June 18, 2016

Dear Editor,

We appreciate the reviewers' suggestions which have considerably improved the manuscript (**acp-2015-939**). Enclosed are point-by-point responses to the reviewers. We hope that with these changes the manuscript will be suitable for publication in "**Atmospheric Chemistry and Physics**"

Thank you very much.

Sincerely,

Seung-Muk Yi

Professor, Dept. of Environmental Health, Graduate School of Public Health

Seoul National University, 1 Gwanak-ro, Gwanak-gu, Seoul 151-742, South Korea

Telephone: (82) 2-880-2736, Fax: (82) 2-762-9105, E-mail: yiseung@snu.ac.kr

● Status: Final Response

● Special Issue: Data collection, analysis and application of speciated atmospheric mercury

Response to Anonymous Referee #1:

General comments

This study analyzed seasonal and diurnal variations of TGM at a sampling site in southern Korea. Sources of TGM affecting the sampling site were investigated by correlating TGM with other pollutants and meteorological data and applying several source-receptor methods utilizing wind direction and back trajectory data. A newer method called the conditional bivariate probability function (CBPF) was used in this study to identify sources of TGM. However, I did not find this method very effective at differentiating between ground and stack emission sources. I find that there are many uncertainties in the CBPF results as well as in the back trajectory results that haven't been addressed in this paper. I have concerns about the methodology (insufficient TGM data, selection of trajectory duration) and interpretation of correlation analysis results. A discussion of how the results vary in the different seasons was also lacking in many places of the paper, even though the results are shown in the figures. Overall, I find that a major revision of this paper is necessary.

Response

Thank you for your comments. We believe we have addressed your concerns in the detailed responses below.

Specific comments

Comment 1

Line 57 – the correlation coefficient of r = -0.08 is very small. It's more accurate to state there is little correlation between TGM and air temperature

Response 1

As suggested, we have rephrased the sentence as follows on Line 56-57.

*"There was a **weak but** statistically significant negative correlation between the TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$)".*

Comment 2

Line 84 – “Atmospheric Hg released from natural and anthropogenic sources leading to enhanced deposition” Please clarify this statement.

Response 2

As suggested, we have rephrased the sentence as follows on Line 85-92.

“*Atmospheric Hg released from natural and anthropogenic sources when introduced into terrestrial and aquatic ecosystem through wet and dry deposition (Mason and Sheu, 2002) can undergo various physical and chemical transformations before being deposited. Its lifetime in the atmosphere depends on its reactivity and solubility so that depending on its form it can have impacts on local, regional and global scales (Lin and Pehkonen, 1999; Lindberg et al., 2007). A portion of the Hg deposited in terrestrial environments through direct industrial discharge or atmospheric deposition is transported to aquatic system through groundwater and surface water runoff (Miller et al., 2013).***”*

Comment 3

Lines 87-89 – Is this sentence about Hg emissions to the atmosphere and the biogeochemical cycling of Hg or the direct release of Hg from industrial effluent?

Response 3

We mean “the direct release of Hg from industrial effluent. In order to more clarify, we corrected “processes” to “**effluent**” on Line 93-95.

“A previous study also reported that Hg directly released into terrestrial and aquatic ecosystems from industrial ***effluent*** *has influenced surface water, sediment and biological tissue (Flanders et al., 2010).”*

Comment 4

Lines 94 – “coal combustion and waste incinerators” was already mentioned in this sentence.

Response 4

As suggested, we have rephrased the sentence as follows on Line 97-100.

“…*including municipal waste incinerators, medical waste incinerators, electric power*

generating facilities and cement kilns (Dvonch et al., 1998), ferrous and non-ferrous metal processing, iron and steel manufacturing facilities, and oil and coal combustion (Hoyer et al., 1995).”

Comment 5

Line 108 – use “data” instead of “information”

Response 5

As suggested, we corrected “information” to “data” as follows on Line 114.

“…combined with concentration **data** were used to identify…”

Comment 6

Line 138 – What temperature was the heated sampling line maintained at? Why is a heated sampling line necessary for sampling TGM?

Response 6

In this study, the sampling line was heated at about **50 ºC** using heat tape to prevent condensation in gold traps because moisture on gold surface interferes with the amalgamation of Hg.

In order to more clarify, we have rephrased the sentence as follows on Line 142-147.

“*Ambient air at a flow rate of 1.5 L min^{-1} was transported through a 3 m-long heated sampling line (1/4” OD Teflon) in to the analyzer. The sampling line was heated at about **50 ºC** using heat tape to prevent water condensation in the gold traps because moisture on gold surfaces interferes with the amalgamation of Hg (Keeler and Barres, 1999). Particulate matter was removed from the sampling line by a 47 mm Teflon filter.*”

Comment 7

2.3 QA/QC – the measurements were made for a one week period in each season. How often were the manual injections performed? Was there any maintenance activities performed prior to re-deployment of the instrument each time? These are important QA/QC procedures to mention because the instruments were offline for a long period of time.

Response 7

The reviewer is correct. In this study, manual injections were performed prior to every field

sampling campaign and we continuously operated Tekran 2537B to measure GEM concentrations in the ambient air.

In order to avoid any confusion, we have rephrased the sentence as follows on Line 159-160.

"*Manual injections were performed prior to every field sampling campaign to evaluate these automated calibrations using a saturated mercury vapor standard.*"

Comment 8

Line 168 – This definition of CPF doesn't seem right because it is not exactly the source contribution. You can replace this sentence with the one in line 177.

Response 8

The reviewer is correct. We have rephrased the sentence as follows on Line 171-173.

"*CPF estimates the probability that the measured concentration will exceed the threshold criterion for a given wind direction.*"

Comment 9

Lines 173-175 – were the wind data measured every 5 min similar to TGM or was it averaged to the nearest hour?

Response 9

In this study, **hourly** meteorological data (air temperature, relative humidity, and wind speed and direction) were obtained from the Automatic Weather Station (AWS) operated by the Korea Meteorological Administration (KMA) (http://www.kma.go.kr).

In order to clarify, we added "hourly" in the sentence as follows on Line 150-152.

"***Hourly*** *meteorological data (air temperature, relative humidity, and wind speed and direction) were obtained from the Automatic Weather Station (AWS) operated by the Korea Meteorological Administration (KMA) (http://www.kma.go.kr) (6 km from the site).*"

This information was also described in Table 2 as follows on Line 539-540.

"***Table 2***. *Summary of atmospheric concentrations of TGM and co-pollutants, and meteorological data. Note that TGM was measured every 5-min, and other pollutants and meteorological data were measured every 1-hour.*"

Comment 10

Lines 183-185 –How does this method account for the full distribution of concentrations rather than concentrations exceeding a threshold? Based on Eq. 2, CBPF analyzes the subset of concentrations above a threshold as well. Another thing is how does this method account for sources with different dispersion characteristics? The equation is based on horizontal wind speeds, which is advection rather than dispersion.

Response 10

The statement in question is incorrect since we used a criteria to determine which concentrations to include so we have deleted the sentence.

Comment 11

Lines 193-195 – This explanation is not clear. Can you give some examples of mercury sources with different wind speed dependencies?

Response 11

In order to more clarify, we rephrased the sentence as follows on Line 195-198.

"*The extension to the bivariate case can provide more information on the nature of the sources because different source types such as stack emission sources and ground-level sources can have different wind speed dependencies (prominent at low and high wind speed).*"

Comment 12

Lines 201-215 – this part needs to be rewritten by improving on the wording

Response 12

As suggested, we rephrased the sentence as follows on Line 204-218.

"*The PSCF is a simple method that links residence time in upwind areas with high concentrations through a conditional probability field and was originally developed by*

Ashbaugh et al. (1985).

$PSCF_{ij}$ is the conditional probability that an air parcel that passed through the ijth cell had a high concentration upon arrival at the monitoring site and is defined as the following Eq. (3).

$$PSCF_{ij} = \frac{m_{ij}}{n_{ij}} \quad (3)$$

where, n_{ij} is the number of trajectory segment endpoints that fall into the ij-th cell, and m_{ij} is the number of segment endpoints in the same grid cell (ij-th cell) when the concentrations are higher than a criterion value as measured at the sampling site.

High PSCF values in those grid cells are regarded as possible source locations. Cells including emission sources can be identified with conditional probabilities close to one if trajectories that have crossed the cells efficiently transport the released pollutant to the receptor site. Therefore, the PSCF model provides a tool to map the source potentials of geographical areas."

Comment 13

Line 220 –Please justify the use of 24 hr trajectories. TGM is mainly GEM which has a longer residence time and capable of long range transport. This means a longer trajectory duration would be more suitable.

Response 13

In this study, 24h backward trajectories starting at every hour at a height of 10, 50 and 100 m above ground level were computed using the vertical velocity model because we identified the diurnal variations in TGM concentrations are due to a combination of 1) reactions with an oxidizing atmosphere, 2) changes in ambient temperature and 3) local emissions related to industrial activities. This information was described in Line 428-430.

Previous studies reported that identified the long-range transport of mercury using the ΔTGM/ΔCO enhancement ratio (Choi et al., 2009; Jaffe et al., 2005; Kim et al., 2009; Weiss-Penzias et al., 2003; Weiss-Penzias et al., 2006). The observed ΔTGM/ΔCO was significantly lower than that of Asian long-range transport, but similar to that of local sources in Korea and in US industrial events suggesting that local sources are more important than that of long-range

transport in this study. This information was also described in Line 336-352.

Based on the above results, PSCF was performed to identify the local sources over grid cells corresponding to Gyeongsangbuk-do in eastern South Korea.

In addition, we did not find significant differences between TPSCF using 24 h and 48 h backward trajectories (Fig R1).

