Point-by-point response to review comments on manuscript acp-2015-997
"Determination of Primary combustion source organic carbon-to-elemental carbon (OC/EC) ratio using ambient OC and EC measurements: Secondary OC-EC correlation minimization method"

By Cheng Wu and Jian Zhen Yu

We thank the two anonymous reviewers for their constructive comments. Our point-by-point responses to the review comments are listed below. Changes to the manuscript are marked in blue in the revised manuscript. The marked manuscript is submitted together with this response document.

## Anonymous Referee \#1

Dear Editor, this MS presents a statistical assessment of an alternative method to quantify secondary organic carbon (SOC) in ambient air samples. This method is an alternative to the classic EC tracer method. It is a useful assessment of an alternative method which seems to perform rather well, and therefore merits publication. Reading is somewhat complicated due to the frequent use of abbreviations (eg, fSOC), though. A more fluent writing style would help the reader.

Author's Response: We add a table (also shown below) in the revised main text to help readers to have a quick check of abbreviations used in the paper. We believe this would be more reader-friendly than looking for definitions that scattered in the main text. Please see below for point-by-point response to reviewers' comments.

Table 1. Acronyms and Abbreviations

| Abbreviation | Definition |
| :---: | :---: |
| EC | elemental carbon |
| $\mathrm{EC}_{1}, \mathrm{EC}_{2}$ | EC from source 1 and source 2 in the two-source scenario |
| $\mathrm{f}_{\mathrm{EC} 1}$ | fraction of EC from source 1 to the total EC |
| $\mathrm{f}_{\text {SOC }}$ | ratio of SOC to OC |
| MRS | minimum R squared method |
| MRS' | A variant of MRS that use EC from individual sources as input |
| MT | Mersenne twister pseudorandom number generator |
| $n$ | sample size in MT data generation |
| OC | organic carbon |
| OC/EC | OC to EC ratio |
| (OC/EC) $)_{\text {pri }}$ | primary OC/EC |
| OC/EC $\mathrm{ES}_{10}$ | OC/EC at $10 \%$ percentile |
| $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ | minimum OC/EC |
| $\mathrm{OC}_{\text {non-comb }}$ | OC from non-combustion sources |
| PDF | probability density function of a distribution |
| POC | primary organic carbon |
| ROA | ratio of averages |
| RSD | relative standard deviation |
| $\mathrm{RSD}_{\text {EC }}$ | RSD of EC |
| $\mathrm{RSD}_{\text {POC }}$ | RSD of POC |
| $\mathrm{RSD}_{\text {soc }}$ | RSD of SOC |
| SOC | secondary organic carbon |
| $\mathrm{SOC}_{\text {svP }}$ | SOC formed from semi-volatile POC |
| $\Upsilon$ ¢pri | ratio of the (OC/EC) pri of source 2 to source 1 |
| $\varepsilon_{\mathrm{EC}}, \varepsilon_{\mathrm{OC}}$ | measurement uncertainty of EC and OC |
| $\Upsilon_{\text {unc }}$ | relative measurement uncertainty |
| $\gamma_{\text {_RSD }}$ | the ratio between the RSD values of (OC/EC) pri and EC |

Some specific comments:

- line 75: I believe Pio et al propose yet another method, using a subset of samples with $5 \%$ lowest ratios and discarding the 3 lowest... I don't have the exact reference right now, but please add.

Author's Response: Suggestion taken. The reference (Pio et al., 2011) is now added in the main text.

## Lines 74-78

"Combinations of the fixed percentile and the minimum (OC/EC) pri approaches were also used in order to accommodate different sample sizes available. For example, Pio et al. (2011) suggested using the lowest $5 \%$ subset to obtain the (OC/EC) pri, and if the sample size of $5 \%$ subset is less than three, the lowest three data points are used to determine (OC/EC) pri."

## Reference

Pio, C., Cerqueira, M., Harrison, R. M., Nunes, T., Mirante, F., Alves, C., Oliveira, C., de la Campa, A. S., Artinano, B., and Matos, M.: OC/EC ratio observations in Europe: Re-thinking the approach for apportionment between primary and secondary organic carbon, Atmos Environ, 45, 6121-6132, DOI 10.1016/j.atmosenv.2011.08.045, 2011.

- line 90: any reason why the Millet method was overlooked?

Author's Response: One reason is that Millet's original paper focused on VOCs, and the MRS approach was used to calculate primary ratio of VOCs/EC to differentiate primary and secondary VOCs. A second reason we believe is a lack of evaluation work for this method. As a result, the approach initially proposed by Millet et al did not draw much attention from the OC/EC measurement community.

- line 211: please elaborate on why the OCEC $10 \%$ method provides worse results

Author's Response: Based on the observational data we have, the ambient conditions most likely falls into the scenario between scenario A and B (Figure 3). As such, ${\mathrm{OC} / \mathrm{EC}_{10 \%} \text { is further away from }}^{2}$ the true $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ than $\mathrm{OC} / \mathrm{EC}_{\text {min }}$, resulting larger bias.

- line 226: I don't understand the different behavior of the OCEC $_{10 \%}$ amend the OCEC $_{\text {min }}$ methods, given that they are both subsets of the total dataset with specific characteristics of representing $1 \%$ and $10 \%$. Why is their behavior different?

Author's Response: Change of $\mathrm{f}_{\mathrm{SOC}}$ not only changes the position of OC/EC distribution relative to $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ distribution, but can also alter the width of OC/EC distribution. Because the subset methods rely on percentile of OC/EC, once the OC/EC distribution is widened, the relative position between $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ is also changed and this results in a non-linear response in SOC differences,

- section uncertainty: with some analytical methods (e.g., TOT) the uncertainty is mostly constant ( $0,1-0,2$ micrograms $/ \mathrm{cm} 2$ ), please discuss how this would affect the results in this section.

Author's Response: Under the scenario of constant absolute uncertainty, the performance of MRS (Figure R1, $0.2 \mathrm{mg} \mathrm{m}^{-3}$ ) is similar to that assuming a fix proportional measurement uncertainty (Figure R2, 10\% measurement uncertainty). Both Figures R1 and R2 are included in the revised main text as Figure 8.

Figure R1. SOC estimation bias as a function of sample size, assuming fixed absolute measurement uncertainty for OC and EC $\left(0.2 \mu \mathrm{gC} \mathrm{m} \mathrm{m}^{-3}\right)$. For each sample size, 500 repeat runs were conducted. The circles represent mean of 500 repeat runs, the whiskers represent one standard deviation. Parameters used for testing: Repeat runs $=500 ; \mathrm{N}=20 \sim 8000 ; \mathrm{EC}=8 \pm 4 \mu \mathrm{gC} \mathrm{m}{ }^{-3} ;(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5 ; \mathrm{POC}=4 \pm 2$ $\mu \mathrm{gC} \mathrm{m}{ }^{-3}, \mathrm{f}_{\mathrm{SOC}}=40 \%$, and $\mathrm{SOC}=2.67 \pm 1.33 \mu \mathrm{gC} \mathrm{m}$.

Figure R2. SOC estimation bias as a function of sample size, assuming a fixed relative measurement uncertainty of $10 \%$ for OC and EC. For each sample size, 500 repeat runs were conducted. The open circle represents the mean of 500 repeat runs, and the whisker represents one standard deviation. Parameters used for testing: Repeat runs $=500 ; \mathrm{N}=8000 ; \mathrm{EC}=8 \pm 4 \mu \mathrm{gC} \mathrm{m}{ }^{-3} ;(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5 ; \mathrm{POC}$ $=4 \pm 2 \mu \mathrm{gC} \mathrm{m}{ }^{-3}, \mathrm{f}_{\mathrm{SOC}}=40 \%$, and $\mathrm{SOC}=2.67 \pm 1.33 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$.

- line 317 , please clarify what the authors mean by "the irrelevance of EC and SOC", it is unclear to me

Author's Response: We now rephrased as "the independence of EC and SOC", by which we mean that SOC and EC come from uncorrelated sources.

## Anonymous Referee \#2

## Generally Comments

Typically the EC tracer method, when used in estimating the secondary organic carbon (SOC), relies on three conditions- 1) the relatively constant ( $\mathrm{OC} / \mathrm{EC}$ ) pri over the period of study; 2) the random nature of SOC formation relative to EC; and 3) a subset of dataset without significant SOC contributions. The $\mathrm{OC} / \mathrm{EC}_{10 \%}$ or $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ essentially utilize the subset in Condition $\# 3$ to derive the (OC/EC) pri if it does have an unique value. Any deviations from the conditions as well as measurement uncertainties will lead to bias in determining ( $\mathrm{OC} / \mathrm{EC})_{\text {pri. }}$. In some environments where SOC dominates, the third condition is generally impossible to be met. This study, through an extensive test, shows that the third condition is not necessary in calculating (OC/EC) pri, if an algorithm, i.e., minimum $\mathrm{R}^{2}$ (MRS), is used looking for (OC/EC) pri that yields SOC least correlated with EC. Without further examinations, the reviewer thinks that MRS is probably mathematically rigorous for any datasets satisfying the first two conditions and, additionally, with sufficient size and accuracy. It can perform better than $\mathrm{OC} / \mathrm{EC}_{10 \%}$ or $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ most of the time because Condition 3 is fortuitous, as described by the authors.
While the reviewer agrees that MRS should be used instead of $\mathrm{OC} / \mathrm{EC}_{10 \%}$ or $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ in calculating SOC, particularly for a large dataset which can support meaningful correlation analysis, MRS does not solve fundamental problems in the EC tracer method. The (OC/EC) priis by no means constant, as it varies with source contributions from day to day and season to season. SOC is likely correlated with EC because in urban areas many SOC precursors originate from the same combustion sources as EC. This paper demonstrates that when Conditions 1 and 2 are in doubt, MRS produces erroneous results. MRS results are also sensitive to measurement uncertainty that impacts the correlation coefficients. These limitations, however, are not emphasized adequately in the abstract, which sounds almost like MRS has tackled all these issues. These issues, still, can only be solved by using multivariate or chemical mass balance analysis with additional markers.

