45 **Abstract**

46 Total gaseous mercury (TGM) concentrations were measured every 5 min in Pohang,
47 Gyeongsangbuk-do, Korea during summer (17 August~23 August 2012), fall (9 October~17
48 October 2012), winter (22 January ~29 January 2013), and spring (26 March~3 April 2013)
49 to: 1) characterize the hourly and seasonal variations of atmospheric TGM concentrations, 2)
50 identify the relationships between TGM and co-pollutants, and 3) identify likely source
51 directions and locations of TGM using conditional probability function (CPF), conditional
52 bivariate probability function (CBPF) and total potential source contribution function
53 (TPSCF).

54 The TGM concentration was statistically significantly highest in fall ($6.7 \pm 6.4 \text{ ng m}^{-3}$),
55 followed by spring ($4.8 \pm 4.0 \text{ ng m}^{-3}$), winter ($4.5 \pm 3.2 \text{ ng m}^{-3}$) and summer ($3.8 \pm 3.9 \text{ ng m}^{-3}$).
56 There was a weak but statistically significant negative correlation between the TGM
57 concentration and ambient air temperature ($r = -0.08$) ($p < 0.05$). Although the daytime
58 temperature ($14.7 \pm 10.0 \text{ }^\circ\text{C}$) was statistically significantly higher than that in the nighttime
59 ($13.0 \pm 9.8 \text{ }^\circ\text{C}$) ($p < 0.05$), the daytime TGM concentration ($5.3 \pm 4.7 \text{ ng m}^{-3}$) was statistically
60 significantly higher than those in the nighttime ($4.7 \pm 4.7 \text{ ng m}^{-3}$) ($p < 0.01$), possibly due to
61 local emissions related to industrial activities and activation of local surface emission
62 sources. The observed $\Delta\text{TGM}/\Delta\text{CO}$ was significantly lower than that of Asian long-range
63 transport, but similar to that of local sources in Korea and in US industrial events suggesting
64 that local sources are more important than that of long-range transport. CPF, CBPF and
65 TPSCF indicated that the main sources of TGM were iron and manufacturing facilities, the
66 hazardous waste incinerators and the coastal areas.

67 **Keywords:** Total gaseous mercury (TGM); co-pollutant; conditional probability function
68 (CPF); conditional bivariate probability function (CBPF); total potential source contribution
69 function (TPSCF)

70 1. Introduction

71 Mercury (Hg) in the atmosphere exists in three major inorganic forms including gaseous
72 elemental mercury (GEM, Hg⁰), gaseous oxidized mercury (GOM, Hg²⁺) and particulate
73 bound mercury (PBM, Hg(p)). GEM which is the dominant form of Hg in ambient air,
74 (>95%) has a relatively long residence time (0.5~2 years) due to its low reactivity and
75 solubility Schroeder and Munthe (1998). However, GOM has high water solubility and
76 relatively strong surface adhesion properties (Han et al., 2005), so it has a short atmospheric
77 residence time (~days). PBM is associated with airborne particles such as dust, soot, sea-salt
78 aerosols, and ice crystals (Lu and Schroeder, 2004) and is likely produced, in part, by
79 adsorption of GOM species such as HgCl₂ onto atmospheric particles (Gauchard et al., 2005;
80 Lu and Schroeder, 2004; Sakata and Marumoto, 2005; Seo et al., 2015).

81 Atmospheric Hg is emitted from both natural sources (volcanoes, volatilization from
82 aquatic and terrestrial environments) and anthropogenic sources (coal combustion, ferrous
83 and non-ferrous metals manufacturing facilities, waste incineration and industrial boilers)
84 (Lindberg et al., 2007; Pirrone et al., 2010; Schmeltz et al., 2011).

85 Atmospheric Hg released from natural and anthropogenic sources when introduced into
86 terrestrial and aquatic ecosystem through wet and dry deposition (Mason and Sheu, 2002) can
87 undergo various physical and chemical transformations before being deposited. Its lifetime in
88 the atmosphere depends on its reactivity and solubility so that depending on its form it can
89 have impacts on local, regional and global scales (Lin and Pehkonen, 1999; Lindberg et al.,
90 2007). A portion of the Hg deposited in terrestrial environments through direct industrial
91 discharge or atmospheric deposition is transported to aquatic system through groundwater
92 and surface water runoff (Miller et al., 2013).

93 A previous study also reported that Hg directly released into terrestrial and aquatic
94 ecosystems from industrial effluent has influenced surface water, sediment and biological
95 tissue (Flanders et al., 2010).

96 Significant spatial variations in atmospheric Hg deposition near urban and industrial areas
97 were due to local anthropogenic sources including municipal waste incinerators, medical
98 waste incinerators, electric power generating facilities and cement kilns (Dvonch et al.,
99 1998), ferrous and non-ferrous metal processing, iron and steel manufacturing facilities, and
100 oil and coal combustion (Hoyer et al., 1995). Miller et al. (2013) also reported that local
101 sources of elemental Hg are typically industrial processes including retort facilities used in
102 the mercury mining industry to convert Hg containing minerals to elemental Hg and chlor-
103 alkali facilities.