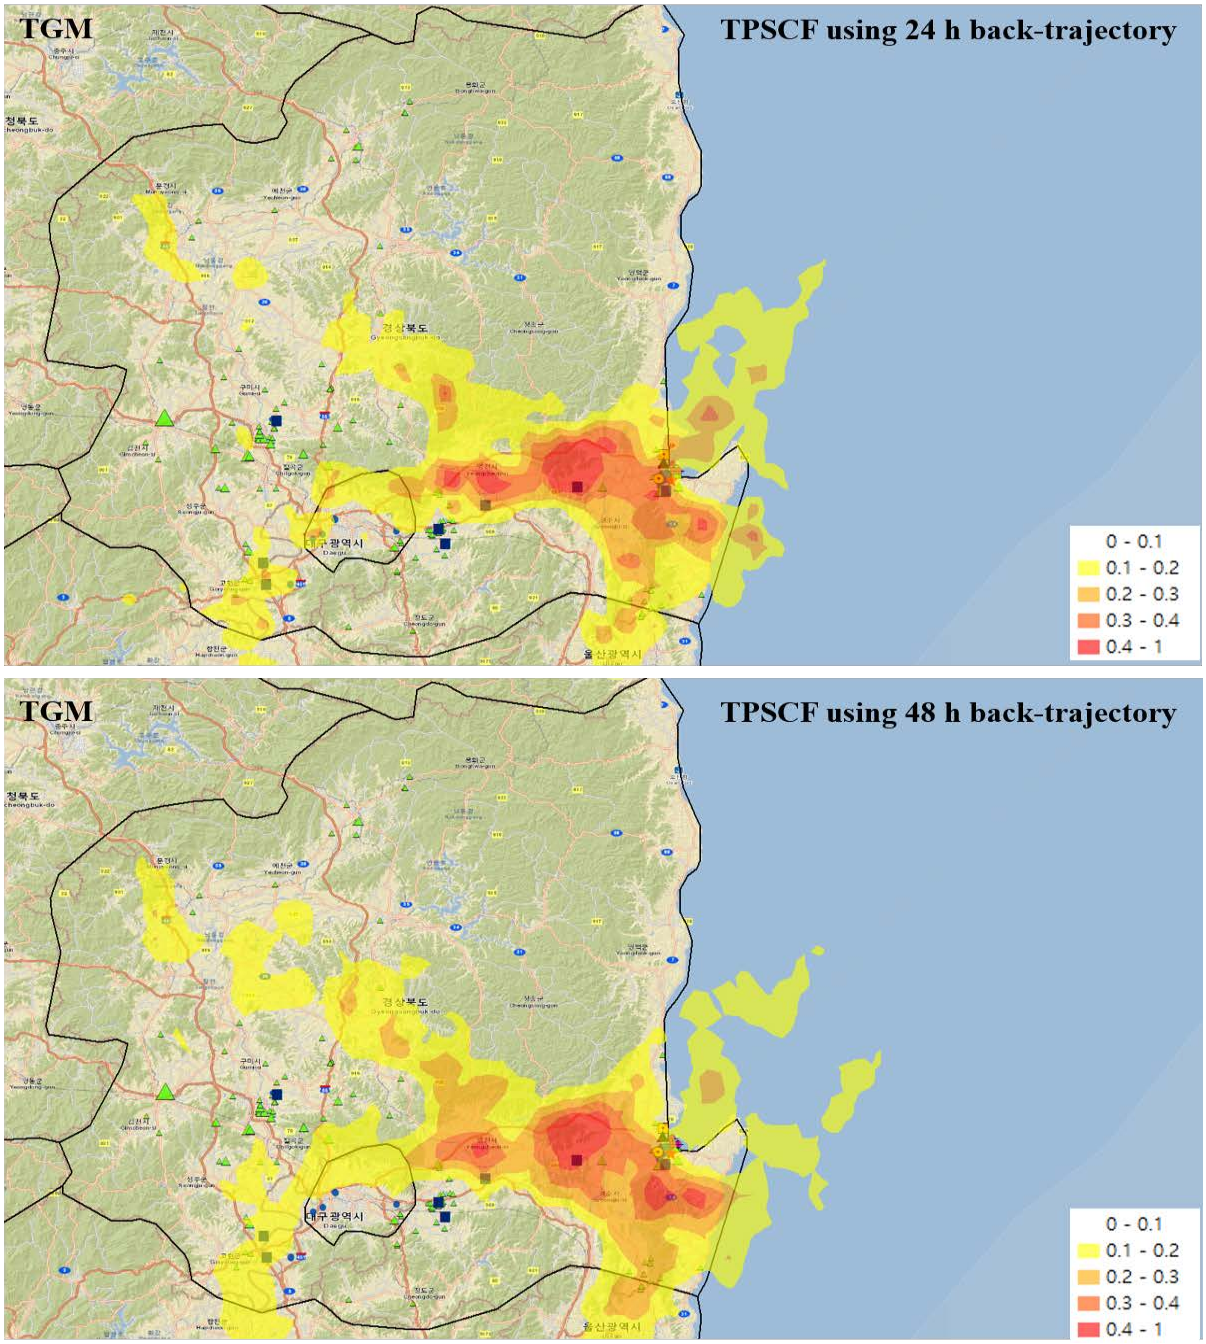

Fig. R1. Comparisons of TPSCF results using 24 h (top) and 48 h (bottom) backward trajectory.

In order to clarify, we have rephrased the sentence as follows on Line 223-227.

"As will be discussed in Section 5.4, 24 h backward trajectories starting at every hour at a height of 10, 50, and 100 m above ground level were computed using the vertical velocity model because local sources are more important than that of long-range transport in this study (It should be noted that PSCF results using 48 h backward trajectories had similar results as the 24 h backward trajectories)."

Comment 14

Line 229 – should be "meteorological data"

Response 14

As suggested, we corrected "meteorology data" to "**meteorological data**" as follows on Line 235.

*"PSCF was calculated with 9 km **meteorological data**"*

Comment 15

Lines 293-294 – This point was not discussed in later sections

Response 15

We have deleted the phrase "*As will be discussed later*" and rephrased as follows on Line 312-314.

"The high TGM concentrations in fall was due to different wind direction (see Fig. S2), sources, relationships with other pollutants and meteorological conditions. More detailed information can be found in Section 5.5."

Comment 16

Lines 299-302 – It should be stated more clearly that combustion was not a source of TGM because of a lack of correlation between TGM and the other combustion pollutant markers.

Response 16

As suggested, we have rephrased the sentence as follows on Line 319-321.

"*However, the TGM concentration was not significantly correlated with NO2, CO or SO2 concentrations, suggesting that combustion associated with space heating was not a significant source of TGM (Choi et al., 2009)*"

Comment 17

Lines 315 – Fig. S4 shows the CPF and CBPF plots in each season. Should this be discussed in section 5.5? It's not clear how these plots relate to the correlation results.

Response 17

In Section 5.3, we investigated the correlation between TGM and CO and found that local sources are more important than that of long-range transport by the observed ΔTGM/ΔCO. In order to avoid confusion, we have deleted Fig. S4 and rephrased the sentence as follows on Line 332 to Line 335.

"On the other hand, there were no statistically significant correlations between TGM and CO in spring (r = 0.02) (p = 0.78), in summer (r = 0.13) (p = 0.08), or in fall (r = -0.03) (p = 0.69), indicating that TGM and CO were affected by different anthropogenic emission sources in these seasons."

Comment 18

Lines 326-333 – It's surprising that long-range transport from China did not impact this site considering that it affected elevated Hg events in Seoul, Japan, and North America in previous studies. I would think long-range transport impacts a larger region including this sampling location. The TGM/CO slopes during elevated Hg events in Seoul were attributed to both long-range transport and local source impacts (Choi et al., 2009). Is it possible that the one-week sampling period in each season did not capture the long-range transport events? More data is needed to confirm these results. There are also uncertainties from the potential mixing between long-range transported airflows and local air making it difficult to distinguish between distant and local source impacts.

Response 18

We agree with the reviewer's comment. We also think it is possible that the one-week sampling period in each season did not capture the long-range transport events, and more data are needed

to confirm these results. Based on the previous studies (Kim et al., 2009; Choi et al., 2009), we analyzed the TGM data in an attempt to identify both long-range transport and local sources of TGM. Unfortunately, we did not find high concentration events which were defined as at least a 10 h period with hourly average TGM and CO concentrations higher than the average monthly TGM and CO concentrations and high values of TGM/CO ratio (ΔTGM/ΔCO) (0.0052-0.0158 ng m^{-3} ppb^{-1}) and high correlations (r^2>0.5) in this study. Therefore, the observed ΔTGM/ΔCO suggested that local sources are more important than that of long-range transport in this study. However, we believe more can be learned using the larger dataset than just using the one-week sampling period.

In order to any confusion, we added a following sentence on Line 353 to Line 357.

"There are also uncertainties from the potential mixing between Hg associated with long-range transported airflows and local air making it difficult to distinguish between distant and local source impacts. However, it is possible that the one-week sampling period in each season did not capture the long-range transport events, and more can be learned using a larger dataset than just using the one-week sampling period to confirm these results."

Comment 19

Lines 345-346 – what are the time periods for daytime and nighttime concentrations? This sentence states daytime TGM were higher during daytime than nighttime. But in the previous sentence, the minimum TGM concentration occurs in the afternoon.

Response 19

As suggested, we added the time periods for daytime and nighttime as follows on Line 361-363.

*"TGM, O_3, CO, SO_2, and temperature in the daytime **(06:00-18:00)** were statistically significantly higher than those in the nighttime **(18:00-06:00)** ($p < 0.05$) except PM_{10} ($p = 0.09$)…"*

In this study, the daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was statistically significantly higher than that in nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$). In order to avoid any confusion, we

corrected “maximum” to “**increase**” and “minimum” to “**decrease**” as follows on Line 365 to Line 366.

*“TGM generally showed a consistent diurnal variation with an **increase** in the early morning (06:00-09:00) and a **decrease** in the afternoon (14:00-17:00), similar to…”*

Comment 20

Lines 353-355 – You discussed about the land-sea/lake breeze effect on TGM diel patterns from another study in the previous sentence. Does this atmospheric process affect this particular site since it is near the ocean and lower TGM were also observed during daytime?

Response 20

It is possible that the land-sea breeze might affect diurnal variations in TGM concentrations since the sampling site was near the ocean and lower TGM concentrations were observed during the daytime in this study. However, there are several known Hg sources such as iron and steel manufacturing facilities including electric and sintering furnaces using coking around the sampling site.

Although the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) ($p < 0.05$), the daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was statistically significantly higher than those in the nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$). This is possibly due to a combination of 1) reactions with an oxidizing atmosphere, 2) changes in ambient temperature and 3) local emissions related to industrial activities. To supplement these conclusions CPF and CBPF were used to identify source directions and TPSCF was used to identify potential source locations in “Section *5.6 CPF, CBPF and TPSCF results of TGM”*.

In order to clarify, we rephrased the sentence as follows on Line 382 to Line 390.