Author's Response: Thanks for the very insightful comments. We agree that ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ varied from day to day and season to season in reality and this limitation is intrinsic in the EC tracer method regardless different approaches in implementing the EC tracer method, unless it is applied in a time frame small enough that variations of ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ is almost negligible. Limits posed by the nature of ambient ECOC data are inherent to the EC tracer method and common to all the variants of the EC tracer method. This study focuses on evaluating different ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ determination approaches within the EC tracer method, with the aim to identify the best approach in applying the EC tracer method. We have revised the wording in the abstract and in main text to emphasize the limitations of the EC tracer method and the MRS approach. Please see below the specific revisions in our point-by-point response to reviewers' comments.

## Specific Comments

Abstract: Please describe the assumptions of MRS, datasets that are suitable for MRS analysis, and potential errors while in the same time shortening the abstract. Just saying MRS is better than $\mathrm{OC} / \mathrm{EC}_{10 \%}$ or $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ is not meaningful because all the three could be very wrong in some cases.

Author's Response: We have made the following revisions in the abstract to clearly state the assumptions of MRS.

Line 28:
"The hypothetical $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ that generates the minimum $\mathrm{R}^{2}(\mathrm{SOC}, \mathrm{EC})$ then represents the actual $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ ratio if variations of EC and SOC are independent and $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ is relatively constant in the study period."

Line 38-41:
"...MRS provides an unbiased SOC estimation when measurement uncertainty is small. MRS results are sensitive to the magnitude of measurement uncertainty but the bias would not exceed $23 \%$ if the uncertainty is controlled within $20 \%$."

We also shortened slightly the abstract by condensing a few sentences and removing the following sentence (this background information is spelled out in the introduction section).

## "The general coneep embedied in the MRS methe was initially proposed by Miller at (2005), but has no bee aluated for aceur atility sinee its debu.".

Line 97-102: While using simulated data is insightful, it offers no proof. The authors may explore if there is a true "proof" from mathematical or statistical derivations that MRS will yield true (OC/EC) pri if SOC is indeed random and the dataset is big enough. This may also answer the question- how big is big? MRS does not seem suitable for a dataset with only dozens of points.

## Author's Response:

We agree that the simulated data alone does not offer proof, as there is no guarantee that the simulated data capture all the essential features of real-world data. In response to this comment, we conducted a series of sensitivity tests to evaluate the SOC estimation dependency on sample size, which was varied from 20 to 8000 . For each sample size, 500 repeat runs were tested, assuming a single value $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ with a measurement uncertainty of $10 \%$. The results are in Fig. R2, showing the average and the standard deviation for each sample size. The standard variation of SOC bias by MRS decreases with increased sample size while the mean of SOC bias remains a constant small value ( $2 \%$ ). The standard variation of SOC bias is $\sim \pm 30 \%$ at the lowest tested sample size $(n=20)$, and decreases to less than $15 \%$ at $n=60$ (the sample size of one-year sampling from an every-six-day sampling program) and to less than $10 \%$ at $n=200$. Other scenarios considering $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ with a distribution and different $\mathrm{f}_{\text {SOC }}$ are discussed in SI. Figure R2 will be included in the main text.

A new section (as shown below) is added to the manuscript to address the sample size question.

Figure R2. SOC estimation bias as a function of sample size, assuming a fixed relative measurement uncertainty of $10 \%$ for OC and EC. For each sample size, 500 repeat runs were conducted. The open circle represents the mean of 500 repeat runs, and the whisker represents one standard deviation. Parameters used for testing: Repeat runs $=500 ; \mathrm{N}=8000 ; \mathrm{EC}=8 \pm 4 \mu \mathrm{gC} \mathrm{m}{ }^{-3} ;(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5 ;$ POC $=1 \pm 0.5 \mu \mathrm{gC} \mathrm{m}^{-3}, \mathrm{f}_{\mathrm{SOC}}=40 \%$, and $\mathrm{SOC}=0.67 \pm 0.34 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$.

## "2.4 Impact of sample size

MRS rely on correlations of input variables and it is expected that MRS performance is sensitive to the sample size of input dataset. This section examines the sensitivity on sample size by the three (OC/EC) pri ${ }^{\text {r }}$ ( applying MRS on ambient OCEC data. Sample sizes ranging from $20 \sim 8000$ are tested and for each sample size 500 repeat runs are conducted to obtain statistically significant results. Both Case A (i.e., a constant relative uncertainty of $10 \%$ ) and Case B (i.e., a constant absolute uncertainty of $\pm 0.2 \mu \mathrm{gC} \mathrm{m}$ m for both OC and EC) are considered. The measurement uncertainties in case B are generated separately by MT following a uniform distribution within the range of $\pm 0.2 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$. The measurement uncertainties of POC and SOC are then back-calculated following the uncertainty propagation formula (Harris, 2010) and assuming the ratio of $\varepsilon_{\mathrm{POC}} / \varepsilon_{\mathrm{SOC}}$ is the same as POC/SOC ratio (controlled by $\mathrm{f}_{\mathrm{SO}}$ ).
The mean SOC bias by MRS is very small ( $<3 \%$ ) for all sample sizes while the standard deviation of SOC bias decreases with sample size (Figure 8). The standard deviation of SOC bias is $\sim \pm 30 \%$ at the lowest test sample size ( $n=20$ ), and decreases to less than $\pm 15 \%$ at $n=60$ (the sample size of one-year sampling from an every-six-day sampling program) and to less than $\pm 10 \%$ at $n=200$. Similar patterns are observed between Case A (Figure 8a) and Case B (Figure 8b) for MRS and $\mathrm{OC}_{\mathrm{OCC}}^{10 \%}$. For $\mathrm{OC} / \mathrm{EC}_{\text {min }}$, a larger bias is observed in Case B than Case A for all sample sizes, as SOC bias by $O C / E C_{\min }$ is more sensitive to measurement uncertainty in the range of $0 \sim 10 \%$ as shown in Figure 7b. The standard deviation of SOC bias by $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ both decreases with sample size as shown in Figure 8. The mean SOC bias of $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ decrease with increased sample size while $\mathrm{OC} / \mathrm{EC}_{10 \%}$ is insensitive to sample size. The sample size dependency of all three (OC/EC) $)_{\text {pri }}$ representations is not sensitive to $f_{\text {SOC }}$ as shown in Figure S16. Other scenarios considering (OC/EC) pri with a distribution and different $\mathrm{f}_{\text {Soc }}$ are discussed in SI."

Line 116-118: How good are the K-S statistics? In other words, how well did the pseudorandom number generator reproduce the statistics in the original dataset?

Author's Response: The K-S statistics for ambient measured data are shown in Figures S1-S4 (This information is now also mentioned in the main text). In Igor Pro's Kolmogorov-Smirnov test, D represents the K-S statistic, C represent critical value. If $\mathrm{D}<\mathrm{C}$, the samples follow the corresponding distribution (e.g., normal or log-normal distribution). The majority of the data can pass the K-S test for log-normal distribution and some exhibit a bimodal distribution. For the performance of the MT pseudorandom number generator, we conduct a series of K-S tests on the generated data for 5000 runs, which show $94.4 \%$ data having D small than C (Fig. R3). Hence, we believe the pseudorandom number generator could produce the data following preset characteristics. Figure R3 is added to the SI and referred to in the main text.

Figure R3 Performance of the MT pseudorandom number generator evaluated by K-S test. The histogram in grey represents D statistic value in $\mathrm{K}-\mathrm{S}$ test and the red dashed-line represents C . The dash line in green represents cumulative distribution of D . Data with $\mathrm{D}<\mathrm{C}$, i.e., data that strictly follow the log-normal distribution, account for $94.4 \%$ in 5000 runs.

The below text is added to the manuscript to describe whether the pseudorandom number generate reproduce the statistics in the original dataset.

Lines 142-145:
"For the verification of the log-normality of MT generated data, a series of K-S tests on the generated data for 5000 runs are conducted. As shown in Figure S6, $94.4 \%$ of runs pass the K-S test. Hence the performance of MT can satisfy the log-normal distributed data generation requirement in this study".