104 Annual anthropogenic Hg emissions in South Korea have been estimated to be 12.8 tons;
105 the major anthropogenic mercury emission sources are coal combustion in thermal power
106 plants (25.8%), oil refineries (25.5%), cement kilns (21%), incinerators (19.3%) including
107 sludge incinerators (4.7%), municipal waste incinerators (MWIs) (3%), industrial waste
108 incinerators (IWIs) (2.7%), hospital/medical/infectious waste incinerators (HMIWIs) (8.8%),
109 and iron manufacturing (7%) (Kim et al., 2010).

110 Receptor models are often used to identify sources of air pollutants and are focused on the
111 pollutants behavior in the ambient environment at the point of impact (Hopke, 2003). In
112 previous studies, conditional probability function (CPF), which utilizes the local wind
113 direction, and potential source contribution function (PSCF), which utilizes longer backward
114 trajectories (typically 3-5 days), combined with concentration data were used to identify
115 possible transport pathways and source locations (Hopke, 2003). While PSCF has been used

116 primarily to identify regional sources, it has also been used to identify local sources (Hsu et
117 al., 2003). The objectives of this study were to characterize the hourly and seasonal variations
118 of atmospheric TGM (the sum of the GEM and the GOM) concentrations, to identify the
119 relationships between TGM and co-pollutant concentrations, and to identify likely source
120 directions and locations of TGM using CPF, conditional bivariate probability function
121 (CBPF) and total PSCF (TPSCF).

122

123 **2. Materials and methods**

124 *2.1. Sampling and analysis*

125 TGM concentrations were measured on the roof of the Korean Federation of
126 Community Credit Cooperatives (KFCCC) building (latitude: 35.992°, longitude: 129.404°,
127 ~10 m above ground) in Pohang city, in Gyeongsangbuk-do, a province in eastern South
128 Korea. Gyeongsangbuk-do has a population of 2.7 million (5% of the total population and the
129 third most populated province in South Korea) and an area of 19,030 km² (19% of the total
130 area of South Korea and the largest province geographically in South Korea). Pohang city has
131 a population of 500,000 (1% of the total population in South Korea) and an area of 605.4 km²
132 (1.1% of the total area in South Korea). It is heavily industrialized with the third largest steel
133 manufacturing facility in Asia and the fifth largest in the world. There are several iron and
134 steel manufacturing facilities including electric and sintering furnaces using coking in
135 Gyeongsangbuk-do including Pohang. In addition, there are several coke plants around the
136 sampling site. The Hyungsan River divides the city into a residential area and the steel
137 complex. Hg emissions data from iron and steel manufacturing, and a hazardous waste
138 incinerator were estimated based on a previous study (Kim et al., 2010) (Fig. 1).

139 TGM concentrations were measured every 5 min during summer (17 August~23 August
140 2012), fall (9 October~17 October 2012), winter (22 January ~29 January 2013), and spring
141 (26 March~3 April 2013) using a mercury vapor analyzer (Tekran 2537B) which has two
142 gold cartridges that alternately collect and thermally desorb mercury. Ambient air at a flow
143 rate of 1.5 L min^{-1} was transported through a 3 m-long heated sampling line (1/4" OD Teflon)
144 in to the analyzer. The sampling line was heated at about $50 \text{ }^{\circ}\text{C}$ using heat tape to prevent
145 water condensation in the gold traps because moisture on gold surfaces interferes with the
146 amalgamation of Hg (Keeler and Barres, 1999). Particulate matter was removed from the
147 sampling line by a 47 mm Teflon filter.

148

149 *2.2. Meteorological data*

150 Hourly meteorological data (air temperature, relative humidity, and wind speed and
151 direction) were obtained from the Automatic Weather Station (AWS) operated by the Korea
152 Meteorological Administration (KMA) (<http://www.kma.go.kr>) (6 km from the site). Hourly
153 concentrations of NO_2 , O_3 , CO , PM_{10} and SO_2 were obtained from the National Air Quality
154 Monitoring Network (NAQMN) (3 km from the site) (Fig. 1).

155

156 *2.3. QA/QC*

157 Automated daily calibrations were carried out for the Tekran 2537B using an internal
158 permeation source. Two-point calibrations (zero and span) were separately performed for
159 each gold cartridge. Manual injections were performed prior to every field sampling
160 campaign to evaluate these automated calibrations using a saturated mercury vapor standard.
161 The relative percent difference (RPD) between automated calibrations and manual injections
162 was less than 2%. The recovery measured by directly injecting known amounts of four

163 mercury vapor standards when the sample line was connected to zero air ranged from 92 to
 164 110% ($99.4 \pm 5.2\%$ in average).