"Although it is possible that the land-sea breeze may affect diurnal variations in TGM concentrations since the sampling site was near the ocean and lower TGM were also observed during the daytime, the higher concentrations in the daytime than those in nighttime were due to local emission sources because the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) (t-test, $p < 0.05$) and there was a weak but statistically significant negative correlation between TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$). In addition, there are several known Hg sources such as iron and steel manufacturing facilities including electric and sintering furnaces using coking between the sampling site and the ocean."

Comment 21

Lines 355-356 – The negative correlation between TGM and temperature is very small (as mentioned in the abstract, r = -0.08) despite a significant p-value. It's more accurate to state there is little relationship between TGM and air temperature.

Response 21

As suggested, we have rephrased the sentence as follows on Line 386-388.

"… and there was a weak but statistically significant negative correlation between the TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$)".

Comment 22

Lines 357-360 – Similar to the above comment, the correlation between TGM and O3 is too small (r = -0.18) to suggest that it is indicative of GEM oxidation. It's more correct to state there is little relationship between TGM and O3. If GEM oxidation occurred, GOM concentrations would increase. There are some uncertainties on the net effect on TGM (GEM+GOM).

Response 22

As suggested, we have rephrased the sentence as follows on Line 391-399.

"…there was a weak but negative relationship between the TGM concentrations and O3

concentrations (r = -0.18) (p < 0.01), suggesting that oxidation of GEM in the oxidizing atmosphere during periods of strong atmospheric mixing was partially responsible for the diurnal variations of TGM concentrations. In addition, oxidation of GEM by bromine species in the coastal area (Obrist et al., 2011) or by chloride radicals in marine boundary layer (Laurier et al., 2003) might play a significant role. If oxidation of GEM occurred, GOM concentrations would increase. However there are uncertainties on the net effects on TGM (the sum of the GEM and the GOM) since we did not measure GOM concentrations."

Comment 23

Lines 369-378 – The results here are inconsistent. If the small negative correlation between TGM and temperature indicates an increase in mixing height which leads to a decrease in TGM, how can it explain surface emissions in the morning which should increase with temperature? Is there a positive correlation between TGM and temperature in the morning?

Response 23

As suggested, we analyzed a relationship between TGM and temperature in the morning (06:00-09:00) and found that there is a positive correlation between TGM and ambient air temperature. In order to clarify, we added a following sentence on Line 414-418.

"Nonparametric correlations revealed that there is a positive correlation between TGM and ambient air temperature (r_s = 0.11, p=0.27) between 06:00-09:00. The TGM concentration was negatively correlated with O_3 (r_s = -0.33, p<0.01) but positively correlated with NO_2 (r_s = 0.21, p<0.05), suggesting that the increased traffic is the main source of TGM during these time periods."

Comment 24

Section 5.4 – This section is lacking discussion on seasonal differences in the diurnal variation. The fall diurnal pattern appears very different from those in other seasons in Fig. 3. Can you discuss why the TGM were much higher overnight in the fall but daytime concentrations were similar to those in other seasons? Why was there a large drop in TGM from 4:00 to 5:00 in the fall?

Response 24

As suggested, we described more detailed information on Line 419-427 as follows.

"Compared to other seasons, significantly different diurnal variations of TGM were observed in fall. The daytime TGM concentrations in fall were similar to those in other seasons, however, the nighttime TGM concentrations in fall were much higher than other seasons. As described earlier in Section 5.3, the high TGM concentrations in fall was possibly due to the relationship between other pollutants and meteorological conditions as well as different wind direction and sources. The nighttime TGM concentrations in fall were simultaneously positively correlated with PM_{10} ($r=0.26$) ($p<0.05$) and CO ($r=0.21$) ($p<0.05$) concentrations and wind speed ($r=0.35$) ($p<0.01$), suggesting that the combustion process is an important source during this period."

We could not identify the reason why there was a large drop in TGM from 4:00 to 5:00 in the fall because there were a limited amount of data. However, we believe more can be learned using a larger dataset.

Comment 25

Lines 381-383 – These conclusions are not well-supported by the correlation analyses because the correlation coefficients were very small.

Response 25

As suggested, we rephrased the "Section 5.5 *Diurnal variations"* on Line 359-432.

Comment 26

Line 390 – What are the potential Hg sources from the northeast direction?

Response 26

The potential Hg sources from the northeast direction is due to lots of domestic passenger ships routes. In response to this comment, we have rephrased the sentence as follows on Line 475-477.

"The northeast direction including the East Sea was also identified as potential source areas likely because this is an area with lots of domestic passenger ships routes."

Comment 27

Lines 391-393 – Please clarify this sentence. Are the higher wind speeds associated with stack emissions and lower wind speeds associated with surface emissions? There are several issues or uncertainties with this point. (1) Wind speeds were only measured at one height. How can you tell that the lower wind speeds are from lower elevation and vice-versa? What is the height of the wind measurements? (2) As mentioned in the diurnal variation section, boundary layer mixing occurs during the day. Is it possible to distinguish between ground emissions and stack emissions? (3) It seems only the west directions had both high and low wind speeds, while the east directions had only lower wind speeds (Fig. S1). Thus, CBPF doesn't seem useful when there is a lack of wind speed variation. It appears that it is by coincidence that both ground level and stack emissions were identified in the west direction because there happened to be a wind speed variation from this direction. Based on these points, the CBPF results don't seem to reveal more about TGM sources than CPF. More discussion is needed on the relationship between specific sources and wind speeds. Instead of wind speed, what other variables would be useful for source identification using CBPF?

Response 27

In this study, hourly meteorological data (air temperature, relative humidity, and wind speed and direction) were obtained from the Automatic Weather Station (AWS) operated by the Korea Meteorological Administration (KMA) (http://www.kma.go.kr). This information was described on Line 150-152. We used the wind data measured at a reference height of 10 m.

Although there is a lack of wind speed variation, we found that the CBPF revealed more about TGM sources than CPF (Fig. S6).

The third variable plotted on the radial axis does not need to be wind speed. A previous study reported that temperature can be a useful radial variable (Carslaw, D.C., Beevers, S.D., 2013. Characterising and understanding emission sources using bivariate polar plots and k-means clustering. Environ. Model. Softw. 40 (0), 325-329).

In order to response to this comment, we rephrased the sentence on Line 195-198 and Line 433-450 as follows.

< Line 195-198>

"The extension to the bivariate case can provide more information on the nature of the sources

because different source types such as stack emission sources and ground-level sources can have different wind speed dependencies (prominent at low and high wind speed).”

< Line 439-456>

“CBPF shows that the high probabilities from the west occurred under high wind speed (> 3 m s^{-1}) indicative of emissions from stacks as well as low wind speed (≤3 m s^{-1}) indicative of non-buoyant ground level sources.

As described in Section 5.4, correlations between TGM and CO revealed that TGM and CO were affected by similar anthropogenic emission sources in winter but affected by different sources in spring, summer and fall, which is supported by Fig. S6 which shows significantly different seasonal patterns of CPF and CBPF for TGM concentrations.

It is difficult to discuss about the different seasonal patterns for CPF and CBPF for TGM concentrations since there were no correlations between TGM and other pollutants in spring, summer and fall except O_3. However, compared to Fig. 4, the CPF and CBPF patterns in fall were similar to those during the whole sampling periods. Especially, the nighttime TGM concentration in fall was simultaneously positively correlated with PM_{10} ($r=0.26$) ($p<0.05$) and CO ($r=0.21$) ($p<0.05$) concentrations and wind speed ($r=0.35$) ($p<0.01$), indicating that the combustion process from the west is an important source during this period.

Since TGM showed a significant correlation with CO ($r=0.25$) ($p<0.05$) and showed a weak positive correlation with PM_{10} ($r=0.08$) ($p=0.33$) in winter with high wind speed, combustion sources from the west are likely partially responsible for this result.”

Comment 28

Lines 394-395 – Are there industrial sources south of the sampling site? High probability areas are also identified in this direction in the TPSCF plot in Fig. 4.

Response 28

There is Ulsan Metropolitan City located to the south from the sampling site. Ulsan is South

Korea's seventh largest metropolis with a population of over 1.1 million and it has more than 700 small and large industrial facilities including petrochemical plants, oil refineries, vehicle and ship factories, and other chemical plants.

In response to this comment, we have added a following sentence on Line 477 to Line 480.

"The south from the sampling was also identified as a likely source area of TGM where Ulsan Metropolitan City, South Korea's seventh largest metropolis with a population of over 1.1 million is located. It includes a large petrochemical complex known as a TGM source (Jen et al., 2013)."

Comment 29

Fig. 4 – the source areas seem confined to the industrial complex near the sampling site because of the short trajectory duration (24 hrs). Use of longer trajectories would help expand the source region and identify potential regional transport to the site. In addition to this uncertainty, other PSCF uncertainties should be discussed.

Response 29

As mentioned earlier in **Response 13**, local sources are more important than that of long-range transport in this study. Therefore PSCF was performed to identify the local sources over grid cells corresponding to Gyeongsangbuk-do in eastern South Korea.

In addition, we did not find significant differences between PSCF using 24 h and 48 h backward trajectories (Fig. R1 in **Response 13**).

In response to this comment, we added a following sentence on Line 240-245.

"Previous studies suggest that there are increasing uncertainties as backward trajectory distances increase (Stohl, et al., 2002) and that PSCF modeling is prone to the trailing effect is which locations upwind of sources are also identified as potential sources (Han, et al., 2004). An alternative to back trajectory calculations in the interpretation of atmospheric trace substance measurements (Stohl, et al., 2002) although this technique does not provide much information on source locations"

Comment 30

Section 5.5 – This section is lacking discussion on the CPF and CBPF results in different seasons. The seasonal plots are shown in Fig. S4, but they are not discussed in this section.

Response 30

In order to response to this comment, we added the sentence as follows on Line 443-456.