Line 126: Eqs. (4)-(5) do not work for all datasets. They are probably asymptotes when datasets are large enough in size.

Author's Response: We agree that they do not necessarily work for all datasets. The reason for translating mean and standard deviations into $\mu$ and $\sigma$ is that the MT pseudorandom number generator in Igor Pro only accepts $\mu$ and $\sigma$ as input parameters, while mean and standard deviations are the parameters that can be obtained from ambient measurements.

Line 136: Mention here that the case with combustion-related SOC is discussed later.
Author's Response: Suggestion taken. The text below is included in the revised manuscript:
Line 140 :
"The case with combustion-related SOC is briefly discussed in section 3."
Line 151-152: The results of log-normally distributed (OE/CC) pri should be summarized in the text if possible.

Author's Response: Suggestion taken. The below text is added to the section 2.2.1:

Lines 219-225:
"For the representation of (OC/EC) pri in the simulated data as lognormally distributed data, analysis is also performed to evaluate SOC estimation bias as a function of $\mathrm{RSD}_{\mathrm{EC}}, \mathrm{RSD}_{\mathrm{SOC}}$, and $\mathrm{f}_{\mathrm{SOC}}$. Table

S2 summarizes the results obtained with adopting most probable ambient conditions (i.e., $\mathrm{RSD}_{\mathrm{EC}}$ : $50-100 \%$, $\mathrm{f}_{\text {SOC }}: 40-60 \%$ ). SOC bias by MRS is within $4 \%$ when measurement uncertainty is ignored. In comparison, SOC bias by $\mathrm{OC} / \mathrm{EC}_{\min }$ is more sensitive to assumption of log-normally distributed $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ than single value $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$, including the dependency on $\mathrm{RSD}_{\mathrm{EC}}$ and $\mathrm{RSD}_{\mathrm{SOC}}$ with varied $\mathrm{f}_{\text {SOC... }}$

Line 220-222: It is not clear if $\mathrm{f}_{E C 1}$ was varied from sample to sample in a single test or only varied from test to test. If the former, how could you make sure EC1 and EC2 are highly correlated?

Author's Response: $\mathrm{f}_{E C 1}$ was varied from test to test. The text is now clarified as below:
Lines 229-231:
"By varying $\mathrm{f}_{\mathrm{EC} 1}$ (proportion of source 1 EC to total EC ) from test to test, the effect of different mixing ratios of the two sources can be examined."

Line 284-286: Since POC and SOC are not directly measured, what is the meaning to simulate their measurement uncertainty?

Author's Response: Once OC and EC data are considered to have measurement uncertainty, the derived quantities POC and SOC (using Eq (1) and Eq (2)) consequently also have associated uncertainty, which can be calculated following uncertainty propagation principle. For the evaluation of SOC estimation, SOC calculated from the EC tracer method needs to be compared with "true SOC plus associated uncertainty". That's the reason why we calculated the uncertainties of POC and SOC

Line 384: How were the six subsets selected?

Author's Response: With a given one-year data set, there are six possible extractions of daily data sets corresponding to the assumed every-six-day sampling schedule, i.e., set $1:\{$ Day $1,7,13, .$.$\} , set 2$ :
$\{$ Day $2,8,14, .$.$\} , set 3:\{$ Day $3,9,15, .$.$\} , etc. The text below is added to clarify this point:$
Lines 368-371:
"The one-year data yields six subsets of daily samples, corresponding to six possible schedules of sampling days with the every-six-day sampling frequency. The MRS calculation produces the $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ in the range of $2.37-2.75 \ldots$ "

Line 360-362: Emphasize that this only happens when measurement uncertainties are small.
Author's Response: Suggestion taken. This sentence is revised as below:

Lines 408-413:
"In the scenarios of a single primary source and two well-correlated primary combustion sources, SOC estimates by MRS are unbiased while $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ consistently underestimate SOC when measurement uncertainty is neglected. When measurement uncertainty is considered, all three approaches produce biased SOC estimates, with MRS producing the smallest bias. The bias by MRS is less than $25 \%$ when measurement uncertainty is within $20 \%$ and $\mathrm{f}_{\text {SOC }}$ is not lower than 20\%."

# Determination of Primary combustion source organic carbon-to-elemental carbon (OC/EC) ratio using ambient OC and EC measurements: Secondary OC-EC correlation minimization method

#### Abstract

Elemental carbon (EC) has been widely used as a tracer to track the portion of co-emitted primary organic carbon (OC) and, by extension, to estimate secondary OC (SOC) from ambient observations of EC and OC. Key to this EC tracer method is to determine an appropriate $\mathrm{OC} / \mathrm{EC}$ ratio that represents primary combustion emission sources (i.e., $\left.(\mathrm{OC} / \mathrm{EC})_{\text {pri }}\right)$ at the observation site. The conventional approaches include regressing OC against EC within a fixed percentile of the lowest (OC/EC) ratio data (usually 5-20\%) or relying on a subset of sampling days with low photochemical activity and dominated by local emissions. The drawback of these approaches is rooted in its empirical nature, i.e., a lack of clear quantitative criteria in the selection of data subsets for the $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ determination. We examine here a method that derives $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ through calculating a hypothetical set of (OC/EC) pri and SOC followed by seeking the minimum of the coefficient of correlation ( $\mathrm{R}^{2}$ ) between SOC and EC. The hypothetical (OC/EC) pri that generates the minimum $\mathrm{R}^{2}$ (SOC,EC) then represents the actual (OC/EC) pri ratio if variations of EC and SOC are independent and (OC/EC) pri is relatively constant in the study period. This Minimum R Squared (MRS) method has a clear quantitative criterion for the (OC/EC) pri calculation. This work uses numerically simulated data to evaluate the accuracy of SOC estimation by the MRS method

and to compare with two commonly used methods: minimum $\mathrm{OC} / \mathrm{EC}\left(\mathrm{OC} / \mathrm{EC}_{\min }\right)$ and $\mathrm{OC} / \mathrm{EC}$ percentile ( $\mathrm{OC} / \mathrm{EC}_{10 \%}$ ). Log-normally distributed EC and OC concentrations with known proportion of SOC are numerically produced through a pseudorandom number generator. Three scenarios are considered, including a single primary source, two independent primary sources, and two correlated primary sources. The MRS method consistently yields the most accurate SOC estimation. Unbiased SOC estimation by OC/EC min and $\mathrm{OC} / \mathrm{EC}_{10}$ \% only occurs when the left tail of OC/EC distribution is aligned with the peak of the (OC/EC) pri distribution, which is fortuitous rather than norm. In contrast, MRS provides an unbiased SOC estimation when measurement uncertainty is small. MRS results are sensitive to the magnitude of measurement uncertainty but the bias would not exceed $23 \%$ if the uncertainty is within $20 \%$.

## 1 Introduction

Organic carbon (OC) and elemental carbon (EC) are among the major components of fine particular matter $\left(\mathrm{PM}_{2.5}\right)$ (Malm et al., 2004). EC is a product of carbon fuel-based combustion processes and is exclusively associated with primary emissions whereas OC can be from both direct emissions and be formed through secondary pathways. Differentiation between primary organic carbon (POC) and secondary organic carbon (SOC) is indispensable for probing atmospheric aging processes of organic aerosols and formulating effective emission control policies. However, direct SOC measurement is not yet feasible, as there lacks knowledge of its chemical composition at the molecular level. Due to its exclusive origin in primary combustion sources, EC was first proposed by Turpin and Huntzicker (1991) to serve as the tracer to track POC from primary combustion sources and, by extension, to estimate SOC as SOC is simply the difference between OC and POC. This EC tracer method only requires measurements of OC and EC. Due to its simplicity, the EC tracer method has been widely adopted in studies reporting ambient OC and EC measurements (e.g., Castro et al., 1999;Cao et al., 2004;Yu et al., 2004). If OC and EC concentrations are available and primary OC from non-combustion sources ( $\mathrm{OC}_{\text {non-comb }}$ ) is negligible, SOC can be estimated using EC as the tracer for combustion source POC (Turpin and Huntzicker, 1995):

$$
\begin{gather*}
P O C=(O C / E C)_{p r i} \times E C  \tag{1}\\
S O C=O C_{\text {total }}-(O C / E C)_{p r i} \times E C \tag{2}
\end{gather*}
$$

where $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ is the $\mathrm{OC} / \mathrm{EC}$ ratio in freshly emitted combustion aerosols, and $\mathrm{OC}_{\text {total }}$ and EC are available from ambient measurements. Abbreviations used in this study are summarized in Table 1.

