface. Significance tests on the CR and AR results indicate that, generally, the differences in their  
757 performance are significant at the 99% confidence level. This indicates that the S-5P CO total column  
758 measurements provide a significant benefit to monitor surface CO.

759

760 We further show that, locally, the AR is capable of reproducing the peak in the CO distribution at the surface  
761 due to forest fires (albeit, weaker than the NR signal), even if the CR does not have the signature of the fires  
762 in its emission inventory. A second OSSE shows that this relatively weak signal of the forest fires in the AR  
763 arises from the use of a default criterion to discard CO total column observations too far from model values,

764 a criterion not appropriate to situations resulting in excessive values in the CO concentrations, as is the case  
765 for forest fires. This second OSSE shows a much stronger signal in the AR, which is now much closer to the  
766 NR than the CR, confirming the benefit of S-5P CO total column measurements and the limitations of using  
767 standard operational criteria in this case.

768

769 Further work will involve extending the OSSE approach to other S-5P measurements, such as ozone total  
770 column, and NO<sub>2</sub> and formaldehyde tropospheric columns. These studies will complement similar studies on  
771 the benefit from Sentinel-4 and -5 measurements. Collectively, these OSSE studies will provide insight into  
772 the relative benefits from the Sentinel-4, -5 and -5P platforms for monitoring atmospheric pollution  
773 processes.

774

## 775 **5. Acknowledgments**

776 Support for this work came partly from the ESA funded project “Impact of Spaceborne Observations on  
777 Tropospheric Composition Analysis and Forecast” (ISOTROP –ESA contract number 4000105743). WAL  
778 acknowledges support from an internal project from NILU. RA, JLA, PR, LE and WAL acknowledge  
779 support from the RTRA/STAE. JK and JT acknowledge support from the Academy of Finland (Project no.  
780 267442).

1049 **Tables**

1050

1051 **Table 1:** Spectral and radiometric settings for DISAMAR, and the look-up table node points.

<b>Spectral and radiometric settings</b>	
Spectral range [nm]	2330-2345
Spectral resolution (FWHM) [nm]	0.25
Spectral sampling [nm]	0.1
SNR Earth radiance	120
SNR Solar irradiance	5000
Additional calibration error (%)	1.0, correlation length 100 nm
<b>Node points</b>	
cos(SZA)	0.1 - 1.0, step 0.1
cos(VZA)	0.3 - 1.0, step 0.1
Relative azimuth [degree]	0.0, 180.0
Cloud/surface pressure [hPa]	1100 - 200, step -100
Cloud/surface albedo	0.0, 0.005, 0.01, 0.02, 0.04, 0.06, 0.1, 0.2, 0.3, 0.4, 0.8, 0.9
Pressure layers [hPa]	1100, 1000, 900, 800, 700, 600, 500, 400, 300, 200, 137.50, 68.75, 34.38, 17.19, 8.59, 4.30, 2.15, 1.07, 0.54, 0.27, 0.13, 0.07

1058 **Table 2:** Description of the configuration used in the assimilation system

	<b>Description</b>
Assimilation	3D-var, 1 hour window
Background standard deviation	As % of the background field (vertically variable)
Background correlation zonal Length scale ( $L_x$ )	Constant, 35 km
Background correlation meridional length scale ( $L_y$ )	Constant, 35 km
Background correlation vertical length scale ( $L_z$ )	One vertical model layer
S-5P total column CO observation errors	From retrieval product and weighted to account for the total column

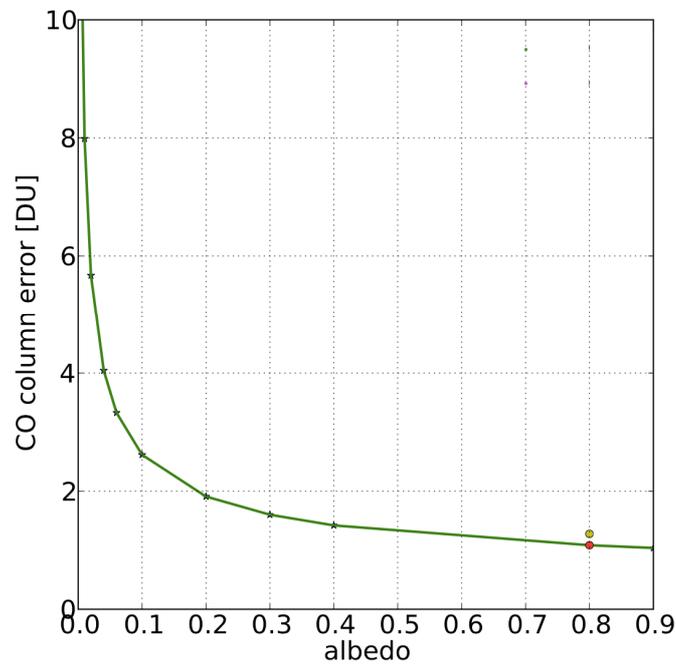

**Figure 2:** Top panel: location of selected ground-based stations for CO measurements taken from the Airbase database during northern summer 2003 (1 June – 31 August). There are 171 sites with locations shown by circles. The labels show longitude, degrees (x-axis) by latitude, degrees (y-axis). Middle panel: simulated and measured time-series of CO concentrations in surface air from nature run (blue line), the control run (red line) and from the selected 171 Airbase sites (green line). We form the CO time-series for the ground-based stations by averaging the hourly data representative of the 171 sites. The labels show time in MMDD format (x-axis) by CO concentration, parts per billion by volume, ppbv (y-axis). Bottom panel: The grey curve shows the relative error of the nature run (NR) with respect to the observations, defined as NR value minus ground station value divided by the ground station value and multiplied by 100. The labels show time in MMDD format (x-axis) by relative error, percent (y-axis). The vertical red dashed lines in the middle and bottom panels delineate the 2003 European heat wave period (31 July – 15 August).