"*As described in Section 5.4, correlations between TGM and CO revealed that TGM and CO were affected by similar anthropogenic emission sources in winter but affected by different sources in spring, summer and fall, which is supported by Fig. S6 which shows significantly different seasonal patterns for CPF and CBPF for TGM concentrations. It is difficult to interpret differences in the seasonal patterns of CPF and CBPF results for TGM concentrations since there were no correlations between TGM and other pollutants in spring, summer and fall except* O_3*. However, compared to Fig. 4, the CPF and CBPF patterns in fall were similar to those during the complete sampling period. The nighttime TGM concentration in fall was simultaneously positively correlated with* PM_{10} *(*$r=0.26$*) (*$p<0.05$*) and CO (*$r=0.21$*) (*$p<0.05$*) concentrations and wind speed (*$r=0.35$*) (*$p<0.01$*), indicating that the combustion process from the west is an important source during this period. Since TGM showed a significant correlation with CO (*$r=0.25$*) (*$p<0.05$*) and showed a weak positive correlation with* PM_{10} *(*$r=0.08$*) (*$p=0.33$*) in winter with high wind speed, combustion sources from the west are likely partially responsible for this result."*

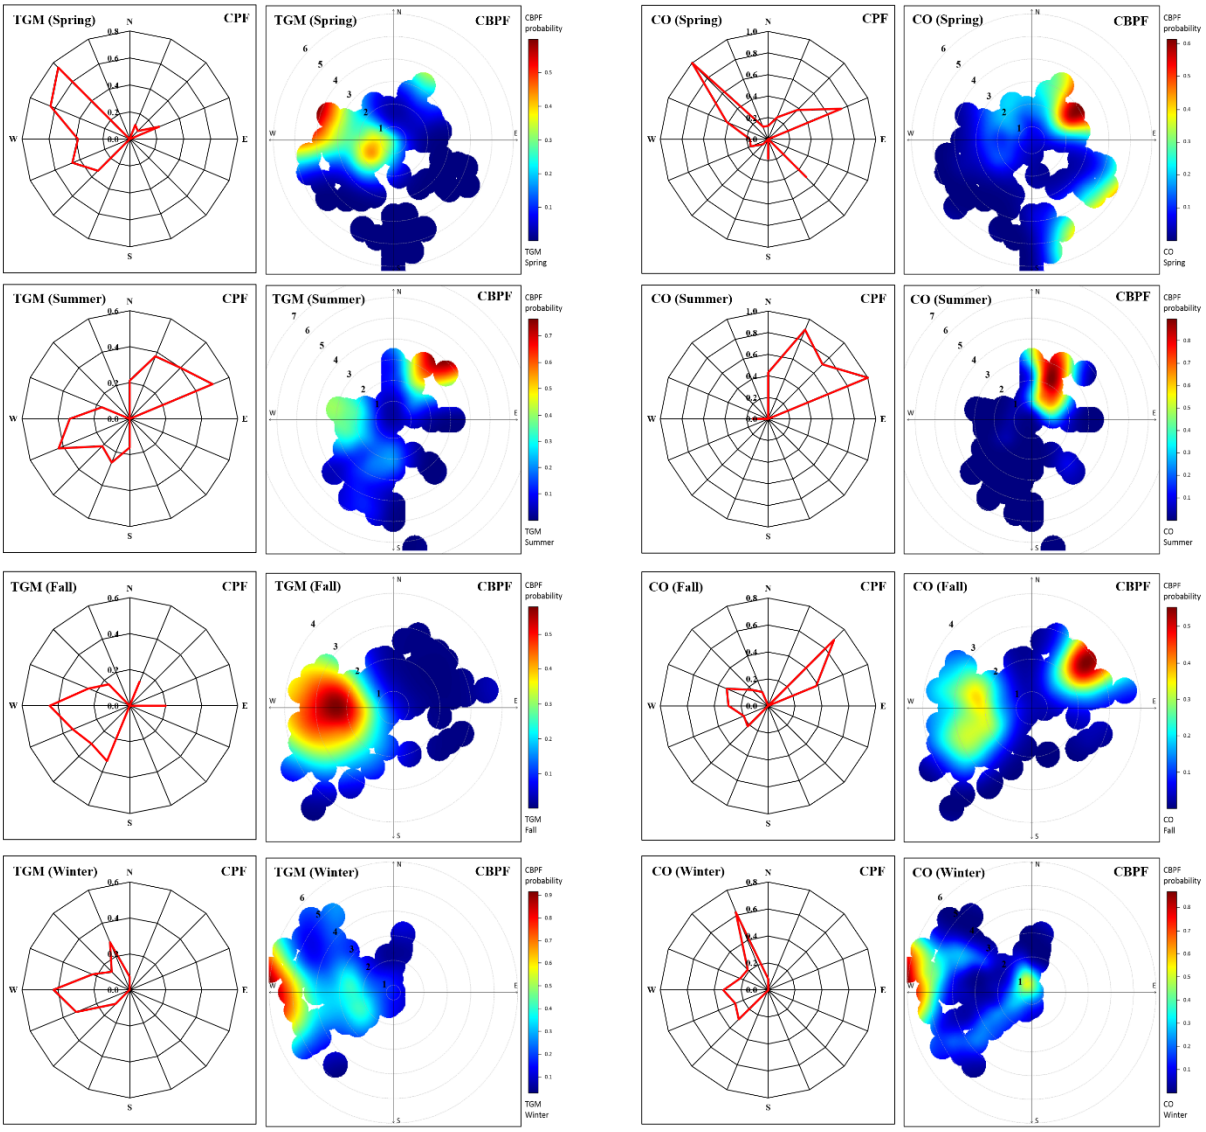

Fig. S6. Comparisons of CPF and CBPF plots for TGM and CO higher than average concentration. The radial axes of CPF and CBPF are the probability and the wind speed (m s^{-1}), respectively.

Comment 31

Lines 421-423 – This conclusion was not discussed in the results section. The wind direction frequency plots in different seasons are shown in Fig. S1 but the results were not discussed in the paper.

Response 31

As suggested, we rephrased the sentence on Line 419-427 as follows.

Comment 32

Lines 427-430 – p-value was significant but the correlation coefficient (magnitude of the relationship) is too small. I also don't understand the logic in these results. There should be a positive TGM and temperature correlation if daytime TGM concentrations were related to surface emissions.

Response 32

In response to this comment, we have rephrased the sentence on Line 369-377 and Line 382-390 as follows.

< Line 369-377>

"The daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was higher than that in nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$), which was similar to several previous studies (Cheng et al., 2014; Gabriel et al., 2005; Nakagawa, 1995; Stamenkovic et al., 2007) but different than other study (Lee et al., 1998). Previous studies reported that this is due to local sources which is close to the sampling site (Cheng et al., 2014; Gabriel et al., 2005), positive correlation between TGM concentration and ambient air temperature (Nakagawa, 1995) and increased traffic (Stamenkovic et al., 2007). However, other study suggested that the higher TGM concentration than that in daytime was due to the shallow boundary layer in nighttime, resulting in concentrating the TGM near the surface (Lee et al., 1998)."

< Line 382-390>

"*Although it is possible that the land-sea breeze may affect diurnal variations in TGM concentrations since the sampling site was near the ocean and lower TGM were also observed during the daytime, the higher concentrations in the daytime than those in nighttime were due to local emission sources because the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) (t-test, $p < 0.05$) and there was a weak but statistically significant negative correlation between TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$). In addition, there are several known Hg sources such as iron and steel manufacturing facilities including electric and sintering furnaces using coking around the sampling site.*"

Comment 33

Line 434 – JP-PSCF was not used anywhere else in the paper. Did you mean TPSCF?

Response 33

The reviewer is correct. As suggested, we corrected “JP-PSCF” to “TPSCF” as follows on Line 503.

“However, CBPF and TPSCF indicated that…”

Response to Anonymous Referee #2:

General comments

This study measured TGM concentrations in South Korea and analyzed seasonal and diurnal variations of TGM. They also used the statistics analysis to correlate TGM with other pollutants and meteorological data. They tried to identify the possible TGM sources using CPF, CBPF, and TPSCF models. They found that the nearby local sources are more significant than others. Over all, this paper meets the original contributions and contains unique TGM data nearby industrial areas. The authors performed the appropriate modeling approaches to identify possible mercury sources. However, the presentation quality doesn't meet the ACP's requirement. I suggest that the paper should be carefully revised and edited prior to publication on ACP.

Comment

Response

Thank you for your comments. We carefully revised and edited that paper as suggested as is detailed in our responses to the specific comments.

Specific comments

Introduction section contains too basic and out of dated information. I suggest adding some recent mercury inventory/modeling studies in East Asia. Result and discussion contains unnecessarily much literature review. More discussions are needed. The author used statistics analysis in many places. Please provide the type of analysis in this paper.

Comment 1

Line 118 – 133: it should be combined into one paragraph.

Response 1

As suggested, the sentence was combined into one paragraph as follows on Line 125-138.

Comment 2

Line 133: So what are their results in Kim et al. 2010? What did they find?

Response 2

This meant that we got and used the Hg emissions data from the authors (Kim et al., 2010) about iron and steel manufacturing, and a hazardous waste incinerator.

In order to clarify, we have revised the sentence as follows on Line 137 to Line 138.

*"Hg emissions **data** from iron and steel manufacturing, and a hazardous waste incinerator were estimated **based on** a previous study (Kim et al., 2010)"*

Their results in Kim et al. (2010) were described in Line 104-109.

Comment 3

Line 146-151: it doesn't fit in material & method section. Please move to results & discussion section.

Response 3

As suggested, we moved that sentence to "5. Results and Discussions" on Line 281-286 as follows.

"5.1. Meteorological data analysis

Fig. S2 shows the frequency of counts of measured wind direction occurrence by season during the sampling period. The predominant wind direction at the sampling site was W (20.9%) and WS (19.2%), and calm conditions of wind speed less than 1 m s^{-1} occurred 7.6% of the time. Compared to other seasons, however, the prevailing winds in summer were N (17.0%), NE (16.4%), S (16.4%), and SW (15.8%)."

Comment 4

Line 156-157: need to explain how often manual injections were conducted.

Response 4

Manual injections were performed prior to every field sampling campaign and we continuously operated Tekran 2537B to measure GEM concentrations in the ambient air.

In order to avoid any confusion, we have rephrased the sentence as follows on Line 159 to Line

160.

"*Manual injections were performed prior to every field sampling campaign to evaluate these automated calibrations using a saturated mercury vapor standard.*"

Comment 5

Line 164: already used CPF in Line 163. Replace "Conditional Probability Function (CPF)" with "CPF"

Response 5

As suggested, "Conditional Probability Function (CPF)" was replaced with CPF on Line 168.

Comment 6

Line 220 – 222 and line 230 – 233 are same.

Response 6

The sentence on Line 220-222 means that we computed 24hr backward trajectories starting at every hour at a height of 10, 50, and 100 m above ground level.