The key step in the EC tracer method is to determine an appropriate OC/EC ratio that represents primary combustion emission sources (i.e., $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ ) at the observation site. Various approaches in deriving ( $\mathrm{OC} / \mathrm{EC}$ ) pri reported in the literature are either based on emission inventory (Gray et al., 1986) or ambient observation data. Using ambient observation data, three approaches are the most common: 1) regressing measured OC vs. EC data from times of low photochemical activity and dominated by local emissions; 2) regressing measured OC vs. EC data on a fixed percentile of the lowest OC/EC ratio (usually $5-20 \%$ ) data to represent samples dominated by primary emissions (Lim and Turpin, 2002;Lin et al., 2009;Pio et al., 2011); and 3) simply taking the minimum OC/EC ratio during the study period to approximate (OC/EC) pri (Castro et al., 1999). Combinations of the fixed
percentile and the minimum ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ approaches were also used in order to accommodate different sample sizes available. For example, Pio et al. (2011) suggested using the lowest $5 \%$ subset to obtain the (OC/EC) pri, and if the sample size of $5 \%$ subset is less than three, the lowest three data points are used to determine $(\mathrm{OC} / E C)_{\text {pri }}$. These approaches have the drawback in that there is not a clear quantitative criterion in the data selection for the (OC/EC) pri determination. Millet et al. (2005) was the first to propose an algorithm that explores the inherent independency between pollutants from primary emissions (e.g., EC) and products of secondary formation processes (e.g., SOC) to derive the primary ratios (e.g., $\left.(\mathrm{OC} / \mathrm{EC})_{\text {pri }}\right)$ for species with multiple source types. More specifically, for the determination of $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$, the assumed $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ value is varied continuously. At each hypothetical ( $\mathrm{OC} / \mathrm{EC})_{\text {pri, }}$, SOC is calculated for the data set and a correlation coefficient value $\left(R^{2}\right)$ of EC vs. SOC (i.e., $\left.R^{2}(E C, S O C)\right)$ is generated. The series of $R^{2}(E C, S O C)$ values are then plotted against the assumed (OC/EC) pri values. If variations of EC and SOC are independent, the assumed $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ corresponding to the minimum $R^{2}(E C, S O C)$ would then represent the actual (OC/EC) pri ratio. Such an approach obviates the need for an arbitrary selection criterion, as the algorithm seeks the minimum point, which is unique to the dataset. However, this method has largely been overlooked, with only one study reporting its use (Hu et al., 2012) since its debut, which may be a result of a lack of evaluation of its method performance. Hereafter for the convenience of discussion, we call this method the minimum $R$ squared (MRS) method, with a conceptual illustration of the MRS method shown in Figure 1. A computer program written in Igor Pro (WaveMetrics, Inc. Lake Oswego, OR, USA) is developed to feasible MRS calculation and it is available from https://sites.google.com/site/wuchengust.

With ambient OC and EC samples, the accuracy of estimated SOC by different (OC/EC) pri methods is difficult to evaluate due to the lack of a direct SOC measurement. The objective of this study is to investigate, through numerical simulations, the bias of SOC estimates by three different implementations of the EC tracer method. Hypothetic EC, OC, and (OC/EC) pri datasets with known break-down of POC and SOC values are numerically synthesized, then SOC is estimated and compared with the "true" SOC as defined by the synthetic datasets. As such, bias of SOC estimates using the various implementations of the EC tracer method can be quantified.

## 2 Evaluation of the Minimum R Squared Method

### 2.1 Data generation

We first examine ambient OC and EC for the purpose of identifying distribution features that can serve as the reference basis for parameterizing the numerical experiments. The one-year hourly EC and OC measurement data from three sites in the PRD (one suburban site in Guangzhou, a general urban site and a roadside site in Hong Kong, with more than 7000 data at each site), are plotted in Figure S1 in the supplemental information (SI) document for the whole year datasets and Figures S2-S4 for the seasonal subsets using the Nansha site as the example. A brief account of the field ECOC analyzers and their field operation is provided in the SI document. A detailed description of the measurement results and data interpretation for the sites will be given in a separate paper. The distributions of measured OC, EC and OC/EC are fitted by both normal and log-normal distribution curves and then examined by the Kolmogorov-Smirnov (K-S) test. The K-S statistic, D, indicates that log-normal fits all three distributions better than the normal distribution (D values are shown in Figure S1-S4). Therefore, log-normal distributions are adopted to define the OC, EC and OC/EC distributions during data generation in our numerical experiments. Statistics of these ambient OC and EC, along with a few other measurements reported in the literature, are summarized in Table 2 and are considered as the reference for data generation to better represent the real situation.

The probability density function (PDF) for the log-normal distribution of variable x is:

$$
\begin{equation*}
\mathrm{f}(\mathrm{x} ; \mu, \sigma)=\frac{1}{x \sigma \sqrt{2 \pi}} \times e^{-\frac{(\ln (x)-\mu)^{2}}{2 \sigma^{2}}} \tag{3}
\end{equation*}
$$

The two parameters, $\mu$ and $\sigma$, of the log-normal PDF are related to the average and standard deviation of $x$ through the following equations:

$$
\begin{gather*}
\mu=\ln (a v g)-0.5 \times \ln \left(1+\frac{s t d^{2}}{a v g^{2}}\right)  \tag{4}\\
\sigma=\sqrt{\ln \left(1+\frac{s t d^{2}}{a v g^{2}}\right)} \tag{5}
\end{gather*}
$$

First, realistic average and standard deviation values of EC, (OC/EC) pri, and OC (e.g. Figure S1 - S5) are adopted to calculate $\mu$ and $\sigma$. Then pseudo random number generator use $\mu$ and $\sigma$ to synthesize EC and OC data sets.

The Mersenne twister (MT) (Matsumoto and Nishimura, 1998), a pseudorandom number generator, is used in data generation. MT is provided as a function in Igor Pro. The system clock is utilized as the initial condition for generation of pseudorandom numbers. The data generated by MT has a very long period of $2^{19937}-1$, permitting large data size and ensuring
that pseudorandom numbers are statistically independent between each data generation. The latter feature ensures the independent relationship between EC and non-combustion related SOC data. The case with combustion-related SOC is briefly discussed in section 3. MT also allows assigning a log-normal distribution during pseudorandom number generation to constrain the data. For the verification of the log-normality of MT generated data, a series of K-S tests on the generated data for 5000 runs are conducted. As shown in Figure S6, 94.4\% of runs pass the K-S test. Hence the performance of MT can satisfy the log-normal distributed data generation requirement in this study. In a previous study, Chu (2005) used a variant of sine functions to simulate POC and EC, which limited the data size to 120 , and the frequency distributions of POC and EC exhibited multiple peaks, a characteristic that is not realistic for ambient measurements. The key information utilized in the EC tracer method is the correlation between EC and POC as well as the irrelevance between EC and SOC. The time series information is not needed in EC tracer method, making pseudorandom number generator a good fit for the evaluation purpose.

The procedure of data generation for the single emission source scenario is illustrated in Figure 2 and implemented by scripts written in Igor Pro. EC is first generated with the following parameters specified: sample size ( $n$ ), average and relative standard deviation (RSD\%) of the whole data set (see SI). The EC dataset statistically follows a log-normal distribution, while the sequence of each data point is randomly assigned. POC is then calculated by multiplying EC by (OC/EC) pri (Eq. 1). For simplicity, (OC/EC) pri is set to be a single value, while an analysis incorporating randomly generated log-normally distributed ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ values can be found in the SI material, and a brief summary is given in section 2.2. SOC data is independently generated in a similar way to that for EC. The sum of POC and SOC then yields the synthesized OC. OC and EC data generated in this way are used to calculate SOC by different implementations of the EC tracer method. The bias of SOC estimation can then be evaluated by comparing the calculated SOC with the 'true' SOC values. Data generation for the scenarios with two primary emission sources is similar to the single source scenario and the steps are illustrated in Figure S7.

### 2.2 Scenario Study

Three scenarios are considered. Scenario $1(\mathrm{~S} 1)$ considers one single primary emission source. Scenario 2 (S2) considers two correlated primary emission sources, i.e., two sets of EC, POC, and each source has a single but different $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ value. An example of S 2 is combined vehicular emissions from diesel-fuel and gasoline-fuel vehicles. These two sources of
vehicular emissions have different (OC/EC) pri, but often share a similar temporal variation pattern, making them well correlated. Scenario 3 (S3) considers two independent primary emission sources and simulates an ambient environment influenced by two independent primary emission sources, e.g. local vehicular emissions (lower (OC/EC) pri) and regional biomass burning (higher (OC/EC) $)_{\text {pri }}$ ).

In the following numerical experiments, three $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ estimation methods are examined and compared, including MRS, $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$. As a single point, $\mathrm{OC} / \mathrm{EC}_{\text {min }}$, in ambient samples may be subjected to large random uncertainties, thus data with the lowest $1 \% \mathrm{OC} / \mathrm{EC}$ are adopted instead to derive the $\mathrm{OC} / \mathrm{EC}_{\text {min }}$.