165

166 **3. Model descriptions**

167 *3.1. Conditional Probability Function (CPF)*

168 CPF was originally performed to determine which wind directions dominate during high
 169 concentration events to evaluate local source impacts (Ashbaugh et al., 1985). It has been
 170 successfully used in many previous studies (Begum et al., 2004; Kim et al., 2003a; Kim et al.,
 171 2003b; Xie and Berkowitz, 2006; Zhao et al., 2004; Zhou et al., 2004). CPF estimates the
 172 probability that the measured concentration will exceed the threshold criterion for a given
 173 wind direction. The CPF is defined as follows Eq. (1).

174

$$175 \quad CPF_{\Delta\theta} = \frac{m_{\Delta\theta|C \geq x}}{n_{\Delta\theta}} \quad (1)$$

176

177 where, $m_{\Delta\theta}$ is the number of samples from the wind sector θ having concentration C greater
 178 than or equal to a threshold value x , and $n_{\Delta\theta}$ is the total number of samples from wind sector
 179 $\Delta\theta$. In this study, 16 sectors ($\Delta\theta = 22.5^\circ$) were used and calm winds ($\leq 1 \text{ m s}^{-1}$) were excluded
 180 from the analysis. The threshold criterion was set at above the overall average TGM
 181 concentration (5.0 ng m^{-3}). Thus, CPF indicates the potential for winds from a specific
 182 direction to contribute to high air pollution concentrations.

183

184 *3.2. Conditional Bivariate Probability Function (CBPF)*

185 CBPF couples ordinary CPF with wind speed as a third variable, allocating the measured
 186 concentration of pollutant to cells defined by ranges of wind direction and wind speed rather
 187 than to only wind direction sectors.

188 The CBPF is defined as follows Eq. (2).

189

$$190 \quad CBPF_{\Delta\theta,\Delta u} = \frac{m_{\Delta\theta,\Delta u}|_{C \geq x}}{n_{\Delta\theta,\Delta u}} \quad (2)$$

191

192 where, $m_{\Delta\theta,\Delta u}$ is the number of samples in the wind sector $\Delta\theta$ with wind speed interval Δu
 193 having concentration C greater than a threshold value x , and $n_{\Delta\theta,\Delta u}$ is the total number of
 194 samples in that wind direction-speed interval. The threshold criterion was set at above the
 195 overall average TGM concentration (5.0 ng m^{-3}). The extension to the bivariate case can
 196 provide more information on the nature of the sources because different source types such as
 197 stack emission sources and ground-level sources can have different wind speed dependencies
 198 (prominent at low and high wind speed). More detailed information is described in a previous
 199 study (Uria-Tellaetxe and Carslaw, 2014).

200

201 *3.3. Potential Source Contribution Function (PSCF)*

202 The PSCF model has been extensively and successfully used in the previous studies to
 203 identify the likely source areas (Cheng et al., 1993; Han et al., 2004; Hopke et al., 2005; Lai
 204 et al., 2007; Lim et al., 2001; Poissant, 1999; Zeng and Hopke, 1989). The PSCF is a simple
 205 method that links residence time in upwind areas with high concentrations through a
 206 conditional probability field and was originally developed by Ashbaugh et al. (1985). $PSCF_{ij}$
 207 is the conditional probability that an air parcel that passed through the ij th cell had a high
 208 concentration upon arrival at the monitoring site and is defined as the following Eq. (3).

209

$$PSCF_{ij} = \frac{m_{ij}}{n_{ij}} \quad (3)$$

211

212 where, n_{ij} is the number of trajectory segment endpoints that fall into the ij -th cell, and m_{ij} is the
213 number of segment endpoints in the same grid cell (ij -th cell) when the concentrations are higher
214 than a criterion value as measured at the sampling site.

215 High PSCF values in those grid cells are regarded as possible source locations. Cells including
216 emission sources can be identified with conditional probabilities close to one if trajectories that
217 have crossed the cells efficiently transport the released pollutant to the receptor site. Therefore,
218 the PSCF model provides a tool to map the source potentials of geographical areas.

219 The criterion value of PSCF for TGM concentration was set at above the overall average
220 concentration (5.0 ng m^{-3}) to identify the emission sources associated with high TGM
221 concentrations and provide a better estimation and resolution of source locations during the
222 sampling periods. The geographic area covered by the computed trajectories was divided into
223 an array of 0.05° latitude by 0.05° longitude grid cells. As will be discussed in Section 5.4, 24
224 h backward trajectories starting at every hour at a height of 10, 50, and 100 m above ground
225 level were computed using the vertical velocity model because local sources are more
226 important than that of long-range transport in this study (It should be noted that PSCF results
227 using 48 h backward trajectories had similar results as the 24 h backward trajectories). Each
228 trajectory was terminated if they exit the model top (5,000m), but advection continues along
229 the surface if trajectories intersect the ground. To generate horizontally highly resolved
230 meteorological inputs for trajectory calculations, the Weather Research and Forecast (WRF)
231 model was used to generate a coarse domain at a resolution of 27 km and a nested domain at
232 a horizontal resolution of 9 km, which geographically covers northeast Asia and the southern

233 part of the Korean Peninsula, respectively. The nested domain has 174 columns in the east-
234 west direction and 114 rows in the north-south direction. PSCF was calculated with 9 km
235 meteorological data.