The sentence on Line 230-233 means that TPSCF which incorporates probability from **above different starting heights (10, 50, and 100 m above ground level)** was calculated.

In order to more clarify, we rephrased the sentence as follows on Line 236-237.

"*In this study, TPSCF which incorporates probability from above different starting heights was calculated…*"

Comment 7

Line 237: what is n_{ij} values here?

Response 7

n_{ij} is the number of trajectory segment endpoints that fall into the *ij*-th cell. This information was described in the sentence on Line 212.

In order to clarify, we added "the number of trajectory segment endpoints that fall into the *ij*-th cell" to the sentence on Line 249 as follows.

"To minimize the effect of small n_{ij} (the number of trajectory segment endpoints that fall into the ij-th cell) values, resulting in high TPSCF values …."

Comment 8

Line 272-275: Can the author provide recent TGM data from China and other country?

Response 8

As suggested, we added recent TGM data from China and other countries in Table 1 on Line 537 and rephrased the sentence on Line 293-294.

"…and those measured in China, in Japan and other locations in Korea, however considerably lower than those measured near large Hg sources in Guangzhou, China (Table 1)."

Comment 9

Line 285 and later: if the author mentioned p-value ($p < 0.01$ or $p < 0.05$), "statistically significantly" does not have to be addressed every time. Readers already know that the author performed statistical analysis.

Response 9

After Line 285, we deleted the phrase "statistically significantly" as suggested (after Line 304).

Comment 10

Line 293: "as will be discussed later: : :." Can you indicate where and which section it was discussed?

Response 10

We have deleted the phrase "*As will be discussed later*" as follows on Line 312.

"The high TGM concentrations in fall was due to …"

Comment 11

This 5.4 section is for result and discussion. It includes too much literature review rather than

discussion.

Response 11

As suggested, we rephrased the 5.4 section as following Section "*5.5. Diurnal variations*" on Line 359-432.

Comment 12

Line 346 – 348: can you explain what previous studies concluded about these diurnal variations? Needs more discussion.

Response 12

As suggested, we rephrased the sentence on Line 369-377 as follows.

"The daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was higher than that in the nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$), which was similar to several previous studies (Cheng et al., 2014; Gabriel et al., 2005; Nakagawa, 1995; Stamenkovic et al., 2007) but different than another studies (Lee et al., 1998). Previous studies reported that this different is due to local sources close to the sampling site (Cheng et al., 2014; Gabriel et al., 2005), a positive correlation between TGM concentration and ambient air temperature (Nakagawa, 1995) and increased traffic (Stamenkovic et al., 2007). However, another study suggested that the higher TGM concentration during the night was due to the shallowing of the boundary layer, which concentrated the TGM near the surface (Lee et al., 1998)"

Comment 13

Line 353: "as will be discussed later…" Indicate where and which section it was discussed? What is "this" mean here? Does "this" mean lower TGM in daytime?

Response 13

In order to clarify, we have rephrased the sentence on Line 382-390 as follows.

"*Although it is possible that the land-sea breeze may affect diurnal variations in TGM concentrations since the sampling site was near the ocean and lower TGM were also observed during the daytime, the higher concentrations in the daytime than those in nighttime were due to local emission sources because the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) (t-test, $p < 0.05$) and there was a*

weak but statistically significant negative correlation between TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$). In addition, there are several known Hg sources such as iron and steel manufacturing facilities including electric and sintering furnaces using coking between the sampling site and the ocean."

Comment 14

Line 355 – 356 and line 369 – 370 are same. Please rephrase or rewrite.

Response 14

As suggest, we rephrased the sentence as follows on Line 406-407.

"TGM concentration was negatively correlated with ambient air temperature ($r = -0.08$) ($p <$ 0.05) *because high ambient air temperature…"*

Comment 15

Line 369 – 378: this paragraph is vague. Please clarify.

Response 15

In response to this comment, we added a following sentence as follows on Line 414-418.

"*Nonparametric correlations revealed that there is a positive correlation between TGM and ambient air temperature ($r_s = 0.11$, $p=0.27$) between 06:00-09:00. The TGM concentration was negatively correlated with O_3 ($r_s = -0.33$, $p<0.01$) but positively correlated with NO_2 ($r_s = 0.21$, $p<0.05$), suggesting that the increased traffic is the main source of TGM during these time periods.*"

Comment 16

This 5.5 section also has too much literature review rather than discussion.

Response 16

As suggested, we rephrased the Section 5.5 as follows on Line 434-480 (see the Section *5.6. CPF, CBPF and TPSCF results of TGM)*

Comment 17

Line 381 – 385: this paragraph is the result from the Section 5.4. Please move it to Section 5.4.

Response 17

As suggested, we moved the paragraph to Line 428 to Line 432.

Comment 18

Line 388 – 389: is this the only result from CPF model? Please explain the reason to adopt this model?

Response 18

We showed the CBPF result as well as CPF result. This information was described in the sentence on Line 439 to Line 442 as follows.

"…CBPF shows that the high probabilities from the west occurred under high wind speed (> 3 m s^{-1}) indicative of emissions from stacks as well as low wind speed (≤ 3 m s^{-1}) indicative of non-buoyant ground level sources (Uria-Tellaetxe and Carslaw, 2014)."

Comment 19

Line 391-393: Needs more detail explanations to clarify.

Response 19

In order to clarify, we rephrased the sentence on Line 439 to Line 442 as follows.

"CBPF shows that the high probabilities from the west occurred under high wind speed ***(> 3 m s^{-1})*** *indicative of emissions from stacks as well as low wind speed* ***(≤ 3 m s^{-1})*** *indicative of non-buoyant ground level sources (Uria-Tellaetxe and Carslaw, 2014)."*

Comment 20

Line 434: is it "TPSCF"?

Response 20

The reviewer is correct. As suggested, we corrected "JP-PSCF" to "TPSCF".

Comment 21

Line 434 – 436: the author mentioned that CPF only can provide high probabilities from the west of the site. Please delete the CPF in this sentence.

Response 21

In order to response to this comment, we rephrased the sentence as follows on Line 501-506.

"CPF only shows high probabilities to the west from the sampling site where there are large steel manufacturing facilities and waste incinerators. However, CBPF and TPSCF indicated that the dominant sources of TGM were the hazardous waste incinerators and the coastal areas in the northeast as well as the iron and manufacturing facilities in the west."

Comment 22

Line 436 – 437: same sentence as Line 412 – 413. Please rephrase or rewrite.

Response 22

As suggested, we rephrased the sentence on Line 436-437 as a following sentence on Line 505 to 506.

"The domestic passenger ships routes in the East Sea were also identified as possible source areas."

Characteristics of total gaseous mercury (TGM) concentrations in an industrial complex in southern Korea: Impacts from local sources

Abstract

Total gaseous mercury (TGM) concentrations were measured every 5 min in Pohang, Gyeongsangbuk-do, Korea during summer (17 August~23 August 2012), fall (9 October~17 October 2012), winter (22 January ~29 January 2013), and spring (26 March~3 April 2013) to: 1) characterize the hourly and seasonal variations of atmospheric TGM concentrations, 2) identify the relationships between TGM and co-pollutants, and 3) identify likely source directions and locations of TGM using conditional probability function (CPF), conditional bivariate probability function (CBPF) and total potential source contribution function (TPSCF).

The TGM concentration was statistically significantly highest in fall (6.7 ± 6.4 ng m^{-3}), followed by spring (4.8 ± 4.0 ng m^{-3}), winter (4.5 ± 3.2 ng m^{-3}) and summer (3.8 ± 3.9 ng m^{-3}). There was a weak but statistically significant negative correlation between the TGM concentration and ambient air temperature *($r = -0.08$) ($p < 0.05$)*. Although the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) ($p < 0.05$), the daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was statistically significantly higher than those in the nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$), possibly due to local emissions related to industrial activities and activation of local surface emission sources. The observed ΔTGM/ΔCO was significantly lower than that of Asian long-range transport, but similar to that of local sources in Korea and in US industrial events suggesting that local sources are more important than that of long-range transport. CPF, CBPF and TPSCF indicated that the main sources of TGM were iron and manufacturing facilities, the hazardous waste incinerators and the coastal areas.

Keywords: Total gaseous mercury (TGM); co-pollutant; conditional probability function (CPF); conditional bivariate probability function (CBPF); total potential source contribution function (TPSCF)

1. Introduction

Mercury (Hg) in the atmosphere exists in three major inorganic forms including gaseous elemental mercury (GEM, Hg^0), gaseous oxidized mercury (GOM, Hg^{2+}) and particulate bound mercury (PBM, Hg(p)). GEM which is the dominant form of Hg in ambient air, (>95%) has a relatively long residence time (0.5~2 years) due to its low reactivity and solubility Schroeder and Munthe (1998). However, GOM has high water solubility and relatively strong surface adhesion properties (Han et al., 2005), so it has a short atmospheric residence time (~days). PBM is associated with airborne particles such as dust, soot, sea-salt aerosols, and ice crystals (Lu and Schroeder, 2004) and is likely produced, in part, by adsorption of GOM species such as $HgCl_2$ onto atmospheric particles (Gauchard et al., 2005; Lu and Schroeder, 2004; Sakata and Marumoto, 2005; Seo et al., 2015).

Atmospheric Hg is emitted from both natural sources (volcanoes, volatilization from aquatic and terrestrial environments) and anthropogenic sources (coal combustion, ferrous and non-ferrous metals manufacturing facilities, waste incineration and industrial boilers) (Lindberg et al., 2007; Pirrone et al., 2010; Schmeltz et al., 2011).

Atmospheric Hg released from natural and anthropogenic sources when introduced into terrestrial and aquatic ecosystem through wet and dry deposition (Mason and Sheu, 2002) can undergo various physical and chemical transformations before being deposited. Its lifetime in the atmosphere depends on its reactivity and solubility so that depending on its form it can have impacts on local, regional and global scales (Lin and Pehkonen, 1999; Lindberg et al., 2007). A portion of the Hg deposited in terrestrial environments through direct industrial discharge or atmospheric deposition is transported to aquatic system through groundwater and surface water runoff (Miller et al., 2013).

A previous study also reported that Hg directly released into terrestrial and aquatic ecosystems from industrial effluent has influenced surface water, sediment and biological tissue (Flanders et al., 2010).