### 2.2.1 Single primary source scenario

Both $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ methods rely on a subset of ambient OC and EC data to approximate $(\mathrm{OC} / \mathrm{EC})_{\text {pri. }}$. Figure 3 provides a conceptual illustration of the relationships between (OC/EC) pri and the ambient OC/EC data, both are described to exhibit a log-normal distribution. As primary emissions move away from sources and aging processes start in the atmosphere, SOC is added to the particle OC fraction, elevating OC/EC above (OC/EC) pri. This in effect broadens the OC/EC distribution curve and shifts the distribution to the right along the OC/EC axis, and the degree of broadening and shift depends on degree of aging process. The conventional EC tracer method using $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ assumes that the left tail of ambient OC/EC distribution is very close to (OC/EC) pri. This assumption, however, is fortuitous, rather than the norm. Two parameters, the distance between the means of the (OC/EC) $)_{\text {pri }}$ and ambient OC/EC distributions and the relative breadth of the two distributions, largely determines the closeness of the approximation of $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\min }$ to (OC/EC) $)_{\text {pri. }}$. The distance between the two distributions depends on the fraction of SOC in OC (i.e., $\mathrm{f}_{\mathrm{SOC}}$ ), while the width of the ambient OC/EC distribution is closely associated with RSD of SOC ( $\mathrm{RSD}_{\mathrm{SOC}}$ ) and the width of the $(\mathrm{OC} / E C)_{\text {pri }}$ distribution is reflected in $\mathrm{RSD}_{\text {POC }}$ and $\mathrm{RSD}_{\mathrm{EC}}$. As shown in Figure 3a, only an appropriate combination of distance of the two distribution means and variances could lead to a close approximation of the (OC/EC) pri by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ or $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ (i.e., the left tail of $\mathrm{OC} / \mathrm{EC}$ distribution). If the ambient aerosol has a significant $\mathrm{f}_{\text {SOC }}$ shifting the ambient $\mathrm{OC} / \mathrm{EC}$ distribution such that its left tail is beyond $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ (Figure3b), then the left tail would overestimate $(\mathrm{OC} / \mathrm{EC})_{\text {pri. }}$. Underestimation of (OC/EC) $)_{\text {pri }}$ could also happen in theory as shown in Figure 3c if the ambient minimum OC/EC (left tail) is less than the mean of the (OC/EC) pri distribution (i.e., under conditions of very small $\mathrm{f}_{\mathrm{SOC}}$ ).

The above analysis reveals $f_{S O C}, R S D_{\text {SOC }}, R_{\text {RDOC }}$, and $R S D_{E C}$ are key parameters in influencing the accuracy of SOC estimation. As a result, they are chosen in the subsequent sensitivity tests in probing the SOC estimate bias under conditions of different carbonaceous aerosol compositions.

SOC estimation bias in S 1 as a function of $\mathrm{RSD}_{\mathrm{SOC}}$ and $\mathrm{RSD}_{\mathrm{EC}}$ are shown in Figures 4a and $4 b$. The SOC estimate by MRS is not affected by the magnitude of $\mathrm{RSD}_{\mathrm{EC}}$ and $\mathrm{RSD}_{\mathrm{SOC}}$, and is in excellent agreement with the true values (Figure 4). In comparison, SOC by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\mathrm{min}}$ is consistently biased lower and the degree of negative bias becomes larger with decreasing $\mathrm{RSD}_{\mathrm{SOc}}$ or $\mathrm{RSD}_{\mathrm{EC}}$. The $\mathrm{OC} / \mathrm{EC}_{10 \%}$ method always produces larger negative bias than the $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ method. At $\mathrm{RSD}_{\mathrm{SOC}}$ and $\mathrm{RSD}_{\mathrm{EC}}$ at $50 \%$, SOC estimate has a $-14 \%$ bias by $(\mathrm{OC} / \mathrm{EC})_{\min }$ and a $-45 \%$ bias by $\mathrm{OC} / \mathrm{EC}_{10 \%}$. These results confirm the hypothesis illustrated in the conceptual diagram (Figure 3) that the validity of using the left tail of OC/EC distribution depends on the distance of its distribution mean from ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ and the distribution breadth. Both $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and the $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ methods underestimate SOC and the degree of underestimation by the $\mathrm{OC} / \mathrm{EC}_{10 \%}$ method is worse.

For the representation of $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ in the simulated data as lognormally distributed data, analysis is also performed to evaluate SOC estimation bias as a function of $\mathrm{RSD}_{\mathrm{EC}}, \mathrm{RSD}_{\mathrm{SOC}}$, and $f_{\text {soc }}$. Table S 2 summarizes the results obtained with adopting most probable ambient conditions (i.e., $\mathrm{RSD}_{\mathrm{EC}}: 50-100 \%$, $\mathrm{f}_{\mathrm{SO}}: 40-60 \%$ ). SOC bias by MRS is within $4 \%$ when measurement uncertainty is ignored. In comparison, SOC bias by $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ is more sensitive to assumption of log-normally distributed (OC/EC) pri than single value (OC/EC) pri, including the dependency on $\mathrm{RSD}_{\mathrm{EC}}$ and $\mathrm{RSD}_{\mathrm{SOC}}$ with varied $\mathrm{f}_{\mathrm{SOC}}$.

### 2.2.2 Scenarios assuming two primary sources

In the real atmosphere, multiple combustion sources impacting a site is normal. We next evaluate the performance of the MRS method in scenarios of two primary sources and arbitrarily dictate that the $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ of source 1 is lower than source 2 . By varying $\mathrm{f}_{\mathrm{EC} 1}$ (proportion of source 1 EC to total EC ) from test to test, the effect of different mixing ratios of the two sources can be examined. Common configurations in S2 and S3 include: $\mathrm{EC}_{\text {total }}=2 \pm 0.4 \mu \mathrm{gC} \mathrm{m}{ }^{-3} ; \mathrm{f}_{\mathrm{EC} 1}$ varies from 0 to $100 \%$; ratio of the two $O C / E C_{\text {pri }}$ values $\left(\gamma_{\_ \text {pri }}\right)$ vary in the range of $2 \sim 8$.

In Scenario 2 (i.e., two correlated primary sources), three factors are examined, including $\mathrm{f}_{\mathrm{EC} 1}$, $\gamma_{-p r i}$ and $f_{S O C}$, to probe their effects on SOC estimation. By varying $f_{\mathrm{ECL}}$, the effect of
different mixing ratios of two sources can be examined, as $\mathrm{f}_{\mathrm{EC} 1}$ is expected to vary within the same ambient dataset as a result of spatiotemporal dynamics of air masses. MRS reports unbiased SOC, irrespective of different $\mathrm{f}_{\mathrm{EC} 1}$ and $\mathrm{f}_{\mathrm{SOC}}$ or $\gamma_{\text {_pri }}$ (Figure 5). In comparison, SOC by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\min }$ are underestimated. The degree of underestimation depends on $\mathrm{f}_{\text {SOC }}$, e.g., $-12 \%$ at $\mathrm{f}_{\text {SOC }}=25 \%$ versus $-20 \%$ at $\mathrm{f}_{\text {SOC }}=40 \%$ in the $\mathrm{OC} / E C_{\text {min }}$ method while the magnitude of underestimation has a very weak dependence on $\mathrm{f}_{\mathrm{SOC}}$ in the $\mathrm{OC} / \mathrm{EC}_{10 \%}$ method, staying around $-40 \%$ as $\mathrm{f}_{\text {SOc }}$ is doubled from $20 \%$ to $40 \%$. The degree of SOC bias by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ are independent of $\mathrm{f}_{\mathrm{EC} 1}$ and $\gamma_{\_ \text {pri, }}$, as SOC bias is associated with $\mathrm{RSD}_{\mathrm{EC}}, \mathrm{RSD}_{\mathrm{SOC}}$ and $\mathrm{f}_{\mathrm{SOC}}$. Since two primary sources are well correlated, $\mathrm{RSD}_{\mathrm{EC}}$ is equivalent between the two sources. As a result, the overall $\mathrm{RSD}_{\mathrm{EC}}$ is constant when $\mathrm{f}_{\mathrm{EC} 1}$ and $\gamma_{-}$pri vary, and the SOC bias is independent of $\mathrm{f}_{\mathrm{EC} 1}$ and $\gamma_{\_ \text {pri }}$

In summary, in scenarios of two well-correlated primary combustion sources, MRS always produces unbiased SOC estimates while $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ consistently underestimate SOC , with $\mathrm{OC} / \mathrm{EC}_{10 \%}$ producing larger negative bias.

As for Scenario 3 in which two independent primary sources co-exist, SOC estimates by MRS could be biased and the degree and direction of bias depends on $\mathrm{f}_{\mathrm{EC} 1}$. Figure 6a shows the variation of SOC bias with $\mathrm{f}_{\mathrm{EC} 1}$ when $\mathrm{f}_{\mathrm{SOC}}$ is fixed at $40 \%$. The variation of SOC bias by MRS with $\mathrm{f}_{\mathrm{EC} 1}$ follows a pseudo-sine curve, exhibiting negative bias when $\mathrm{f}_{\mathrm{EC} 1}<50 \%$ (i.e., EC is dominated by source 2 , the higher ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ source) and positive bias when $\mathrm{f}_{\mathrm{EC}}>50 \%$ and the range of bias are confined to $-20 \%$ to $-40 \%$ under the condition of $\mathrm{f}_{\mathrm{SOC}}=40 \%$. In comparison, the $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ methods again consistently underestimate SOC by more than $-50 \%$, with the bias worsened in the $\mathrm{OC} / \mathrm{EC}_{10 \%}$ method.