236 In this study, TPSCF which incorporates probability from above different starting
237 heights was calculated since backward trajectories starting at different heights traverse
238 different distances and pathways, thus providing information that cannot be obtained from a
239 single starting height (Cheng et al., 1993).

240 Previous studies suggest that there are increasing uncertainties as backward trajectory
241 distances increase (Stohl et al., 2002) and that PSCF modeling is prone to the trailing effect is
242 which locations upwind of sources are also identified as potential sources (Han et al., 2004).
243 An alternative to back trajectory calculations in the interpretation of atmospheric trace
244 substance measurements (Stohl et al., 2002) although this technique does not provide much
245 information on source locations.

246 Generally, PSCF results show that the potential sources covered wide areas instead of
247 indicating individual sources due to the trailing effect. The trailing effect appears since PSCF
248 distributes a constant weight along the path of the trajectories. To minimize the effect of
249 small n_{ij} (the number of trajectory segment endpoints that fall into the ij -th cell) values,
250 resulting in high TPSCF values with high uncertainties, an arbitrary weight function $W(n_{ij})$
251 was applied to down-weight the PSCF values for the cell in which the total number of end
252 points was less than three times the average value of the end points (Choi et al., 2011; Heo et
253 al., 2009; Hopke et al., 1995; Polissar et al., 2001). The TPSCF value for a grid cell was
254 defined with following Eq. (4).

255

$$P(TPSCF_{ij}) = \frac{P(m_{ij})_{10m} + P(m_{ij})_{50m} + P(m_{ij})_{100m}}{P(n_{ij})_{10m} + P(n_{ij})_{50m} + P(n_{ij})_{100m}} \times W \quad (4)$$

257

258 where,

$$W(n_{ij}) = \begin{cases} 1.0, & 3n_{ave} < n_{ij} \\ 0.8, & 2n_{ave} < n_{ij} \leq 3n_{ave} \\ 0.6, & n_{ave} < n_{ij} \leq 2n_{ave} \\ 0.4, & 0.5n_{ave} < n_{ij} \leq n_{ave} \\ 0.2, & n_{ij} \leq 0.5n_{ave} \end{cases}$$

259

260

261 4. Clean Air Policy Support System (CAPSS) data

262 In this study, the Korean National Emission Inventory estimated using Clean Air Policy
 263 Support System (CAPSS) data developed by the National Institute of Environmental
 264 Research (NIER) were used (<http://airemiss.nier.go.kr/main.jsp> (accessed December 09,
 265 2015)). The CAPSS is the national emission inventory system for the air pollutants (CO,
 266 NO_x, SO_x, TSP, PM₁₀, PM_{2.5}, VOCs and NH₃) which utilizes various national, regional and
 267 local statistical data collected from about 150 organizations in Korea. In CAPSS, the Source
 268 Classification Category (SCC) excluding fugitive dust and biomass burning based on the
 269 European Environment Agency's (EEA) CORE Inventory of AIR emissions was classified
 270 into the following four levels (EMEP/CORINAIR) (NIER, 2011).

271 (1) The upper level (SCC1): 11 source categories ,

272 (2) The intermediate level (SCC2): 42 source categories and

273 (3) The lower level (SCC3): 173 source categories

274

275 The sectoral contributions of emissions of South Korea, Gyeongsangbuk-do and Pohang
276 for CO, NO_x, SO_x, TSP, PM₁₀, PM_{2.5}, VOC and NH₃ are shown in Fig. S1 (See SI for
277 details).

278 More detailed information about SCCs in CAPSS is described in Table S1.

279

280 **5. Results and Discussions**

281 *5.1. Meteorological data analysis*

282 Fig. S2 shows the frequency of counts of measured wind direction occurrence by season
283 during the sampling period. The predominant wind direction at the sampling site was W
284 (20.9%) and WS (19.2%), and calm conditions of wind speed less than 1 m s⁻¹ occurred 7.6%
285 of the time. Compared to other seasons, however, the prevailing winds in summer were N
286 (17.0%), NE (16.4%), S (16.4%), and SW (15.8%).