Significant spatial variations in atmospheric Hg deposition near urban and industrial areas were due to local anthropogenic sources including municipal waste incinerators, medical waste incinerators, electric power generating facilities and cement kilns (Dvonch et al., 1998), ferrous and non-ferrous metal processing, iron and steel manufacturing facilities, and oil and coal combustion (Hoyer et al., 1995). Miller et al. (2013) also reported that local sources of elemental Hg are typically industrial processes including retort facilities used in the mercury mining industry to convert Hg containing minerals to elemental Hg and chlor-alkali facilities.

Annual anthropogenic Hg emissions in South Korea have been estimated to be 12.8 tons; the major anthropogenic mercury emission sources are coal combustion in thermal power plants (25.8%), oil refineries (25.5%), cement kilns (21%), incinerators (19.3%) including sludge incinerators (4.7%), municipal waste incinerators (MWIs) (3%), industrial waste incinerators (IWIs) (2.7%), hospital/medical/infectious waste incinerators (HMIWIs) (8.8%), and iron manufacturing (7%) (Kim et al., 2010).

Receptor models are often used to identify sources of air pollutants and are focused on the pollutants behavior in the ambient environment at the point of impact (Hopke, 2003). In previous studies, conditional probability function (CPF), which utilizes the local wind direction, and potential source contribution function (PSCF), which utilizes longer backward trajectories (typically 3-5 days), combined with concentration data were used to identify possible transport pathways and source locations (Hopke, 2003). While PSCF has been used

primarily to identify regional sources, it has also been used to identify local sources (Hsu et al., 2003). The objectives of this study were to characterize the hourly and seasonal variations of atmospheric TGM (the sum of the GEM and the GOM) concentrations, to identify the relationships between TGM and co-pollutant concentrations, and to identify likely source directions and locations of TGM using CPF, conditional bivariate probability function (CBPF) and total PSCF (TPSCF).

2. Materials and methods

2.1. Sampling and analysis

TGM concentrations were measured on the roof of the Korean Federation of Community Credit Cooperatives (KFCCC) building (latitude: 35.992°, longitude: 129.404°, ~10 m above ground) in Pohang city, in Gyeongsangbuk-do, a province in eastern South Korea. Gyeongsangbuk-do has a population of 2.7 million (5% of the total population and the third most populated province in South Korea) and an area of 19,030 km^2 (19% of the total area of South Korea and the largest province geographically in South Korea). Pohang city has a population of 500,000 (1% of the total population in South Korea) and an area of 605.4 km^2 (1.1% of the total area in South Korea). It is heavily industrialized with the third largest steel manufacturing facility in Asia and the fifth largest in the world. There are several iron and steel manufacturing facilities including electric and sintering furnaces using coking in Gyeongsangbuk-do including Pohang. In addition, there are several coke plants around the sampling site. The Hyungsan River divides the city into a residential area and the steel complex. Hg emissions data from iron and steel manufacturing, and a hazardous waste incinerator were estimated based on a previous study (Kim et al., 2010) (Fig. 1).

TGM concentrations were measured every 5 min during summer (17 August~23 August 2012), fall (9 October~17 October 2012), winter (22 January ~29 January 2013), and spring (26 March~3 April 2013) using a mercury vapor analyzer (Tekran 2537B) which has two gold cartridges that alternately collect and thermally desorb mercury. Ambient air at a flow rate of 1.5 L min^{-1} was transported through a 3 m-long heated sampling line (1/4" OD Teflon) in to the analyzer. The sampling line was heated at about 50 ^{o}C using heat tape to prevent water condensation in the gold traps because moisture on gold surfaces interferes with the amalgamation of Hg (Keeler and Barres, 1999). Particulate matter was removed from the sampling line by a 47 mm Teflon filter.

2.2. Meteorological data

Hourly meteorological data (air temperature, relative humidity, and wind speed and direction) were obtained from the Automatic Weather Station (AWS) operated by the Korea Meteorological Administration (KMA) (http://www.kma.go.kr) (6 km from the site). Hourly concentrations of NO_2, O_3, CO, PM_{10} and SO_2 were obtained from the National Air Quality Monitoring Network (NAQMN) (3 km from the site) (Fig. 1).

2.3. QA/QC

Automated daily calibrations were carried out for the Tekran 2537B using an internal permeation source. Two-point calibrations (zero and span) were separately performed for each gold cartridge. Manual injections were performed prior to every field sampling campaign to evaluate these automated calibrations using a saturated mercury vapor standard. The relative percent difference (RPD) between automated calibrations and manual injections was less than 2%. The recovery measured by directly injecting known amounts of four

mercury vapor standards when the sample line was connected to zero air ranged from 92 to 110% (99.4 ± 5.2% in average).

3. Model descriptions

3.1. Conditional Probability Function (CPF)

CPF was originally performed to determine which wind directions dominate during high concentration events to evaluate local source impacts (Ashbaugh et al., 1985). It has been successfully used in many previous studies (Begum et al., 2004; Kim et al., 2003a; Kim et al., 2003b; Xie and Berkowitz, 2006; Zhao et al., 2004; Zhou et al., 2004). CPF estimates the probability that the measured concentration will exceed the threshold criterion for a given wind direction. The CPF is defined as follows Eq. (1).

$$CPF_{\Delta\theta} = \frac{m_{\Delta\theta|C\geq x}}{n_{\Delta\theta}} \quad (1)$$

where, $m_{\Delta\theta}$ is the number of samples from the wind sector θ having concentration C greater than or equal to a threshold value x, and $n_{\Delta\theta}$ is the total number of samples from wind sector $\Delta\theta$. In this study, 16 sectors ($\Delta\theta = 22.5^{o}$) were used and calm winds ($\leq$ 1 m s^{-1}) were excluded from the analysis. The threshold criterion was set at above the overall average TGM concentration (5.0 ng m^{-3}). Thus, CPF indicates the potential for winds from a specific direction to contribute to high air pollution concentrations.

3.2. Conditional Bivariate Probability Function (CBPF)

CBPF couples ordinary CPF with wind speed as a third variable, allocating the measured concentration of pollutant to cells defined by ranges of wind direction and wind speed rather than to only wind direction sectors.

The CBPF is defined as follows Eq. (2).

$$CBPF_{\Delta\theta,\Delta u} = \frac{m_{\Delta\theta,\Delta u|C\geq x}}{n_{\Delta\theta,\Delta u}} \quad (2)$$

where, $m_{\Delta\theta,\Delta u}$ is the number of samples in the wind sector $\Delta\theta$ with wind speed interval Δu having concentration C greater than a threshold value x, and $n_{\Delta\theta\Delta u}$ is the total number of samples in that wind direction-speed interval. The threshold criterion was set at above the overall average TGM concentration (5.0 ng m^{-3}). The extension to the bivariate case can provide more information on the nature of the sources because different source types such as stack emission sources and ground-level sources can have different wind speed dependencies (prominent at low and high wind speed). More detailed information is described in a previous study (Uria-Tellaetxe and Carslaw, 2014).

3.3. Potential Source Contribution Function (PSCF)

The PSCF model has been extensively and successfully used in the previous studies to identify the likely source areas (Cheng et al., 1993; Han et al., 2004; Hopke et al., 2005; Lai et al., 2007; Lim et al., 2001; Poissant, 1999; Zeng and Hopke, 1989). The PSCF is a simple method that links residence time in upwind areas with high concentrations through a conditional probability field and was originally developed by Ashbaugh et al. (1985). $PSCF_{ij}$ is the conditional probability that an air parcel that passed through the ijth cell had a high concentration upon arrival at the monitoring site and is defined as the following Eq. (3).

209

210 $$PSCF_{ij} = \frac{m_{ij}}{n_{ij}} \quad (3)$$

211

212 where, n_{ij} is the number of trajectory segment endpoints that fall into the ij-th cell, and m_{ij} is the
213 number of segment endpoints in the same grid cell (ij-th cell) when the concentrations are higher
214 than a criterion value as measured at the sampling site.
215 High PSCF values in those grid cells are regarded as possible source locations. Cells including
216 emission sources can be identified with conditional probabilities close to one if trajectories that
217 have crossed the cells efficiently transport the released pollutant to the receptor site. Therefore,
218 the PSCF model provides a tool to map the source potentials of geographical areas.
219 The criterion value of PSCF for TGM concentration was set at above the overall average
220 concentration (5.0 ng m^{-3}) to identify the emission sources associated with high TGM
221 concentrations and provide a better estimation and resolution of source locations during the
222 sampling periods. The geographic area covered by the computed trajectories was divided into
223 an array of 0.05º latitude by 0.05º longitude grid cells. As will be discussed in Section 5.4, 24
224 h backward trajectories starting at every hour at a height of 10, 50, and 100 m above ground
225 level were computed using the vertical velocity model because local sources are more
226 important than that of long-range transport in this study (It should be noted that PSCF results
227 using 48 h backward trajectories had similar results as the 24 h backward trajectories). Each
228 trajectory was terminated if they exit the model top (5,000m), but advection continues along
229 the surface if trajectories intersect the ground. To generate horizontally highly resolved
230 meteorological inputs for trajectory calculations, the Weather Research and Forecast (WRF)
231 model was used to generate a coarse domain at a resolution of 27 km and a nested domain at
232 a horizontal resolution of 9 km, which geographically covers northeast Asia and the southern

233 part of the Korean Peninsula, respectively. The nested domain has 174 columns in the east-
234 west direction and 114 rows in the north-south direction. PSCF was calculated with 9 km
235 meteorological data.

236 In this study, TPSCF which incorporates probability from above different starting
237 heights was calculated since backward trajectories starting at different heights traverse
238 different distances and pathways, thus providing information that cannot be obtained from a
239 single starting height (Cheng et al., 1993).

240 Previous studies suggest that there are increasing uncertainties as backward trajectory
241 distances increase (Stohl et al., 2002) and that PSCF modeling is prone to the trailing effect is
242 which locations upwind of sources are also identified as potential sources (Han et al., 2004).
243 An alternative to back trajectory calculations in the interpretation of atmospheric trace
244 substance measurements (Stohl et al., 2002) although this technique does not provide much
245 information on source locations.