1105

1106

1107

**Figure 3:** Dependence of the CO column uncertainty (Dobson Unit) on the surface albedo. Simulation settings are: solar zenith angle 53 degrees, viewing zenith angle 26 degrees, relative azimuth angle 0 degrees, cloud/surface pressure 1100 hPa.

1127 **Figure 4:** Left panel: S-5P CO averaging kernel values at the surface. Labels are longitude, degrees (x-axis)  
 1128 by latitude, degrees (y-axis). Right panel: Averaging kernels for land pixels with cloud fraction less than 10%  
 1129 (dashed red lines); for land pixels with cloud fraction greater than 30% (dashed yellow lines); and for sea  
 1130 pixels with cloud fraction greater than 80% (dashed blue lines). The averaging kernels are for an average of  
 1131 the data shown on the swath for 1 June 2003 at 12:34 UTC. Labels are averaging kernel, normalized (x-axis)  
 1132 by pressure level, hPa (y-axis).

1167 **Figure 6:** Self-consistency tests. Top panel: time-series (red line) of  $\chi^2$  for OmF and its associated auto-  
 1168 correlation signal (green line). For the  $\chi^2$  diagnostic, we normalize the OmF differences by the background  
 1169 error. The labels show time, days (x-axis) and  $\chi^2$  value (y-axis) for the  $\chi^2$  plot, and time gap, days (x-axis) and  
 1170 auto-correlation (y-axis) for the auto-correlation plot. Bottom panel: histograms of Observations minus  
 1171 Analysis (OmA -red solid line), Observations minus Forecast (OmF -blue solid line), and Observations  
 1172 minus Control run (OmC -black solid line). We normalize these differences by the observation error. The  
 1173 dashed lines correspond to the Gaussian fits of the different histograms. The labels show the OmA, OmF or  
 1174 OmC differences (x-axis) and the frequency of occurrence of the differences (y-axis). We calculate the  
 1175 diagnostics OmA, OmF, and OmC over the period of 1 June – 31 August 2003.

1193 **Figure 7:** S-5P CO analysis increments, units of ppbv, at 14:00 UTC on 15 June 2003: Top panel:  
1194 geographical distribution at the model surface. Red dashed lines show zonal and meridional vertical slices at  
1195 48°8 N, and 2°6 E, respectively. The black dashed line shows the S-5P cross-track at 13:12 UTC, clipped to  
1196 fit the OSSE simulation domain. Note that we measure the S-5P CO observations at 13:12 UTC. The labels  
1197 show longitude, degrees (x-axis) and latitude, degrees (y-axis). Left and right bottom panels show,  
1198 respectively, the longitude-height and latitude-height cross-sections at a location near Paris. The labels for  
1199 the bottom panels show longitude, degrees (x-axis, left panel), latitude, degrees (x-axis, right panel), and  
1200 pressure, hPa (y-axis, both panels). Green/purple colours indicate positive/negative values in the increment  
1201 fields.

1209 **Figure 8:** Distribution of CO surface concentrations, units of ppbv, averaged for the period 1 June – 31  
 1210 August 2003. Top left panel: the control run (CR) from MOCAGE; right top panel: the nature run (NR) from  
 1211 LOTOS-EUROS; bottom panel: the assimilation run (AR) from MOCAGE obtained after assimilating the S-  
 1212 5P CO total column simulated data sampled from the NR. In all panels, the labels show longitude, degrees  
 1213 (x-axis) and latitude, degrees (y-axis). Red/blue colours indicate relatively high/low values of the CO surface  
 1214 concentrations.

1255 **Figure 10:** Mean bias reduction at the surface for CO, units of ppbv: Left top panel shows the CR mean bias  
1256 with respect to the NR (CR-NR). Right top panel shows the AR mean bias with respect to the NR (AR-NR).  
1257 Bottom panel shows the mean bias magnitude reduction (absolute value of the mean bias for CR minus the  
1258 absolute value of the mean bias for AR). We average the data over northern summer 2003 (1 June – 31  
1259 August). The labels show longitude, degrees (x-axis) and latitude, degrees (y-axis). The hatched area in the  
1260 bottom panel shows where the mean bias plotted in this panel (MBMR) is not statistically significant at the  
1261 99% confidence level. The three squares in the bottom panel represent the locations for the three time-series  
1262 shown in Fig. 13. Red/blue colours indicate positive/negative values in the MB/MBMR.