The bias variation range becomes narrower with increasing $\mathrm{f}_{\mathrm{SOC}}$ in the MRS method, as shown by the boxplots for four $\mathrm{f}_{\text {SOC }}$ conditions ( $20 \%, 40 \%, 60 \%$, and $80 \%$ ) in Figure 6 b. The MRS-derived SOC bias range is reduced from $-20-+40 \%$ at $\mathrm{f}_{\text {SOC }}=40 \%$ to $-10-+20 \%$ at $\mathrm{f}_{\text {SOC }}$ $=60 \%$, further to $-6-+10 \%$ at $\mathrm{f}_{\text {SOC }}=80 \%$. In the other two methods, the SOC bias does not improve with increasing $\mathrm{f}_{\text {SOC }}$. Dependence of the SOC estimation bias on $\gamma_{\_ \text {pri }}$ is examined in Figure 6 c showing the higher $\gamma_{-p r i}$ induces a higher amplitude of the SOC bias. If OC is dominated by SOC (e.g., $\mathrm{f}_{\text {SOC }}=80 \%$ ), SOC bias by MRS is within $10 \%$.

A variant of MRS implementation (denoted as MRS') is examined, with the important difference that $\mathrm{EC}_{1}$ and $\mathrm{EC}_{2}$, attributed to source 1 and source 2, respectively, are used as inputs instead of total EC. With the knowledge of EC breakdown between the two primary
sources, $(\mathrm{OC} / \mathrm{EC})_{\text {pri1 }}$ can be determined by MRS from $\mathrm{EC}_{1}$ and $\mathrm{OC}_{\text {totala }}$. Similarly $(\mathrm{OC} / \mathrm{EC})_{\text {pri2 }}$ can be calculated by MRS from $\mathrm{EC}_{2}$ and $\mathrm{OC}_{\text {total }}$. SOC is then calculated with the following equation:

$$
\begin{equation*}
S O C=O C_{\text {total }}-(O C / E C)_{\text {pri1 }} \times E C_{1}-(O C / E C)_{\text {pri2 }} \times E C_{2} \tag{6}
\end{equation*}
$$

MRS' produces unbiased SOC, irrespective of the different carbonaceous compositions (Figure 6). However, we note that there is a great challenge in meeting the data needs of $\mathrm{MRS}^{\prime}$ as $\mathrm{EC}_{1}$ and $\mathrm{EC}_{2}$ are not available.

In scenario 3, the simulation results imply that three factors are associated with the SOC bias by MRS, including: $\mathrm{f}_{\mathrm{EC} 1}, \gamma_{\text {_pri }}$ and $\mathrm{f}_{\mathrm{SOC}}$. The first factor controls whether SOC bias by MRS is positive or negative. The latter two affect the degree of SOC bias. For high $\mathrm{f}_{\text {soc }}$ conditions, the bias could be acceptable. If $\mathrm{EC}_{1}$ and $\mathrm{EC}_{2}$ can be differentiated for calculating individual $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ of each source, unbiased SOC estimation is achievable regardless of what values $\mathrm{f}_{\mathrm{EC} 1}, \gamma_{\_ \text {pri }}$ and $\mathrm{f}_{\mathrm{SOC}}$ take.

### 2.3 Impact of measurement uncertainty

In the preceding numerical analysis, the simulated EC and OC are not assigned any measurement uncertainty; however, in reality, every EC and OC measurement is associated with a certain degree of measurement uncertainty. We next examine the influence of OC and EC measurement uncertainty on SOC estimation accuracy by different EC tracer methods. Two uncertainty types are tested, i.e., constant relative uncertainty (Case A); constant absolute uncertainty (Case B). This section mainly focuses on sensitivity tests assuming different degree of Case A uncertainties. Results assuming Case B uncertainties are discussed in the next section. The uncertainties are assumed to follow a uniform distribution and generated separately by MT. It is also assumed that the uncertainty ( $\varepsilon_{\mathrm{EC}}$ or $\varepsilon_{O C}$ ) is proportional to the concentration of EC and OC through the multiplier $\gamma_{u n c}$ (i.e., relative measurement uncertainty).

$$
\begin{align*}
& -\gamma_{u n c} E C \leq \varepsilon_{E C} \leq \gamma_{u n c} E C  \tag{7}\\
& -\gamma_{u n c} O C \leq \varepsilon_{O C} \leq \gamma_{u n c} O C \tag{8}
\end{align*}
$$

In order to compare the estimated SOC with simulated SOC with $\varepsilon_{S O C}$, the measurement uncertainties of POC and SOC are then back-calculated following the uncertainty propagation formula and assuming the same relative measurement uncertainty for POC and SOC (Harris, 2010)

$$
\begin{gather*}
\gamma_{u n c}^{\prime}=\gamma_{u n c} \sqrt{\frac{O C^{2}}{P O C^{2}+S O C^{2}}}  \tag{9}\\
-\gamma_{u n c}^{\prime} P O C \leq \varepsilon_{P O C} \leq \gamma_{u n c}^{\prime} P O C  \tag{10}\\
-\gamma_{u n c}^{\prime} S O C \leq \varepsilon_{S O C} \leq \gamma_{u n c}^{\prime} S O C \tag{11}
\end{gather*}
$$

The simulated EC, POC and SOC with measurement uncertainties (abbreviated as $\mathrm{EC}_{\text {simulated }}$, $\mathrm{POC}_{\text {simulated }}$ and SOC $_{\text {simulated }}$ respectively) are determined as:

$$
\begin{align*}
& E C_{\text {simulated }}=E C_{\text {true }}+\varepsilon_{E C}  \tag{12}\\
& P O C_{\text {simulated }}=P O C_{\text {true }}+\varepsilon_{P O C}  \tag{13}\\
& S O C_{\text {simulated }}=S O C_{\text {true }}+\varepsilon_{S O C} \tag{14}
\end{align*}
$$

Sensitivity tests of SOC estimation as a function of relative measurement uncertainty ( $\gamma_{u n c}$ ) and $f_{\text {SOC }}$ is performed as shown in Figure 7 by comparing the estimated SOC with $S O C_{\text {simulated }}$. Fixed input parameters include: $n=8000 ; \mathrm{EC}=2 \pm 1 \mu \mathrm{gC} \mathrm{m}{ }^{-3} ;(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5$. Studies by Chu (2005) and Saylor et al. (2006) both suggest ratio of average POC to average EC (ROA, see SI for details) is the best estimator of the expected primary OC/EC ratio because it is mathematically equivalent to the true regression slope when the data contains no intercept. ROA is confirmed as the best representation of (OC/EC) pri for SOC estimation, which shows no bias towards $\gamma_{u n c}$ or $\mathrm{f}_{\text {SOC }}$ change. MRS overestimates SOC and the positive bias increases with $\gamma_{u n c}$ while decreases with $\mathrm{f}_{\text {Soc }}$ (Figure 7). The SOC estimates by $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ exhibit larger bias than those by MRS. For example, as shown in Figure 7 a , when $\mathrm{f}_{\text {SOC }}=20 \%$ and $\gamma_{u n c}=10 \%$, the bias of SOC by MRS, OC/EC $10 \%$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ is $8 \%,-28 \%$ and $36 \%$, respectively. With increasing $\mathrm{f}_{\text {SOC }}$, the bias of SOC by $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ decreases while the bias of SOC by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ increases when $\gamma_{u n c}=10-20 \%$. MRS always demonstrates the best performance in SOC determination amongst the three (OC/EC) pri estimation methods. When $\gamma_{u n c}$ could be controlled within $20 \%$, the SOC bias by MRS does not exceed $23 \%$ when $\mathrm{f}_{\text {SOC }}=20 \%$. If the $\mathrm{f}_{\text {SOC }}$ ratio falls in the range of $60-80 \%$ and $\gamma_{u n c}$ is $<20 \%$, the $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ has a similar performance as MRS, but SOC by $\mathrm{OC} / \mathrm{EC}_{10 \%}$ still shows a large bias ( $\sim 41 \%$ ) (Figures 7c and 7d).

Sensitivity studies of SOC estimation as a function of $\gamma_{u n c}$ and (OC/EC) pri are performed and the results are shown in Figure S8. In all the three (OC/EC) pri representations, SOC estimates are sensitive to $\gamma_{u n c}$ but insensitive to the magnitude of $(\mathrm{OC} / \mathrm{EC})_{\text {pri. }}$. In the single primary source scenario ( S 1 ), it is proved that the performance of MRS regarding SOC estimation is
mainly affected by $\gamma_{u n c}$ and to a less degree by $\mathrm{f}_{\text {soc }}$. Other variables such as $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ and EC concentration do not affect the accuracy of SOC estimation.