246 Generally, PSCF results show that the potential sources covered wide areas instead of
247 indicating individual sources due to the trailing effect. The trailing effect appears since PSCF
248 distributes a constant weight along the path of the trajectories. To minimize the effect of
249 small n_{ij} (the number of trajectory segment endpoints that fall into the ij-th cell) values,
250 resulting in high TPSCF values with high uncertainties, an arbitrary weight function $W(n_{ij})$
251 was applied to down-weight the PSCF values for the cell in which the total number of end
252 points was less than three times the average value of the end points (Choi et al., 2011; Heo et
253 al., 2009; Hopke et al., 1995; Polissar et al., 2001). The TPSCF value for a grid cell was
254 defined with following Eq. (4).
255

$$P(TPSCF_{ij}) = \frac{P(m_{ij})_{10m} + P(m_{ij})_{50m} + P(m_{ij})_{100m}}{P(n_{ij})_{10m} + P(n_{ij})_{50m} + P(n_{ij})_{100m}} \times W \quad (4)$$

where,

$$W(n_{ij}) = \begin{cases} 1.0, & 3n_{ave} < n_{ij} \\ 0.8, & 2n_{ave} < n_{ij} \le 3n_{ave} \\ 0.6, & n_{ave} < n_{ij} \le 2n_{ave} \\ 0.4, & 0.5n_{ave} < n_{ij} \le n_{ave} \\ 0.2, & n_{ij} \le 0.5n_{ave} \end{cases}$$

4. Clean Air Policy Support System (CAPSS) data

In this study, the Korean National Emission Inventory estimated using Clean Air Policy Support System (CAPSS) data developed by the National Institute of Environmental Research (NIER) were used (http://airemiss.nier.go.kr/main.jsp (accessed December 09, 2015)). The CAPSS is the national emission inventory system for the air pollutants (CO, NOx, SOx, TSP, PM_{10}, $PM_{2.5}$, VOCs and NH_3) which utilizes various national, regional and local statistical data collected from about 150 organizations in Korea. In CAPSS, the Source Classification Category (SCC) excluding fugitive dust and biomass burning based on the European Environment Agency's (EEA) CORe Inventory of AIR emissions was classified into the following four levels (EMEP/CORINAIR) (NIER, 2011).

(1) The upper level (SCC1): 11 source categories ,

(2) The intermediate level (SCC2): 42 source categories and

(3) The lower level (SCC3): 173 source categories

The sectoral contributions of emissions of South Korea, Gyeongsangbuk-do and Pohang for CO, NOx, SOx, TSP, PM_{10}, $PM_{2.5}$, VOC and NH_3 are shown in Fig. S1 (See SI for details).

More detailed information about SCCs in CAPSS is described in Table S1.

5. Results and Discussions

5.1. Meteorological data analysis

Fig. S2 shows the frequency of counts of measured wind direction occurrence by season during the sampling period. The predominant wind direction at the sampling site was W (20.9%) and WS (19.2%), and calm conditions of wind speed less than 1 m s^{-1} occurred 7.6% of the time. Compared to other seasons, however, the prevailing winds in summer were N (17.0%), NE (16.4%), S (16.4%), and SW (15.8%).

5.2. General characteristics of TGM

The seasonal distributions of TGM were characterized by large variability during each sampling period (Fig. 2). The average concentration of TGM during the complete sampling period was 5.0 ± 4.7 ng m^{-3} (range: 1.0-79.6 ng m^{-3}). This is significantly higher than the Northern Hemisphere background concentration (~1.5 ng m^{-3}) (Sprovieri et al., 2010) and those measured in China, in Japan and other locations in Korea, however considerably lower than those measured near large Hg sources in Guangzhou, China (Table 1). The median TGM concentration was 3.6 ng m^{-3} which was much lower than that of the average, suggesting that there were some extreme pollution episodes with very high TGM concentrations.

The TGM concentration follows a typical log-normal distribution (Fig. S3). The range of 2 to 5 ng m^{-3} dominated the distribution, accounting for more than half of the total number of

299 samples (60.8%). The maximum frequency of 28.1% occurred between 2 and 3 ng m^{-3}.
300 Extremely high TGM concentration events (>20 ng m^{-3}) were also observed (1.7% of the
301 time).
302
303 *5.3. Seasonal variations*
304 The TGM concentration was statistically significantly higher in fall (6.7 ± 6.4 ng m^{-3}) (p <
305 0.01), followed by spring (4.8 ± 4.0 ng m^{-3}), winter (4.5 ± 3.2 ng m^{-3}) and summer (3.8 ± 3.9
306 ng m^{-3}) (Table 2). The highest concentrations (TGM > 10 ng m^{-3}) were measured more
307 frequently in fall (24.7%), and the lowest concentrations (TGM < 3 ng m^{-3}) mainly occurred
308 in summer (49.7%). The low TGM concentration in summer is likely because increased
309 mixing height (Friedli et al., 2011), and gas phase oxidation (Choi et al., 2013; Huang et al.,
310 2010; Lynam and Keeler, 2006) at higher temperatures particularly at this sampling site
311 which is close to the ocean (2 km) where oxidation involving halogens may be enhanced
312 (Holmes et al., 2009; Lin et al., 2006). The high TGM concentrations in fall was due to
313 different wind direction (see Fig. S2), sources, relationships with other pollutants and
314 meteorological conditions. More detailed information can be found in Section 5.5.
315 The average concentrations of NO_2, O_3, CO, PM_{10} and SO_2 during the complete sampling
316 period were 23.1 ± 10.8 ppbv, 24.6 ± 12.5 ppbv, 673.7 ± 487.3 ppbv, 55.5 ± 26.4 μg m^{-3} and
317 6.7 ± 4.3 ppbv, respectively. NO_2, O_3, CO, PM_{10} and SO_2 concentrations were highest in
318 spring (Table 2). There was a statistically significant positive correlation between the TGM
319 and PM_{10} (r = 0.10) (p < 0.01). However, the TGM concentration was not significantly
320 correlated with NO_2, CO or SO_2 concentrations, suggesting that combustion associated with
321 space heating was not a significant source of TGM (Choi et al., 2009).
322

323 *5.4. Relationship between TGM and CO*

324 CO has a significant anthropogenic source and is considered to be an indicator of
325 anthropogenic emissions (Mao et al., 2008). Previous studies reported that TGM and CO
326 have a strong correlation because they have similar emission sources (combustion processes)
327 and similar long atmospheric residence times (Weiss-Penzias et al., 2003).

328 There was a weak positive correlation between TGM and CO in this study (r = 0.04) (p =
329 0.27). However there was a statistically significant correlation between TGM and CO in
330 winter (r = 0.25) ($p < 0.05$), suggesting that TGM and CO were affected by similar, possibly
331 distant, anthropogenic emission sources in winter.

332 On the other hand, there were no statistically significant correlations between TGM and
333 CO in spring (r = 0.02) ($p = 0.78$), in summer (r = 0.13) ($p = 0.08$), or in fall (r = -0.03) (p =
334 0.69), indicating that TGM and CO were affected by different anthropogenic emission
335 sources in these seasons.

336 Previous studies identified the long-range transport of mercury using the ΔTGM/ΔCO
337 enhancement ratio (Choi et al., 2009; Jaffe et al., 2005; Kim et al., 2009; Weiss-Penzias et al.,
338 2003; Weiss-Penzias et al., 2006). Kim et al. (2009) and Choi et al. (2009) investigated high
339 concentration events which were defined as at least a 10 h period with hourly average TGM
340 and CO concentrations higher than the average monthly TGM and CO concentrations. They
341 reported that long-range transport events were characterized by high values of TGM/CO ratio
342 (ΔTGM/ΔCO) (0.0052-0.0158 ng m^{-3} ppb^{-1}) and high correlations (r^2>0.5), whereas local
343 events showed low ΔTGM/ΔCO (0.0005 ng m^{-3} ppb^{-1} in average) and weak correlations (r^2 <
344 0.5).

345 The observed ΔTGM/ΔCO was 0.0001 ng m^{-3} ppb^{-1} in spring, 0.0005 ng m^{-3} ppb^{-1} in
346 summer, -0.0007 ng m^{-3} ppb^{-1} in fall, 0.0011 ng m^{-3} ppb^{-1} in winter, which are significantly
347 lower than that indicative of Asian long-range transport (0.0046-0.0056 ng m^{-3} ppb^{-1}) (Friedli
348 et al., 2004; Jaffe et al., 2005; Weiss-Penzias et al., 2006), suggesting that local sources are
349 more important than that of long-range transport in this study. The ΔTGM/ΔCO in winter
350 (0.0011 ng m^{-3} ppb^{-1}) was similar to that of a site impacted by local sources in Korea (Kim et
351 al., 2009) and in US industrially related events (0.0011 ng m^{-3} ppb^{-1}) (Weiss-Penzias et al.,
352 2007).
353 There are also uncertainties from the potential mixing between Hg associated with long-
354 range transported airflows and local air making it difficult to distinguish between distant and
355 local source impacts. However, it is possible that the one-week sampling period in each
356 season did not capture the long-range transport events, and more can be learned using a larger
357 dataset than just using the one-week sampling period to confirm these results.
358
359 *5.5. Diurnal variations*
360 Diurnal variations of TGM (Fig. 3), co-pollutants concentrations, and meteorological
361 data were observed (Fig. S4). TGM, O_3, CO, SO_2, and temperature in the daytime (06:00-
362 18:00) were higher than those in the nighttime (18:00-06:00) ($p < 0.05$) except PM_{10} ($p =$
363 0.09) (Fig. S5). However, NO_2 during the nighttime because of relatively lower
364 photochemical reactivity with O_3 was higher than that in daytime ($p < 0.05$) (Adame et al.,
365 2012). TGM generally showed a consistent diurnal variation with an increase in the early
366 morning (06:00-09:00) and a decrease in the afternoon (14:00-17:00), similar to previous

studies (Dommergue et al., 2002; Friedli et al., 2011; Li et al., 2011; Liu et al., 2011; Mao et al., 2008; Shon et al., 2005; Song et al., 2009; Stamenkovic et al., 2007).

The daytime TGM concentration (5.3 ± 4.7 ng m^{-3}) was higher than that in the nighttime (4.7 ± 4.7 ng m^{-3}) ($p < 0.01$), which was similar to several previous studies (Cheng et al., 2014; Gabriel et al., 2005; Nakagawa, 1995; Stamenkovic et al., 2007) but different than another studies (Lee et al., 1998). Previous studies reported that this different is due to local sources close to the sampling site (Cheng et al., 2014; Gabriel et al., 2005), a positive correlation between TGM concentration and ambient air temperature (Nakagawa, 1995) and increased traffic (Stamenkovic et al., 2007). However, another study suggested that the higher TGM concentration during the night was due to the shallowing of the boundary layer, which concentrated the TGM near the surface (Lee et al., 1998).