287

288 *5.2. General characteristics of TGM*

289 The seasonal distributions of TGM were characterized by large variability during each
290 sampling period (Fig. 2). The average concentration of TGM during the complete sampling
291 period was 5.0 ± 4.7 ng m⁻³ (range: 1.0-79.6 ng m⁻³). This is significantly higher than the
292 Northern Hemisphere background concentration (~1.5 ng m⁻³) (Sprovieri et al., 2010) and
293 those measured in China, in Japan and other locations in Korea, however considerably lower
294 than those measured near large Hg sources in Guangzhou, China (Table 1). The median TGM
295 concentration was 3.6 ng m⁻³ which was much lower than that of the average, suggesting that
296 there were some extreme pollution episodes with very high TGM concentrations.

297 The TGM concentration follows a typical log-normal distribution (Fig. S3). The range of 2
298 to 5 ng m⁻³ dominated the distribution, accounting for more than half of the total number of

299 samples (60.8%). The maximum frequency of 28.1% occurred between 2 and 3 ng m⁻³.
300 Extremely high TGM concentration events (>20 ng m⁻³) were also observed (1.7% of the
301 time).

302

303 5.3. Seasonal variations

304 The TGM concentration was statistically significantly higher in fall (6.7 ± 6.4 ng m⁻³) ($p <$
305 0.01), followed by spring (4.8 ± 4.0 ng m⁻³), winter (4.5 ± 3.2 ng m⁻³) and summer (3.8 ± 3.9
306 ng m⁻³) (Table 2). The highest concentrations (TGM > 10 ng m⁻³) were measured more
307 frequently in fall (24.7%), and the lowest concentrations (TGM < 3 ng m⁻³) mainly occurred
308 in summer (49.7%). The low TGM concentration in summer is likely because increased
309 mixing height (Friedli et al., 2011), and gas phase oxidation (Choi et al., 2013; Huang et al.,
310 2010; Lynam and Keeler, 2006) at higher temperatures particularly at this sampling site
311 which is close to the ocean (2 km) where oxidation involving halogens may be enhanced
312 (Holmes et al., 2009; Lin et al., 2006). The high TGM concentrations in fall was due to
313 different wind direction (see Fig. S2), sources, relationships with other pollutants and
314 meteorological conditions. More detailed information can be found in Section 5.5.

315 The average concentrations of NO₂, O₃, CO, PM₁₀ and SO₂ during the complete sampling
316 period were 23.1 ± 10.8 ppbv, 24.6 ± 12.5 ppbv, 673.7 ± 487.3 ppbv, 55.5 ± 26.4 μg m⁻³ and
317 6.7 ± 4.3 ppbv, respectively. NO₂, O₃, CO, PM₁₀ and SO₂ concentrations were highest in
318 spring (Table 2). There was a statistically significant positive correlation between the TGM
319 and PM₁₀ ($r = 0.10$) ($p < 0.01$). However, the TGM concentration was not significantly
320 correlated with NO₂, CO or SO₂ concentrations, suggesting that combustion associated with
321 space heating was not a significant source of TGM (Choi et al., 2009).

322

323 *5.4. Relationship between TGM and CO*

324 CO has a significant anthropogenic source and is considered to be an indicator of
325 anthropogenic emissions (Mao et al., 2008). Previous studies reported that TGM and CO
326 have a strong correlation because they have similar emission sources (combustion processes)
327 and similar long atmospheric residence times (Weiss-Penzias et al., 2003).

328 There was a weak positive correlation between TGM and CO in this study ($r = 0.04$) ($p =$
329 0.27). However there was a statistically significant correlation between TGM and CO in
330 winter ($r = 0.25$) ($p < 0.05$), suggesting that TGM and CO were affected by similar, possibly
331 distant, anthropogenic emission sources in winter.

332 On the other hand, there were no statistically significant correlations between TGM and
333 CO in spring ($r = 0.02$) ($p = 0.78$), in summer ($r = 0.13$) ($p = 0.08$), or in fall ($r = -0.03$) ($p =$
334 0.69), indicating that TGM and CO were affected by different anthropogenic emission
335 sources in these seasons.

336 Previous studies identified the long-range transport of mercury using the $\Delta\text{TGM}/\Delta\text{CO}$
337 enhancement ratio (Choi et al., 2009; Jaffe et al., 2005; Kim et al., 2009; Weiss-Penzias et al.,
338 2003; Weiss-Penzias et al., 2006). Kim et al. (2009) and Choi et al. (2009) investigated high
339 concentration events which were defined as at least a 10 h period with hourly average TGM
340 and CO concentrations higher than the average monthly TGM and CO concentrations. They
341 reported that long-range transport events were characterized by high values of TGM/CO ratio
342 ($\Delta\text{TGM}/\Delta\text{CO}$) (0.0052 - $0.0158 \text{ ng m}^{-3} \text{ ppb}^{-1}$) and high correlations ($r^2 > 0.5$), whereas local
343 events showed low $\Delta\text{TGM}/\Delta\text{CO}$ ($0.0005 \text{ ng m}^{-3} \text{ ppb}^{-1}$ in average) and weak correlations ($r^2 <$
344 0.5).