### 2.4 Impact of sample size

MRS relies on correlations of input variables and it is expected that MRS performance is sensitive to the sample size of input dataset. This section examines the sensitivity on sample size by the three $(O C / E C)_{\text {pri }}$ representations and aims to provide suggestions for an appropriate sample size when applying MRS on ambient OCEC data. Sample sizes ranging from $20 \sim 8000$ are tested and for each sample size 500 repeat runs are conducted to obtain statistically significant results. Both Case A (i.e., a constant relative uncertainty of $10 \%$ ) and Case B (i.e., a constant absolute uncertainty of $\pm 0.2 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$ for both OC and EC) are considered. The measurement uncertainties in case B are generated separately by MT following a uniform distribution within the range of $\pm 0.2 \mu \mathrm{gC} \mathrm{m}$. The measurement uncertainties of POC and SOC are then back-calculated following the uncertainty propagation formula (Harris, 2010) and assuming the ratio of $\varepsilon_{\mathrm{POC}} / \varepsilon_{\mathrm{SOC}}$ is the same as POC/SOC ratio (controlled by $\mathrm{f}_{\mathrm{SOC}}$ ).

The mean SOC bias by MRS is very small ( $<3 \%$ ) for all sample sizes while the standard deviation of SOC bias decreases with sample size (Figure 8). The standard deviation of SOC bias is $\sim \pm 30 \%$ at the lowest test sample size $(n=20)$, and decreases to less than $\pm 15 \%$ at $n=$ 60 (the sample size of one-year sampling from an every-six-day sampling program) and to less than $\pm 10 \%$ at $n=200$. Similar patterns are observed between Case A (Figure 8a) and Case B (Figure 8 b ) for MRS and $\mathrm{OC} / \mathrm{EC}_{10 \%}$. For $\mathrm{OC} / \mathrm{EC}_{\text {min }}$, a larger bias is observed in Case B than Case A for all sample sizes, as SOC bias by $\mathrm{OC} / \mathrm{EC}_{\min }$ is more sensitive to measurement uncertainty in the range of $0 \sim 10 \%$ as shown in Figure 7 b. The standard deviation of SOC bias by $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ both decreases with sample size as shown in Figure 8 . The mean SOC bias of $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ decrease with increased sample size while $\mathrm{OC} / \mathrm{EC}_{10 \%}$ is insensitive to sample size. The sample size dependency of all three (OC/EC) pri representations is not sensitive to $\mathrm{f}_{\mathrm{SOC}}$ as shown in Figure S16. Other scenarios considering (OC/EC) $)_{\text {pri }}$ with a distribution and different $\mathrm{f}_{\text {SOC }}$ are discussed in SI.

### 2.5 Impact of sampling time resolution

Besides hourly measurements of EC and EC by online aerosol carbon analyzers, the MRS method could also be applied to offline measurements of OC and EC based on filters collected over longer durations (i.e., 24 h ), which are more readily available around the world.

To explore the impact of sampling duration (e.g., hourly vs. daily), we here use one-year hourly data at the suburban site of Guangzhou to average them into longer intervals of 2-24 h. The 24 h -averaged samples yield a ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ of $2.53,12 \%$ higher than the $(\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ derived from hourly data (2.26). This comes as a result of that OC/EC distributions are narrowed when the averaging interval lengthens (Figure 8), leading to elevation of the MRSderived ( $\mathrm{OC} / \mathrm{EC})_{\text {pri. }}$ As many $\mathrm{PM}_{2.5}$ speciation networks adopt a sampling schedule of one 24-h sample every six days, we further extract the every-six-day samples to do the MRS calculation. The one-year data yields six subsets of daily samples, corresponding to six possible schedules of sampling days with the every-six-day sampling frequency. The MRS calculation produces the $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ in the range of $2.37-2.75(5-22 \%$ higher than the $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ from the hourly data). This example illustrates that if 24-h sample ECOC data are used, SOC would be biased slightly lower in comparison with those derived from the hourly data.

## 3 Caveats of the MRS method in its applications to ambient data

Table 3 summarizes the performance in terms of SOC estimation bias by the different implementations of the EC tracer method, assuming typical variation characteristics for ambient ECOC data. When employing the EC tracer method on ambient samples, it is clear that MRS is preferred since it can provide more accurate SOC estimation.

If the sampling site is dominated by a single primary source (similar to Scenario 1), MRS can perform much better than the traditional OC/EC percentile and minimum approaches. Two issues should be paid attention to when applying MRS: (1) MRS relies on the independence of EC and SOC. This assumption could be invalid if a fraction of SOC is formed from semivolatile POC (here referred as $\mathrm{SOC}_{\text {svP }}$ ) (Robinson et al., 2007). Since POC is well correlated with EC, this $\mathrm{SOC}_{\text {svP }}$ would be attributed to POC by MRS, causing SOC underestimation. The interference of $\mathrm{SOC}_{\text {svP }}$ will be discussed in a separate paper. (2) $\mathrm{OC}_{\text {non-comb }}$ will be attributed to SOC if only EC is used as a tracer. If $\mathrm{OC}_{\text {non-comb }}$ is small compared to SOC, such approximation is acceptable. Otherwise quantification of its contribution is needed. If a stable tracer for $\mathrm{OC}_{\text {non-comb }}$ is available, determination of $\mathrm{OC}_{\text {non-comb }}$ contribution by MRS is possible, since this scenario is mathematically equivalent to S 3 (e.g., relabel EC 2 to tracer of $\mathrm{OC}_{\text {non- }}$ comb and POC to $\mathrm{OC}_{\text {non-comb }}$ ).

If the sampling site is influenced by two correlated primary sources with distinct (OC/EC) pri (Scenario 2, e.g. urban areas that have vehicular emission from both gasoline and diesel),

MRS is still much more reliable than the traditional OC/EC percentile and minimum approaches. If the sampling site is influenced by two independent primary sources with distinct (OC/EC) pri (Scenario 3, e.g. vehicular emission and biomass burning), SOC estimation by MRS is better than the other two conventional methods. But it should be noted that possible bias may exist and the magnitude of bias depends on the relative abundance between the two sources. If tracers are available to demarcate the EC contributions by the different primary sources, unbiased SOC estimation is possible by employing these tracers in MRS.

## 4 Conclusions

In this study, the accuracy of SOC estimation by EC tracer method is evaluated by comparing three (OC/EC) pri determination approaches using numerically simulated data. The MRS method has a clear quantitative criterion for the ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ calculation, while the other two commonly used methods, namely minimum $\mathrm{OC} / \mathrm{EC}\left(\mathrm{OC} / \mathrm{EC}_{\text {min }}\right.$ ) and $\mathrm{OC} / \mathrm{EC}$ percentile (e.g. $\mathrm{OC} / \mathrm{EC}_{10 \%}$ ), are empirical in nature. Three scenarios are considered in the numerical simulations to evaluate the SOC estimation bias by the different EC tracer methods assuming typical variation characteristics for ambient ECOC data. In the scenarios of a single primary source and two well-correlated primary combustion sources, SOC estimates by MRS are unbiased while $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$ consistently underestimate SOC when measurement uncertainty is neglected. When measurement uncertainty is considered, all three approaches produce biased SOC estimates, with MRS producing the smallest bias. The bias by MRS is less than $25 \%$ when measurement uncertainty is within $20 \%$ and $f_{\text {SOC }}$ is not lower than $20 \%$. In the scenario of two independent primary sources, SOC by MRS exhibit bias but still perform better than $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$. If EC from each independent source can be differentiated to allow calculation of individual (OC/EC) pri for each source, unbiased SOC estimation is achievable. Sensitivity tests of OC and EC measurement uncertainty on SOC estimation demonstrate the superior accuracy of MRS over the other two approaches.

Sensitivity tests show that MRS produces a mean SOC values with a very small bias for all sample sizes while the precision worsens as the sample size decreases. For a dataset with a sample size of 60 , SOC bias by MRS is $2 \pm 15 \%$. When the sample is 200 , the results by MRS are improved to $2 \pm 8 \%$. It is clear that when employing the EC tracer method to estimate SOC, MRS is preferred over the two conventional methods ( $\mathrm{OC} / \mathrm{EC}_{10 \%}$ and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ ) since it can provide more accurate SOC estimation. We also evaluated the impact of longer sampling
duration on derived (OC/EC) pri and found that if 24 -h sample ECOC data are used, SOC would be biased slightly lower in comparison with those derived from the hourly data.