In a previous study the daytime TGM concentration was relatively lower than that in the nighttime because the sea breeze transported air containing low amounts of TGM from the ocean during the daytime whereas the land breeze transported air containing relatively high concentrations of TGM from an urban area during the nighttime (Kellerhals et al., 2003). Although it is possible that the land-sea breeze may affect diurnal variations in TGM concentrations since the sampling site was near the ocean and lower TGM were also observed during the daytime, the higher concentrations in the daytime than those in nighttime were due to local emission sources because the daytime temperature (14.7 ± 10.0 ºC) was statistically significantly higher than that in the nighttime (13.0 ± 9.8 ºC) (t-test, $p < 0.05$) and there was a weak but statistically significant negative correlation between TGM concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$). In addition, there are several known Hg sources such as iron and steel manufacturing facilities including electric and sintering furnaces using coking between the sampling site and the ocean.

As shown in Fig. 3 and Fig. S4, there was a weak but negative relationship between the TGM concentrations and O_3 concentrations ($r = -0.18$) ($p < 0.01$), suggesting that oxidation of GEM in the oxidizing atmosphere during periods of strong atmospheric mixing was partially responsible for the diurnal variations of TGM concentrations. In addition, oxidation of GEM by bromine species in the coastal area (Obrist et al., 2011) or by chloride radicals in marine boundary layer (Laurier et al., 2003) might play a significant role. If oxidation of GEM occurred, GOM concentrations would increase. However there are uncertainties on the net effects on TGM (the sum of the GEM and the GOM) since we did not measure GOM concentrations.

Significantly different diurnal patterns have been observed at many suburban sites with the daily maximum occurring in the afternoon (12:00-15:00), possibly due to local emission sources and transport (Fu et al., 2010; Fu et al., 2008; Kuo et al., 2006; Wan et al., 2009). Other studies in Europe reported that TGM concentrations were relatively higher early in the morning or at night possibly due to mercury emissions from surface sources that accumulated in the nocturnal inversion layer (Lee et al., 1998; Schmolke et al., 1999).

TGM concentration was negatively correlated with ambient air temperature *($r = -0.08$) ($p < 0.05$)* because high ambient air temperature in the daytime will increase the height of the boundary layer and dilute the TGM, and the relatively lower boundary layer at nighttime could concentrate the TGM in the atmosphere (Li et al., 2011). Although there was a statistically significant negative correlation between the TGM concentration and ambient air temperature, there was a rapid increase in TGM concentration between 06:00-09:00 when ambient temperatures also increased possibly due to local emissions related to industrial activities, increased traffic, and activation of local surface emission sources. Similar patterns were found in previous studies (Li et al., 2011; Stamenkovic et al., 2007). Nonparametric

415 correlations revealed that there is a positive correlation between TGM and ambient air
416 temperature (r_s = 0.11, *p=0.27*) between 06:00-09:00. The TGM concentration was
417 negatively correlated with O_3 (r_s = -0.33, *p<0.01*) but positively correlated with NO_2 (r_s =
418 0.21, *p<0.05*), suggesting that the increased traffic is the main source of TGM during these
419 time periods.

420 Compared to other seasons, significantly different diurnal variations of TGM were
421 observed in fall. The daytime TGM concentrations in fall were similar to those in other
422 seasons, however, the nighttime TGM concentrations in fall were much higher than other
423 seasons. As described earlier in Section 5.3, the high TGM concentrations in fall was
424 possibly due to the relationship between other pollutants and meteorological conditions as
425 well as different wind direction and sources. The nighttime TGM concentrations in fall were
426 simultaneously positively correlated with PM_{10} (r=0.26) (*p*<0.05) and CO (r=0.21) (*p*<0.05)
427 concentrations and wind speed (r=0.35) (*p*<0.01), suggesting that the combustion process is
428 an important source during this period.

429 Based on the above results, the diurnal variations in TGM concentration are due to a
430 combination of: 1) reactions with an oxidizing atmosphere, 2) changes in ambient
431 temperature and 3) local emissions related to industrial activities. To supplement these
432 conclusions CPF and CBPF were used to identify source directions and TPSCF was used to
433 identify potential source locations.

434

435 *5.6. CPF, CBPF and TPSCF results of TGM*

436 Conventional CPF, CBPF and TPSCF plots for TGM concentrations higher than the
437 average concentration show high source probabilities to the west in the direction of large steel
438 manufacturing facilities and waste incinerators (Fig. 4). The CPF only shows high

probabilities from the west and provides no further information, however, the CBPF shows groups of sources with the high probabilities from the west and the northeast. CBPF shows that the high probabilities from the west occurred under high wind speed (> 3 m s^{-1}) indicative of emissions from stacks as well as low wind speed (≤3 m s^{-1}) indicative of non-buoyant ground level sources (Uria-Tellaetxe and Carslaw, 2014).

As described in Section 5.4, correlations between TGM and CO revealed that TGM and CO were affected by similar anthropogenic emission sources in winter but affected by different sources in spring, summer and fall, which is supported by Fig. S6 which shows significantly different seasonal patterns of CPF and CBPF for TGM concentrations.

It is difficult to discuss about the different seasonal patterns for CPF and CBPF for TGM concentrations since there were no correlations between TGM and other pollutants in spring, summer and fall except O_3. However, compared to Fig. 4, the CPF and CBPF patterns in fall were similar to those during the whole sampling periods. Especially, the nighttime TGM concentration in fall was simultaneously positively correlated with PM_{10} (r=0.26) (p<0.05) and CO (r=0.21) (p<0.05) concentrations and wind speed (r=0.35) (p<0.01), indicating that the combustion process from the west is an important source during this period.

Since TGM showed a significant correlation with CO (r=0.25) (p<0.05) and showed a weak positive correlation with PM_{10} (r=0.08) (p=0.33) in winter with high wind speed, combustion sources from the west are likely partially responsible for this result.

TPSCF identified the likely sources of TGM as the iron and manufacturing facilities and the hazardous waste incinerators which are located to the west from the sampling site. A previous study reported that the waste incinerators (9%) and iron and steel manufacturing (7%) were relatively high Hg emissions sources in Korea (Kim et al., 2010). Waste incinerators emissions were due to the high Hg content in the waste (Lee et al., 2004).

Emissions from iron and steel manufacturing are due to the numerous electric and sintering furnaces using coking which emits relatively high mercury concentrations (Lee et al., 2004) in Gyeongsangbuk-do including Pohang. There are several coke plants around the sampling site (http://www.poscoenc.com/upload/W/BUSINESS/PDF/ENG_PLANT_2_1_3_5.pdf (accessed December 09, 2015)). They are essential parts of the iron and steel manufacturing, and the major source of atmospheric mercury related to the iron and steel manufacturing is from coke production (Pacyna et al., 2006).

The coastal areas east of the sampling site where there are large ports were also identified as the likely source areas of TGM. A previous study reported that the emissions of gaseous and particulate pollutants were high during vehicular operations in port areas and from marine vessel and launches (Gupta et al., 2002). Another possibility is that significant amount of GEM are emitted from the ocean surface because of photo-chemically and microbiologically mediated photo-reduction of dissolved GOM (Amyot et al., 1994; Zhang and Lindberg, 2001). The northeast direction including the East Sea was also identified as potential source areas likely because this is an area with lots of domestic passenger ships routes. The south from the sampling was also identified as a likely source area of TGM where Ulsan Metropolitan City, South Korea's seventh largest metropolis with a population of over 1.1 million is located. It includes a large petrochemical complex known as a TGM source (Jen et al., 2013).

Conclusions

During the sampling periods, the average TGM concentration was higher than the Northern Hemisphere background concentration, however, considerably lower than those near industrial areas in China and higher than those in Japan and other locations in Korea. The median concentration of TGM was much lower than that of the average, suggesting that there were some extreme pollution episodes with very high TGM concentrations. The TGM concentration was highest in fall, followed by spring, winter and summer. The high TGM concentration in fall is due to transport from different wind directions than during the other periods. The low TGM concentration in summer is likely due to increased mixing height and gas phase oxidation at higher temperatures particularly at this sampling site which is close to the ocean (2 km) where oxidation involving halogens may be enhanced.

TGM consistently showed a diurnal variation with a maximum in the early morning (06:00-09:00) and minimum in the afternoon (14:00-17:00). Although there was a statistically significant negative correlation between the TGM concentration and ambient air temperature, the daytime TGM concentration was higher than those in the nighttime, suggesting that local emission sources are important. There was a negative relationship between the TGM concentrations and O_3 concentrations, indicating that the oxidation was partially responsible for the diurnal variations of TGM concentrations. The observed $\Delta TGM/\Delta CO$ was significantly lower than that indicative of Asian long-range transport, suggesting that local sources are more important than that of long-range transport. CPF only shows high probabilities to the west from the sampling site where there are large steel manufacturing facilities and waste incinerators. However, CBPF and TPSCF indicated that the dominant sources of TGM were the hazardous waste incinerators and the coastal areas in the northeast

as well as the iron and manufacturing facilities in the west. The domestic passenger ships routes in the East Sea were also identified as possible source areas.

Author contribution

Yong-Seok Seo conducted a design of the study, the experiments and analysis of data, wrote the initial manuscript, and finally approved the final manuscript. Seung-Pyo Jeong, Eun Ha Park, Tae Young Kim, Hee-Sang Eum, Dae Gun Park, Eunhye Kim, Jaewon Choi and Jeong-Hun Kim conducted the experiments, analysis of data, and finally approved the final manuscript. Thomas M. Holsen, Young-Ji Han and Eunhwa Choi and Soontae Kim conducted interpretation of the results, revision of the initial manuscript, and finally approved the final manuscript. Seung-Muk Yi conducted a design of the study, acquisition of data of the study, interpretation of data, and revision of the initial manuscript, and finally approved the final manuscript.

Acknowledgments

We thank National Institute of Environmental Research (NIER) for providing CAPSS data. This work was supported by Brain Korea 21 (BK21) Plus Project (Center for Healthy Environment Education and Research) through the National Research Foundation (NRF) of Korea and Korea Ministry of Environment (MOE) as “the Environmental Health Action Program”.