345 The observed $\Delta\text{TGM}/\Delta\text{CO}$ was $0.0001 \text{ ng m}^{-3} \text{ ppb}^{-1}$ in spring, $0.0005 \text{ ng m}^{-3} \text{ ppb}^{-1}$ in
346 summer, $-0.0007 \text{ ng m}^{-3} \text{ ppb}^{-1}$ in fall, $0.0011 \text{ ng m}^{-3} \text{ ppb}^{-1}$ in winter, which are significantly
347 lower than that indicative of Asian long-range transport ($0.0046\text{-}0.0056 \text{ ng m}^{-3} \text{ ppb}^{-1}$) (Friedli
348 et al., 2004; Jaffe et al., 2005; Weiss-Penzias et al., 2006), suggesting that local sources are
349 more important than that of long-range transport in this study. The $\Delta\text{TGM}/\Delta\text{CO}$ in winter
350 ($0.0011 \text{ ng m}^{-3} \text{ ppb}^{-1}$) was similar to that of a site impacted by local sources in Korea (Kim et
351 al., 2009) and in US industrially related events ($0.0011 \text{ ng m}^{-3} \text{ ppb}^{-1}$) (Weiss-Penzias et al.,
352 2007).

353 There are also uncertainties from the potential mixing between Hg associated with long-
354 range transported airflows and local air making it difficult to distinguish between distant and
355 local source impacts. However, it is possible that the one-week sampling period in each
356 season did not capture the long-range transport events, and more can be learned using a larger
357 dataset than just using the one-week sampling period to confirm these results.

358

359 5.5. Diurnal variations

360 Diurnal variations of TGM (Fig. 3), co-pollutants concentrations, and meteorological
361 data were observed (Fig. S4). TGM, O_3 , CO, SO_2 , and temperature in the daytime (06:00-
362 18:00) were higher than those in the nighttime (18:00-06:00) ($p < 0.05$) except PM_{10} ($p =$
363 0.09) (Fig. S5). However, NO_2 during the nighttime because of relatively lower
364 photochemical reactivity with O_3 was higher than that in daytime ($p < 0.05$) (Adame et al.,
365 2012). TGM generally showed a consistent diurnal variation with an increase in the early
366 morning (06:00-09:00) and a decrease in the afternoon (14:00-17:00), similar to previous

367 studies (Dommergue et al., 2002; Friedli et al., 2011; Li et al., 2011; Liu et al., 2011; Mao et
368 al., 2008; Shon et al., 2005; Song et al., 2009; Stamenkovic et al., 2007).

369 The daytime TGM concentration ($5.3 \pm 4.7 \text{ ng m}^{-3}$) was higher than that in the nighttime
370 ($4.7 \pm 4.7 \text{ ng m}^{-3}$) ($p < 0.01$), which was similar to several previous studies (Cheng et al.,
371 2014; Gabriel et al., 2005; Nakagawa, 1995; Stamenkovic et al., 2007) but different than
372 another studies (Lee et al., 1998). Previous studies reported that this different is due to local
373 sources close to the sampling site (Cheng et al., 2014; Gabriel et al., 2005), a positive
374 correlation between TGM concentration and ambient air temperature (Nakagawa, 1995) and
375 increased traffic (Stamenkovic et al., 2007). However, another study suggested that the higher
376 TGM concentration during the night was due to the shallowing of the boundary layer, which
377 concentrated the TGM near the surface (Lee et al., 1998).

378 In a previous study the daytime TGM concentration was relatively lower than that in the
379 nighttime because the sea breeze transported air containing low amounts of TGM from the
380 ocean during the daytime whereas the land breeze transported air containing relatively high
381 concentrations of TGM from an urban area during the nighttime (Kellerhals et al., 2003).
382 Although it is possible that the land-sea breeze may affect diurnal variations in TGM
383 concentrations since the sampling site was near the ocean and lower TGM were also observed
384 during the daytime, the higher concentrations in the daytime than those in nighttime were due
385 to local emission sources because the daytime temperature ($14.7 \pm 10.0 \text{ }^\circ\text{C}$) was statistically
386 significantly higher than that in the nighttime ($13.0 \pm 9.8 \text{ }^\circ\text{C}$) (t-test, $p < 0.05$) and there was a
387 weak but statistically significant negative correlation between TGM concentration and
388 ambient air temperature ($r = -0.08$) ($p < 0.05$). In addition, there are several known Hg
389 sources such as iron and steel manufacturing facilities including electric and sintering
390 furnaces using coking between the sampling site and the ocean.