Table 1. Acronyms and Abbreviations

| Abbreviation | Definition |
| :---: | :---: |
| EC | elemental carbon |
| $\mathrm{EC}_{1}, \mathrm{EC}_{2}$ | EC from source 1 and source 2 in the two sources scenario |
| $\mathrm{f}_{\mathrm{EC} 1}$ | fraction of EC from source 1 to the total EC |
| $\mathrm{f}_{\text {SOC }}$ | ratio of SOC to OC |
| MRS | minimum R squared method |
| MRS' | a variant of MRS that use EC from individual sources as input |
| MT | Mersenne twister pseudorandom number generator |
| $n$ | sample size in MT data generation |
| OC | organic carbon |
| OC/EC | OC to EC ratio |
| (OC/EC) $)_{\text {pri }}$ | primary OC/EC |
| OC/EC ${ }_{10 \%}$ | $\mathrm{OC} / \mathrm{EC}$ at $10 \%$ percentile |
| $\mathrm{OC} / \mathrm{EC}_{\text {min }}$ | minimum OC/EC |
| $\mathrm{OC}_{\text {non-comb }}$ | OC from non-combustion sources |
| PDF | probability density function of a distribution |
| POC | primary organic carbon |
| ROA | ratio of averages |
| RSD | relative standard deviation |
| $\mathrm{RSD}_{\mathrm{EC}}$ | RSD of EC |
| $\mathrm{RSD}_{\text {POC }}$ | RSD of POC |
| $\mathrm{RSD}_{\text {SOC }}$ | RSD of SOC |
| SOC | secondary organic carbon |
| $\mathrm{SOC}_{\text {svP }}$ | SOC formed from semi-volatile POC |
| r_pri | ratio of the (OC/EC) $)_{\text {pri }}$ of source 2 to source 1 |
| $\varepsilon_{\text {EC }}, \varepsilon_{\text {OC }}$ | measurement uncertainty of EC and OC |
| $\Upsilon_{\text {unc }}$ | relative measurement uncertainty |
| $\gamma_{\text {_RSD }}$ | the ratio between the RSD values of (OC/EC) $)_{\text {pri }}$ and EC |

${ }^{a}$ Results shown here are obtained assuming the following ambient conditions: $\mathrm{RSD}_{\mathrm{EC}} 50-100 \%$; $\mathrm{f}_{\mathrm{SOC}} 40-60 \%$; $\gamma_{u n c} 20 \%$;
${ }^{\mathrm{b}} \mathrm{l}+\mathrm{+}$ " represents SOC overestimation and "-" represents underestimation;
${ }^{\mathrm{c}}$ MRS': In S3, EC1 and EC2 are used for SOC calculation.

Figure 1. Illustration of the minimum $R$ square method (MRS) to determine $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$ using one year of hourly OC and EC measurements at a suburban site in the Pearl River Delta, China. The red curve shows the correlation coefficient $\left(\mathrm{R}^{2}\right)$ between SOC and EC as a function of assumed OC/EC pri. The black curve is the frequency distribution of the OC/EC ratio for the entire OC and EC data set. The shaded area in tan represents the cumulative frequency curve of OC/EC ratio.

Figure 2. Schematic diagram of pseudorandom number generation for the single emission source scenario that assumes ( $\mathrm{OC} / \mathrm{EC})_{\text {pri }}$ is a single value. The data series (EC and SOC), generated by Mersenne twister (MT) pseudorandom number generator, statistically follow a log-normal distribution, but the sequence of each data point is randomly assigned.

Figure 3. Conceptual diagram illustrating three scenarios of the relationship between (OC/EC) pri and ambient OC/EC measurements. Both are assumed to be log-normally distributed. (a) Ambient minimum (left tail) is equal to the peak of (OC/EC) pri. (b) Ambient minimum OC/EC (left tail) is larger than the mean of (OC/EC) pri. (c) Ambient minimum $\mathrm{OC} / \mathrm{EC}$ (left tail) is less than the peak of $(\mathrm{OC} / \mathrm{EC})_{\text {prii }}$.

Figure 4. Bias of SOC determination as a function of: (a) $\mathrm{RSD}_{\mathrm{EC}}$; (b) $\mathrm{RSD}_{\mathrm{soc}}$. Different representation of (OC/EC) pri include: MRS, $\mathrm{OC} / \mathrm{EC}_{\min }$ and $\mathrm{OC} / \mathrm{EC}_{10 \%}$. Fixed input parameters: $n=8000, \mathrm{EC}=2 \pm 1 \mu \mathrm{gC} \mathrm{m}{ }^{-3},(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5, \mathrm{POC}=1 \pm 0.5 \mu \mathrm{gC} \mathrm{m}{ }^{-3}, \mathrm{f}_{\mathrm{SOC}}$ $=40 \%$, and $\mathrm{SOC}=0.67 \pm 0.34 \mu \mathrm{gC} \mathrm{m}$.

Figure 5. SOC bias in Scenario 2 (two correlated primary emission sources of different $(O C / E C)_{\text {pri }}$ ) as estimated by four different EC tracer methods denoted in red, blue and yellow. (a) SOC bias as a function of $\mathrm{f}_{\mathrm{EC} 1}$. Results shown here are calculated using $\mathrm{f}_{\mathrm{SOC}}=40 \%$ as an example. (b) Range of SOC bias shown in boxplots for four $\mathrm{f}_{\text {SOC }}$ conditions $(20 \%, 25 \%, 30 \%$ and $40 \%$ ). (c) Range of SOC bias shown in boxplots for four $\gamma$ pri conditions ( $2,4,6$ and 8 ). The symbols in the boxplots are white circles for average, the line inside the box for median, the box boundaries representing the $75^{\text {th }}$ and the $25^{\text {th }}$ percentile, and the whiskers representing the $95^{\text {th }}$ and $5^{\text {th }}$ percentile.

Figure 6. SOC bias in Scenario 3 (two independent primary emission sources of different $\left.(O C / E C)_{\text {pri }}\right)$ as estimated by four different $E C$ tracer methods denoted in red, purple, blue and yellow. MRS' differs from MRS in that $E C_{1}$ and $\mathrm{EC}_{2}$ instead of total EC are used as inputs. (a) SOC bias as a function of $\mathrm{f}_{\mathrm{EC} 1}$. Results shown here are calculated using $\mathrm{f}_{\mathrm{SOC}}=40 \%$ as an example. (b) Range of SOC bias shown in boxplots for four $\mathrm{f}_{\text {SOC }}$ conditions $(20 \%, 40 \%, 60 \%$ and $80 \%$ ). (c) Range of SOC bias shown in boxplots for four $\gamma$ pri conditions ( $2,4,6$ and 8 ). The symbols in the boxplots are white circles as average, the line inside the box as median, upper and lower boundaries of the box representing the $75^{\text {th }}$ and the $25^{\text {th }}$ percentile, and the whiskers above and below each box representing the $95^{\text {th }}$ and $5^{\text {th }}$ percentile.

Figure 7. Bias of SOC determination as a function of relative measurement uncertainty ( $\gamma_{\text {unc }}$ ) and SOC/OC ratio ( $\mathrm{f}_{\mathrm{SOC}}$ ) by different approaches of estimating (OC/EC) pri, including ratio of averages (ROA), minimum R square (MRS), $\mathrm{OC} / \mathrm{EC}_{10 \%}$, and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$. Fixed input parameters: $n=8000, \mathrm{EC}=2 \pm 1 \mathrm{gm}^{-3},(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5$. Variable input parameters: (a) f SOC $=20 \%$, $\mathrm{SOC}=0.25 \pm 0.13 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$, (b) $\mathrm{f}_{\mathrm{SOC}}=40 \%$, $\mathrm{SOC}=0.67 \pm 0.33 \mu \mathrm{gC} \mathrm{m}$, (c) $\mathrm{f}_{\mathrm{SOC}}=60 \%$, SOC $=1.5 \pm 0.75 \mu \mathrm{gC} \mathrm{m} ~{ }^{-3}$, and (d) $\mathrm{f}_{\mathrm{SOC}}=80 \%, S O C=4 \pm 2 \mu \mathrm{gC} \mathrm{m} \mathrm{m}^{-3}$

Figure 8. SOC estimation bias as a function of sample size by different approaches of estimating (OC/EC) pri, , including minimum R square (MRS), $\mathrm{OC} / \mathrm{EC}_{10 \%}$, and $\mathrm{OC} / \mathrm{EC}_{\text {min }}$, (a) assuming a fixed relative measurement uncertainty of $10 \%$ for OC and EC ; (b) assuming a fixed absolute measurement uncertainty for OC and EC $\left(0.2 \mu \mathrm{~g} \mathrm{~m}{ }^{-3}\right)$. For each sample size, 500 repeat runs were conducted. The circles represent mean of 500 repeat runs, the whiskers represent one standard deviation. Parameters used for testing: Repeat runs $=500, n=$ $20 \sim 8000, \mathrm{EC}=8 \pm 4 \mu \mathrm{gC} \mathrm{m}{ }^{-3},(\mathrm{OC} / \mathrm{EC})_{\text {pri }}=0.5, \mathrm{POC}=4 \pm 2 \mu \mathrm{gC} \mathrm{m}^{-3}, \mathrm{f}_{\mathrm{SOC}}=40 \%$, and $\mathrm{SOC}=$ $2.67 \pm 1.33 \mu \mathrm{gC} \mathrm{m}{ }^{-3}$.

Figure 9. OC/EC distributions assuming different average intervals from 2 to 24 h and the corresponding MRS-derived $\mathrm{OC} / \mathrm{EC}_{\text {pri }}$. The bottom x -axis represents averaging interval (e.g. 1 h is the original data time resolution, 2 h referring average 1 -h data into 2 -h interval data, etc). The top x -axis represents the number of data point corresponding to the respective data averaging interval. Distributions of OC/EC ratio at various averaging intervals are shown as box plots (Empty circles: average, the line inside the box: median, the box boundaries: $75^{\text {th }}$ and the $25^{\text {th }}$ percentile, and the whiskers: $95^{\text {th }}$ and $5^{\text {th }}$ percentile). The red dots represent calculated ( $\mathrm{OC} / \mathrm{EC}$ ) pri by MRS.