391 As shown in Fig. 3 and Fig. S4, there was a weak but negative relationship between the
392 TGM concentrations and O₃ concentrations ($r = -0.18$) ($p < 0.01$), suggesting that oxidation
393 of GEM in the oxidizing atmosphere during periods of strong atmospheric mixing was
394 partially responsible for the diurnal variations of TGM concentrations. In addition, oxidation
395 of GEM by bromine species in the coastal area (Obrist et al., 2011) or by chloride radicals in
396 marine boundary layer (Laurier et al., 2003) might play a significant role. If oxidation of
397 GEM occurred, GOM concentrations would increase. However there are uncertainties on the
398 net effects on TGM (the sum of the GEM and the GOM) since we did not measure GOM
399 concentrations.

400 Significantly different diurnal patterns have been observed at many suburban sites with
401 the daily maximum occurring in the afternoon (12:00-15:00), possibly due to local emission
402 sources and transport (Fu et al., 2010; Fu et al., 2008; Kuo et al., 2006; Wan et al., 2009).
403 Other studies in Europe reported that TGM concentrations were relatively higher early in the
404 morning or at night possibly due to mercury emissions from surface sources that accumulated
405 in the nocturnal inversion layer (Lee et al., 1998; Schmolke et al., 1999).

406 TGM concentration was negatively correlated with ambient air temperature ($r = -0.08$)
407 ($p < 0.05$) because high ambient air temperature in the daytime will increase the height of the
408 boundary layer and dilute the TGM, and the relatively lower boundary layer at nighttime
409 could concentrate the TGM in the atmosphere (Li et al., 2011). Although there was a
410 statistically significant negative correlation between the TGM concentration and ambient air
411 temperature, there was a rapid increase in TGM concentration between 06:00-09:00 when
412 ambient temperatures also increased possibly due to local emissions related to industrial
413 activities, increased traffic, and activation of local surface emission sources. Similar patterns
414 were found in previous studies (Li et al., 2011; Stamenkovic et al., 2007). Nonparametric

415 correlations revealed that there is a positive correlation between TGM and ambient air
416 temperature ($r_s = 0.11, p=0.27$) between 06:00-09:00. The TGM concentration was negatively
417 correlated with O_3 ($r_s = -0.33, p<0.01$) but positively correlated with NO_2 ($r_s = 0.21, p<0.05$),
418 suggesting that the increased traffic is the main source of TGM during these time periods.

419 Compared to other seasons, significantly different diurnal variations of TGM were
420 observed in fall. The daytime TGM concentrations in fall were similar to those in other
421 seasons, however, the nighttime TGM concentrations in fall were much higher than other
422 seasons. As described earlier in Section 5.3, the high TGM concentrations in fall was
423 possibly due to the relationship between other pollutants and meteorological conditions as
424 well as different wind direction and sources. The nighttime TGM concentrations in fall were
425 simultaneously positively correlated with PM_{10} ($r=0.26$) ($p<0.05$) and CO ($r=0.21$) ($p<0.05$)
426 concentrations and wind speed ($r=0.35$) ($p<0.01$), suggesting that the combustion process is
427 an important source during this period.

428 Based on the above results, the diurnal variations in TGM concentration are due to a
429 combination of: 1) reactions with an oxidizing atmosphere, 2) changes in ambient
430 temperature and 3) local emissions related to industrial activities. To supplement these
431 conclusions CPF and CBPF were used to identify source directions and TPSCF was used to
432 identify potential source locations.

433

434 *5.6. CPF, CBPF and TPSCF results of TGM*

435 Conventional CPF, CBPF and TPSCF plots for TGM concentrations higher than the
436 average concentration show high source probabilities to the west in the direction of large steel
437 manufacturing facilities and waste incinerators (Fig. 4). The CPF only shows high
438 probabilities from the west and provides no further information, however, the CBPF shows

439 groups of sources with the high probabilities from the west and the northeast. CBPF shows
440 that the high probabilities from the west occurred under high wind speed ($> 3 \text{ m s}^{-1}$)
441 indicative of emissions from stacks as well as low wind speed ($\leq 3 \text{ m s}^{-1}$) indicative of non-
442 buoyant ground level sources (Uria-Tellaetxe and Carslaw, 2014).

443 As described in Section 5.4, correlations between TGM and CO revealed that TGM and
444 CO were affected by similar anthropogenic emission sources in winter but affected by
445 different sources in spring, summer and fall, which is supported by Fig. S6 which shows
446 significantly different seasonal patterns of CPF and CBPF for TGM concentrations.

447 It is difficult to discuss about the different seasonal patterns for CPF and CBPF for TGM
448 concentrations since there were no correlations between TGM and other pollutants in spring,
449 summer and fall except O_3 . However, compared to Fig. 4, the CPF and CBPF patterns in fall
450 were similar to those during the whole sampling periods. Especially, the nighttime TGM
451 concentration in fall was simultaneously positively correlated with PM_{10} ($r=0.26$) ($p<0.05$)
452 and CO ($r=0.21$) ($p<0.05$) concentrations and wind speed ($r=0.35$) ($p<0.01$), indicating that
453 the combustion process from the west is an important source during this period.

454 Since TGM showed a significant correlation with CO ($r=0.25$) ($p<0.05$) and showed a
455 weak positive correlation with PM_{10} ($r=0.08$) ($p=0.33$) in winter with high wind speed,
456 combustion sources from the west are likely partially responsible for this result.

457 TPSCF identified the likely sources of TGM as the iron and manufacturing facilities and
458 the hazardous waste incinerators which are located to the west from the sampling site. A
459 previous study reported that the waste incinerators (9%) and iron and steel manufacturing
460 (7%) were relatively high Hg emissions sources in Korea (Kim et al., 2010). Waste
461 incinerators emissions were due to the high Hg content in the waste (Lee et al., 2004).
462 Emissions from iron and steel manufacturing are due to the numerous electric and sintering

463 furnaces using coking which emits relatively high mercury concentrations (Lee et al., 2004)
464 in Gyeongsangbuk-do including Pohang. There are several coke plants around the sampling
465 site (http://www.poscoenc.com/upload/W/BUSINESS/PDF/ENG_PLANT_2_1_3_5.pdf
466 (accessed December 09, 2015)). They are essential parts of the iron and steel manufacturing,
467 and the major source of atmospheric mercury related to the iron and steel manufacturing is
468 from coke production (Pacyna et al., 2006).

469 The coastal areas east of the sampling site where there are large ports were also identified
470 as the likely source areas of TGM. A previous study reported that the emissions of gaseous
471 and particulate pollutants were high during vehicular operations in port areas and from
472 marine vessel and launches (Gupta et al., 2002). Another possibility is that significant amount
473 of GEM are emitted from the ocean surface because of photo-chemically and
474 microbiologically mediated photo-reduction of dissolved GOM (Amyot et al., 1994; Zhang
475 and Lindberg, 2001). The northeast direction including the East Sea was also identified as
476 potential source areas likely because this is an area with lots of domestic passenger ships
477 routes. The south from the sampling was also identified as a likely source area of TGM where
478 Ulsan Metropolitan City, South Korea's seventh largest metropolis with a population of over
479 1.1 million is located. It includes a large petrochemical complex known as a TGM source
480 (Jen et al., 2013).

481

482 **Conclusions**

483 During the sampling periods, the average TGM concentration was higher than the Northern
484 Hemisphere background concentration, however, considerably lower than those near
485 industrial areas in China and higher than those in Japan and other locations in Korea. The
486 median concentration of TGM was much lower than that of the average, suggesting that there
487 were some extreme pollution episodes with very high TGM concentrations. The TGM
488 concentration was highest in fall, followed by spring, winter and summer. The high TGM
489 concentration in fall is due to transport from different wind directions than during the other
490 periods. The low TGM concentration in summer is likely due to increased mixing height and
491 gas phase oxidation at higher temperatures particularly at this sampling site which is close to
492 the ocean (2 km) where oxidation involving halogens may be enhanced.

493 TGM consistently showed a diurnal variation with a maximum in the early morning
494 (06:00-09:00) and minimum in the afternoon (14:00-17:00). Although there was a statistically
495 significant negative correlation between the TGM concentration and ambient air temperature,
496 the daytime TGM concentration was higher than those in the nighttime, suggesting that local
497 emission sources are important. There was a negative relationship between the TGM
498 concentrations and O₃ concentrations, indicating that the oxidation was partially responsible
499 for the diurnal variations of TGM concentrations. The observed $\Delta\text{TGM}/\Delta\text{CO}$ was
500 significantly lower than that indicative of Asian long-range transport, suggesting that local
501 sources are more important than that of long-range transport. CPF only shows high
502 probabilities to the west from the sampling site where there are large steel manufacturing
503 facilities and waste incinerators. However, CBPF and TPSCF indicated that the dominant
504 sources of TGM were the hazardous waste incinerators and the coastal areas in the northeast

505 as well as the iron and manufacturing facilities in the west. The domestic passenger ships
506 routes in the East Sea were also identified as possible source areas.

507

508 **Author contribution**

509 Yong-Seok Seo conducted a design of the study, the experiments and analysis of data, wrote
510 the initial manuscript, and finally approved the final manuscript. Seung-Pyo Jeong, Eun Ha
511 Park, Tae Young Kim, Hee-Sang Eum, Dae Gun Park, Eunhye Kim, Jaewon Choi and Jeong-
512 Hun Kim conducted the experiments, analysis of data, and finally approved the final
513 manuscript. Thomas M. Holsen, Young-Ji Han and Eunhwa Choi and Soontae Kim
514 conducted interpretation of the results, revision of the initial manuscript, and finally approved
515 the final manuscript. Seung-Muk Yi conducted a design of the study, acquisition of data of the
516 study, interpretation of data, and revision of the initial manuscript, and finally approved the final
517 manuscript.
